Hydrocyanic acid dil., in doses from ʒ iij. , gradually increased to ʒ vij. , administered just before each meal, is another remedy. The condition is ordinarily one of irritability, and if the acid can be carried so as to produce quite marked sedative effects, it may be of great service.

Pepsin.—Pepsin and muriatic acid, compressed soda pills (English preparation, grs. viij. each), one before each meal.

Raw beef scraped or cut fine and seasoned.—Let the patient take teaspoonful or half-teaspoonful doses every hour or two, or oftener, and subsist upon this alone for a few days. The effect is very beneficial in many cases. Another method of preparing it is to lay a piece of beef upon *live coals*, immediately turn it, and immediately remove it. This cooks the meat the least possible amount, and yet gives it a flavor which, to many patients, is much more agreeable than when perfectly raw. It is then cut in small pieces, seasoned, placed by the bedside of the patient, and every now and then a piece is taken, chewed, and swallowed. This is a most excellent means for overcoming the vomiting which is sometimes present in chronic Bright's disease.

HEMOPTYSIS.

This, to the patient, is an alarming symptom. As a

general rule, they do not die of hæmoptysis. In fact they do better, and are rather more likely to recover or have an arrest of the disease, when hemorrhage occurs. Those cases which do get well almost invariably have a hemorrhage before recovery takes place. The moral effect produced upon the patient when such encouraging expressions are given him is sometimes wonderful. It is in the early stages that hemorrhage may be beneficial; but from the middle to the latter part of the disease the result may be different. If the patient has bled a small quantity, place him in bed and keep him perfectly quiet. If he belongs to that class who can take opium without producing unpleasant secondary effects, a moderate dose will diminish the moral effect which the hemorrhage has produced, and will also diminish irritability. Salt may have some effect, and certainly it can do no harm. It may be taken in small spoonful doses, followed by water. It sometimes, without doubt, does good, for it ordinarily purges when administered in this manner, and it is a remedy of which the patient will not be afraid. In those cases where the patient occasionally spits up a teaspoonful or so of blood, do not resort to inhalations of nitrate of silver or persulphate of iron.

Ergot is employed as a hæmostatic. Hypodermic injections of ergotine, in doses of one grain to one grain and a half. Fluid extract may be used in doses varying from gttss. xx. to fl. ʒ i. p. r. n. If ergot given by the mouth does not produce vomiting, it is apparently of some service. R. Pulv. ergot exsicc., acid gallic, ʒʒ ss. ; ext. gentian, q. s. M. Div. pil. No. x., one every four hours. *Quinia* in *very large doses*. Five-grain doses every hour until the pulse and temperature are brought down. One of the most powerful hæmostatics in the *materia medica* is turpentine. It is an exceedingly beneficial remedy in the treatment of *all* internal hemorrhages.

It may be administered in ten-drop doses every two hours if necessary. In the treatment of hæmoptysis this remedy is very conveniently administered by inhalation. It is volatile at a low temperature, and a copious vapor can be driven off in a very simple manner.

Take any convenient vessel, partly fill it with hot water; float upon the surface of the water, or suspend over it a shallow dish like a plate or saucer, upon which has been poured a small quantity (ʒ i.) of turpentine, and let the patient inhale the vapor as it arises. In this manner a gentle evaporation of the remedy can be produced which can be inhaled without inconvenience. When administered in this manner, it is especially applicable to those cases in which small hemorrhages occur, continuing for a number of days. The inhalation may be repeated three, four, or more times a day. Strangury is only rarely produced.

When the hemorrhage is profuse, the most certain remedy is to withdraw a given amount of blood from the general circulation. This can be done first by means of *dry cups*. Cover the chest anteriorly and posteriorly, and the thighs, if necessary, with the cups. If a still more powerful means is wished, resort to *ligation of the extremities*. Place a ligature around an arm, making it sufficiently tight to arrest the venous circulation, but permit the arterial circulation to go on. Do not retain the ligature longer than six or eight minutes upon any one limb, and when it is removed, loosen it gradually, thus gradually permitting the blood to again enter the circulation. Two or three minutes before removing the first ligature, a second one may be applied to the opposite arm, and in this manner all the extremities may be subjected to ligation. The amount of blood that can be retained from the

general circulation in this way is large. Hemorrhages may be instantly and repeatedly controlled by resorting to this measure. In quite a proportion of cases hemorrhage precedes the cough.

HECTIC FEVER AND NIGHT-SWEATS.

The fever is one of the principal symptoms which will engage the attention of the physician. Hectic and diarrhoea sometimes alternate. For the fever administer quinia in doses sufficient to diminish the temperature and control the pulse. An average dose is grs. xx. a day.

In occasional cases the remedy produces no marked effect. Another method is to produce ringing in the ears with quinine, and continue the remedy just short of producing that effect. The fever is very commonly controlled by these methods.

For the sweats, it should first be decided whether anything is to be done for their arrest. The sympathetic action between the skin and mucous membrane of the lungs is to be taken into consideration. A sudden arrest of the sweats may do more harm than good. They are, however, sometimes so severe that they must be checked if possible. The following are among the means which may be resorted to for that purpose:

Sponging with *hot water* before the patient goes to bed.

Sufficient flannel clothing to furnish a change whenever the patient awakes and finds himself in one of these sweats. Change the clothes at once, when sweating occurs, immediately preceding the change by sponging with *hot water*.

Arouse the patient a short time before the time for the occurrence of the sweat, and have him bathe his hands and face and take a light lunch.

A large dose of quinine before going to bed. In the experience of some, quinine hardly ever does any good in hectic or habitual sweats.

Aromatic sulphuric acid in gtt. xv. doses, and increased by gtt. v. until gtt. xl. or xlv. are taken at a dose. Its action is slow, but sometimes beneficial.

B. Oxide of zinc,.....grs. v.

Ext. hyoseyamus,....grs. iij. M.

S. C. t. i. d.

Oxide of zinc pills, two grains each, t. i. d.

The zinc and its combination with hyoseyamus are regarded as excellent.

Fld. ext. ergot in drachm doses at bedtime is very beneficial in some cases. If retained by the stomach it is quite apt to be of service.

Ergotine hypodermically; atropine in such doses as will produce some dilatation of the pupil. Doses one-sixtieth to one one-hundredth of a grain. Give a single dose at bedtime.

Hydrate of chloral given in a twenty-grain dose about two hours before the hour for sweating arrives has been attended with success.

THE USE OF COD-LIVER OIL.

Whenever the patient is losing flesh and strength use the oil. That preparation of the oil which is the most agreeable to take is to be preferred. Möller's cod-liver oil is regarded as a superior article. Give it in combination with an alkali. Lime-water answers a very good purpose as a vehicle.

Oil with the phosphates answers well, and when the stomach is sensitive, hydrocyanic acid dilute with ℥ij. doses added, is very beneficial. Commence with drachm doses and gradually increase to half-ounce doses t. i. d., which is regarded as a sufficient quantity. Give it just before or just after meals, according to the election of the patient.

When the oil "rises upon the stomach," if the patient will educate himself to catch his breath, open his mouth, permit the bubble to burst as it reaches the fauces, and then blow his breath out, he will avoid all the disagreeable taste attending the emetations. This simple piece of strategy has enabled many patients to continue the use of the oil, where, before being instructed relative to it, they had been entirely unable to take it.

Nutrition can be very much supported by *inunction* with cod-liver oil. When oily food is not readily assimilable "pancreatic emulsion" is, in many cases, very serviceable.

THE USE OF OXYGEN.

This is of doubtful efficacy as a permanent remedy. It may give some relief. It is not to be lost sight of, and is worthy of trial.

SWELLED FEET.

This symptom is regarded by the laity as one of the latest in the disease. Very great relief can be given to the patient by supporting the weakened vessels with a flannel bandage, smoothly applied.

FISTULA IN ANO.

This is a complication not very infrequently met with in cases of consumption. In case the nutrition of the patient is good, and the fistula is not extensive, an operation may be performed, but the question should always be carefully considered. The liability is, that it will not heal.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, April 22, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

COLOTOMY—EXAMINATION OF RECTUM BY HAND AND FOREARM—POINTS IN DIAGNOSIS—DEATH FROM SHOCK.

DR. SANDS presented a specimen which he had removed from a lady, aged forty-five, upon whom he had performed the operation of colotomy. He was requested to see the patient by Dr. Sheldon, of Riverdale, N. Y. She was said to have suffered from some impassable obstruction of the bowels for four weeks. He found her somewhat feeble, although not prostrated, and, from what could be learned, her constipation had come on gradually, unattended with vomiting, except on one or two occasions, the result of some of the cathartics which she had ineffectually taken. No indication of the nature of the obstruction could be ascertained by external examination. The abdomen was distended pretty evenly with gas in the intestines, but whether the large or small bowel was particularly involved could not be discovered. The track of the colon could not be traced, neither could it be settled that there was a marked accumulation of feces. Pressure upon the abdominal walls was borne without special complaint, and this pressure excited the vermicular motions of the intestine, plainly visible through the thin parietes. The emaciation, although considerable, had been quite gradual.

An examination per rectum was made with the finger on the 12th of March, with the assistance of Dr. Sheldon, but the result was negative. Nothing but an empty sac was discovered, and the finger, on being

withdrawn, was covered with a slimy mucus, but without the stain or odor of feces. The day following, at the second consultation, it was deemed advisable to anesthetize the patient and examine the rectum by the hand. The patient took ether without any trouble. She lay upon her left side, in order to enable Dr. Sands to use his left and smaller hand. This examination was also unattended with any positive result. The hand was passed without any great resistance into the rectum, and with care was gradually and carefully pressed forward until the sigmoid flexure was reached, the distance being about twelve inches from the anal orifice. When the hand had passed as far as this, the forearm was found to be too large to go further. No stricture was detected by this examination, although the coils of the intestine were felt distended with fecal matter. An attempt was made to feel the caput coli, but with an obvious disadvantage, as the left hand being used, the backs of the fingers and the fingernails were only available. The impression was derived, however, that the small intestine was the seat of the disease, an impression which was not confirmed, in consequence of the necessarily incomplete examination. The attending physician shared in this opinion at that time. The alternative of gastro-tomy was thought of, but hardly recommended.

The case was allowed to go on a week or so longer. The urine was watched, and, as it was considerable in quantity, the hope was entertained that the seat of the difficulty might after all be in the large intestine. It was proposed to give ether once more and make another examination, this time to use the right hand for the purpose, with the understanding that, if the large intestine was involved, to resort to colotomy, and if the stricture was found in the small intestine, to perform gastrotomy.

On the 24th of March, in the presence of Dr. Sheldon, Dr. Miner, of Brooklyn, Dr. Foster Jenkins, of Yonkers, and Dr. John Curtis, of this city, Dr. Sands made the examination referred to, and discovered the case to be one of stricture of the colon, the caput coli being enormously distended with fecal matter. No time was then to be lost in performing lumbar colotomy. Even in the second examination the point of stricture was not discovered, a fact of considerable clinical interest, inasmuch as this point was only fifteen inches from the anus.

The operation was performed on the right side, according to Anusar's method, and without accident. On opening the ascending colon the feces escaped pretty copiously. The patient was very feeble at the time, and he was not surprised to learn that she died the next day from the shock of the operation, just about twenty-four hours after its performance.

The autopsy was made by Dr. Curtis the day following. On opening the abdominal cavity, there were no evidences of peritoneal inflammation. The opening made in the colon by the operation was found to be of the usual size and unattended with any injury to the peritoneum. This portion of the gut was removed for a specimen, as well as a portion of the liver adherent. Another specimen removed was the caput coli, which, by a separation of the longitudinal muscular fibres at certain points, and a rupture of the peritoneal coat in two or three places, exhibited in a curious manner the results of extreme distention.

The seat of stricture, which was in the sigmoid flexure, and fifteen inches from the anal orifice, was also exhibited. This stricture, which occupied fully one-half the circumference of the intestine, was formed by a deposit of morbid tissue, the precise nature of which Dr. S. was unable to determine until a thorough examination

of it could be made. It was suspected, however, to be sarcomatous material, judging from the appearance of a similar and secondary deposit found in the liver. By the almost complete limitation of the deposit to the posterior portion of the intestine, the anterior portion of the canal was doubled upon itself, so that the peritoneal folds were in contact, in which position there were slight adhesions. It was in this latter situation that a rupture was made by Dr. Curtis while attempting to distend the stricture during the autopsy.

There were several interesting points in connection with this case that related principally to the method of examination pursued:—

I. Without this method of rectal exploration, Dr. Sands did not think that any one could have decided whether the stricture was in the large or the small intestine. Although it is well known that, as a rule, chronic obstructions were nearly always to be found in the large intestine, and acute obstructions were met with in the small intestines, still the rule had its exceptions. By the last examination he was enabled to decide the point of distention of the descending colon, and to tap it and get rid of the fecal accumulation.

II. Such examinations, judging from the softness of the material composing the stricture, were necessarily attended with considerable risk. In fact, in this particular instance, taking into extra consideration the fact of an ulcerative process going on in the vicinity, which it was thought would soon have gone through the peritoneum, he was rather surprised that the examination, carefully made as it was, had not produced a rupture and occasioned a fit of peritonitis. As it was, some of the longitudinal fibres of the rectum were separated at a place about eight inches from the anus.

III. The examination enabled the operator to map out through the abdominal parietes, by pressure from within, the exact situation of the colon. The operation, although simple enough in principle, was not always easy of performance, and the rules laid down were not reliable in every case. By the method of rectal examination the situation of the incision was found to correspond to a small congenital nevus, which in this case was a convenient mark.

IV. The results of this examination also prove that it is hardly possible, without incurring great danger, to pass higher up than twelve inches. In this case the stricture was but fifteen inches from the anus, and yet it was impossible to touch it during the explorative procedure.

DR. JANEWAY remarked that in those cases in which strictures followed chronic dysentery, there was particular liability to rupture by such examinations, as a large number of ulcers were apt to be in the immediate vicinity. In that connection he referred to a case in point, in which even an ordinary explorative examination, if it had been made during life, would have been attended by rupture.

A NEW METHOD OF MAKING A POST-MORTEM OF THE ABDOMINAL CAVITY.

While speaking of rectal explorations, he referred to a new method of making post-mortem examinations of the abdominal organs without external incision; this was by the introduction of the hand per rectum, and extracting any of the organs within reach. By such a method Dr. Chapin, of Bellevue, recently removed a piece of the liver, and kidneys, not only to the satisfaction of himself, but with a conscientious regard for the order of the friends that the body should not be opened.

STRICTURE OF INTESTINE, AND CONDITIONS INTERFERING WITH COLOMOTOMY.

Dr. E. MASON exhibited a specimen, which being one of colotomy, very appropriately followed the one of Dr. Sands. This specimen was of interest, more particularly as showing an obstacle to the successful performance of operation. The portion of the rectum and colon exhibited was removed from a man, aged thirty, who had been a car-driver for thirteen years, and whose habits were, according to his own account, very dissipated. Four and a half years ago he had his first attack of diarrhoea, which came on suddenly in the night and without known cause. This condition continued up to the time of the patient's death, with the exception of an interval of a few days at a time, when he would suffer from constipation.

The patient had been under Dr. Mason's observation for the past two years, during which time he had been an inmate of several of the hospitals. During the period a stricture of the rectum developed, which was treated from time to time by dilatation with bougies. Towards the last he became quite weak, emaciated, and suffered considerably from cough. For the last two months the patient was in the medical wards of Charity Hospital. His sufferings eventually became so great that he was exceedingly anxious for an operation, and its performance was finally agreed to with reluctance.

At the time of the operation the abdomen was much distended, and in the right iliac region there was marked dulness, which was referred to impacted feces. The incision was made upon the left side. When the fascia was opened and the colon reached, to Dr. Mason's surprise the intestine was immovable, and its walls very much thickened, and showed indentation on pressure. In view of these facts it was determined to abandon the operation. The wound healed kindly in a short space of time, but the patient sank and died from his lung trouble (phthisis) April 11, twenty-eight days after the operation.

Post-mortem.—In opening the abdomen the ascending and transverse colon were much distended, while the portion of intestine exposed was found enormously thickened and perfectly immovable by old adhesions, requiring for its isolation the use of the scalpel and scissors. The stricture was about three and a half inches in extent, and five lines in thickness. The lungs were extensively diseased, and the liver cirrhotic.

[Dr. MASON, in connection with a former case of colotomy, presented at the January 28th meeting, remarked that the age of the patient had been published as seventy-six instead of twenty-six—a typographical error.]

COLLOID CANCER OF GALL-BLADDER, KIDNEY, ETC.

Dr. JANEWAY exhibited the liver of a woman, aged forty, who was admitted into Bellevue Hospital, March 11, 1874, in the service of Dr. Polk. Dr. Janeway saw the patient but once during life. The hospital record of the case was made by Dr. Young, from which the following facts were obtained: About six months ago she noticed a small tumor, the size of a hen's egg, three and a half inches to the right of the umbilicus, and two inches below it. In the course of two months the growth was as large as an orange, and gradually increasing it reached its maximum size, that of a cocoa-nut, two months before admission into the hospital. There was no hereditary taint present. She ceased menstruating some time before admission. On examination after entrance, the tumor was found situated in the right lumbar region, extending thence into the umbilical. It was quite movable, not painful, and was said to be dull on percussion. The patient stated

that for a month previous to admission the tumor had apparently decreased rather than increased. Dr. Janeway, as before stated, saw the patient but once, and then, instead of the dulness over the tumor, there was a tympanitic note. He succeeded in feeling the edge of the liver, but he could not be positive whether the tumor was developed in the tissue of that organ or outside of it. The resonance was accounted for on the supposition that the colon was at the time just underneath the tumor. It was easily ascertained that the tumor was not connected with the kidney of that side; the question of diagnosis was whether the mass was connected with the liver, gall-bladder, colon, or omentum. The patient sank and died of asthenia.

Dr. Janeway was of the impression that the case was one of carcinoma originating in the peritoneum of the transverse colon, or in the colon itself, involving the liver secondarily. He had observed two carcinomas in this situation with these relationships, and which, on post-mortem examination, left one in doubt about real site of origin, because they were so equally situated between the peritoneum in the site mentioned and the liver-tissue.

At the autopsy, April 13th, the brain was not examined; the heart was normal. Both lungs contained numerous small nodules of colloid cancer. These varied in size, but the largest was not more than half an inch across. The majority were situated superficially. In the outer half of lower lobe of the left lung, bordering on the interlobar fissure and protected on its margins by recent exudative plenisy, there was a cavity in the lung-tissue partly occupied by a slough. The size of this spot was about two inches in diameter. Its outer wall was formed by costal pleura, the pulmonary pleura having been destroyed.

On opening the abdomen, a large, whitish tumor was observed projecting from beneath the right lobe of the liver, and situated in the right lumbar and the right side of umbilical region. This tumor was about the size of a cocoa-nut, and was bounded on the inner side by the descending duodenum, and had the transverse colon passing beneath it.

On turning the liver over after its removal with the surrounding parts, the tumor was found to extend from the longitudinal fissure to near the right margin of the liver, and it is impossible to study its exact connection with the liver. On section through the tumor in a vertical direction, its centre was found occupied by a hollow space containing broken-down masses of the colloid cancer forming its walls and very black fecal matter. Three round fistulous openings lead from this sac into the inner right border of the descending portion of the duodenum, the largest about the size of a number 14 sound, and one larger round opening forms a communication with the transverse colon. Except by these facts the intestine is unaffected. The tumor seems to occupy the site of the gall-bladder, and this organ, save as a part of diseased mass, cannot be found. Its right wall is formed by the liver-tissue, which is in a state of carcinoma, but gives the impression that it has become secondarily involved, so that it appears as if a good deal of the upper and under walls and the whole of left border were formed by the diseased gall-bladder with uncut, thickened, carcinomatous walls. In the liver-tissue above the sac was a round mass of colloid cancer, about two and a half inches in diameter, in whose firmer fibrous trabeculae white calcareous spicula were observed.

There were also a number of small places where the liver-tissue was the seat of the disease near the lower part of the right border. All the disease in the liver gave the impression of a spread by contiguity of struc-

ture. A number of the lymphatic glands seated in the transverse fissure were much enlarged, and were marked examples of colloid cancer; they showed to the naked eye a delicate white stroma, whose interspaces, comparatively speaking, were large and filled with the translucent gelatinous colloid matter. In the liver the areolae apparent to the naked eye are larger. The hepatic duct and the ductus communis choled, are pervious. The portal vein appeared to be only slightly compressed. The kidneys, spleen, intestines, uterus, etc., are normal.

The microscopic examination of colloid matter from lymphatic gland showed the greater part to be a homogeneous, gelatinous, delicately striated-like mucus. In this were found cells, the majority of which showed a cylindrical type; some were more rounded and gave evidence of colloid change in interior. Besides, there were a number of small rounded or oblong bodies, apparently free nuclei and remains of cells set free by the disintegration of the cells. Also, in some places, remains of alveolar structure were apparent. The walls were fibrous and the spaces varied in size. The lungs and liver showed the same structure, except that the fibrous partitions in each case were more marked than in the glands, giving to the section a honey-combed appearance. Even in the smaller points of cancer but few cells were found in the alveoli.

It will be seen from the above account how impossible a knowledge of the exact place of origin of the tumor was during life; for at the time she came under observation the liver was considerably involved in the disease, and even after death a section of the tumor and some dissection were necessary to disclose its exact relationship. Colloid cancer of the gall-bladder is rare, and one with fistulous communications with duodenum still more rare; but one with fistulous communications with both duodenum and transverse colon I have not seen described. In conclusion, he remarked that metastases of colloid cancer, such as were observed in the lung in this case, were not of frequent occurrence.

He also presented two other specimens without a history, and removed from dissecting-room subjects. One showed an enormously distended vermiform process, with the orifice occluded, explaining the condition. The other specimen showed an adhesion of the Fallopian tubes to the uterus, with fistulous openings between these and the cavity of the sigmoid flexure.

In answer to a question from Dr. Briddon, he stated that he had seen two cases of great distention of the vermiform process, one as large as the size of a child's head, and in these, as well as in the case just presented, there was an occlusion of the opening to account for it.

CYSTIC SARCOMA.

Dr. BRIDGON presented a cysto-sarcomatous tumor, the size of a billiard-ball, removed by operation from the anterior and middle portions of the thigh of a gentleman aged sixty-five.

ATHEROMA OF CEREBRAL ARTERIES—APOPLEXY AND CONVULSIONS.

Dr. LEALE exhibited the brain, heart, and kidneys of a gentleman whom he saw for the first time on the Saturday previous, and who died shortly after in convulsions. The patient first suffered from obscure cerebral symptoms in 1864, following an attack of sun-stroke. He went on reasonably well, however, until September last, when he suffered from an attack of facial paralysis of the left side. This was in time en-

tirely relieved, and nothing unusual occurred until the attack of convulsions referred to. When Dr. Leale saw him during one of the paroxysms, he discovered partial paralysis of the right side, with dilatation of the left pupil. The attacks came on at intervals of every fifteen or twenty minutes until death. The urine was examined during the visit, and was found to be heavily loaded with albumen.

At the autopsy the membranes of the brain were found adherent at the superior portion of the middle lobes of the cerebrum. There was on the left side a very large clot, completely filling the fissure of Sylvius. The arteries of the circle of Willis presented a moderately healthy appearance, but the arteries beyond were in an atheromatous condition. The anterior and posterior branches of the middle cerebral were found completely occluded by atheromatous deposit. The middle branch of the middle cerebral was also found occluded for a quarter of an inch, and between this plug and the middle cerebral artery, at its termination, was a fissure an eighth of an inch in length, through which a hemorrhage occurred. The heart weighed one pound one ounce and one drachm (*Avoird.*), and measured five inches in length by seven in breadth. It was covered with a large mass of fat. The liver was large and waxy. The gall-bladder contained a glistening calculus about the size of a pigeon's egg. The right kidney weighed five ounces, the left seven and three-quarter ounces; on the surface of the latter were several grayish patches, composed of broken-down tissue and oily matter. The patient had arcus senilis, well marked. There was a large deposit of atheroma in the aorta and coronary arteries. The urine, which was examined before death, was of a slightly acid reaction, had a sp. gr. of 1.005 and contained a large quantity of albumen and casts. The brain weighed fifty-four ounces.

FATTY PLACENTA.

Dr. LEALE presented a second specimen, which was the placenta discharged from a lady confined at her full term. Throughout the substance of the organ were three deposits of fatty substance, about the size of a hen's egg. The patient had no constitutional symptoms of syphilis, but her husband was at the time suffering from secondary sore-throat trouble. The child was puny. The cord was very pale and the pulsation feeble.

The Society went into Executive Session.

Correspondence.

CONCERNING THE AMERICAN MEDICAL ASSOCIATION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In your editorial on the reorganization of the American Medical Association (*RECORD*, April 15, 1874, p. 205), you refer to the proposed change in the manner of electing delegates to the Association, saying that "their choice should be restricted to the county societies principally, and the colleges and other similar institutions should be left out of consideration entirely. By the exercise of due care in this regard, it will by and by be considered an honor to be chosen, and our best men may deem it worth their while to enter the lists on that account."

In the *RECORD* of May 1, 1873, p. 214, you printed some suggestions from me on the above subject. Permit me briefly to reproduce the main point—how to

reduce the number of delegates, and thus increase the usefulness and the respectability of the Association:

"The medical society of each State may send as many delegates as the State has representatives in Congress, but any State that may have only one representative shall be entitled to send two delegates." This "will give a total of delegates from States of 296." Certain other organizations—the Medical Society of the District of Columbia, the Medical Departments of the Army and Navy, &c.—should be allowed delegates. Delegates should hold office four years, one-half being elected every two years. "No State society, after the year 1880, shall be entitled to representation unless it is composed of delegates from county societies." . . .

In your editorial in the same number (p. 205) you did me the honor to "commend them" (my suggestions) "to the attention of all interested in the question of creditable delegateship. Although his" (my) "method is far from perfect, it presents many striking points of practicability. We can at least seize upon it as a starting-point. We care not how the question of delegateship is settled, provided that we attain the results so anxiously, so imperatively desired."

If the plan of restricting the choice of delegates to county societies be adopted, it will be a great advance on the present method, but the evils inherent in a large, badly selected, and unmanageable body will not be corrected. The State of New York has more than 2,750 county society members, from whom there would be selected more than 275 delegates. High as the profession stands in this State, I do not think that there are so many REPRESENTATIVE men in it.

My plan proposes that there shall be chosen by the State Medical Society, from the State at large, or, if it is preferred, by Congressional districts, about thirty-three of our very best men, to go to the American Medical Association to legislate for us, and by their scientific contributions elevate and strengthen the position of our common profession—at any rate, so to conduct themselves as an association as no longer "to make the judicious grieve."

J. S. PROUT, M.D.

BROOKLYN, May 13, 1874.

SKENE'S DILATOR.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In the issue of the RECORD of May 1st, is a letter from Dr. Lente, calling the attention of the profession to the comparative advantages of Molesworth's dilator. As the recommendation of Dr. L. is so deservedly potent in the profession, I deem it all the more proper that notice should be called to another instrument, not a patent, which was devised for the same purpose, and which, while costing very much less to the "country practitioner," is equally efficient, and is easier to manipulate. In the *Am. Journal of Obstetrics* for May, 1873, Dr. A. J. C. Skene, who devised the instrument to which I refer, describes it and explains its use. Every practitioner has at hand a hard-rubber syringe, and obstetricians the Barnes' dilators. "All that is required in addition to these is a hard-rubber tube about ten inches long, terminating in a bulb or knob at one end, having a stop-cock at the other, and a curve to correspond with the axis of the pelvic excavation. . . . It is about the size of a No. 9 catheter, and is slightly flexible. This tube is carried into the rubber bag, and answers three important purposes:

"1st. It guides the introduction of the bag.

"2d. Holds it in place within the os uteri: and,

"3d. Makes a convenient connection with the syringe used to fill the bag with water. . . . By this arrangement much smaller sized dilators can be used than those of Barnes:" indeed, as small as the tube used to guide it. We have, then, an instrument cheaper, and equally efficient and applicable. As the instrument of Dr. Skene is given to the profession without the restrictions of a patent, being equally serviceable, are not its "comparative advantages" greater, and is it not to be preferred in use? * * *

SHORTENING OF LIMBS AFTER FRACTURE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—My friend and colleague, Dr. Sayre, in a clinical lecture on "Ununited Fractures," is reported in THE MEDICAL RECORD of May 1, 1874, as having said, "The law, however, that shortening must necessarily attend the union of a fractured bone, is incorrect, as can be satisfactorily proved by practical demonstration."

"Now you will see the impotence of the law laid down, that shortening must always take place if union is effected."

I am not aware that any one has ever laid down a law of this kind. If any one has, he has rendered himself a proper subject of ridicule. Believing, however, that Dr. Sayre has been reported incorrectly, or that, in an oral lecture, he has spoken inadvertently, I wish to call his attention to the paragraphs above quoted, and to ask him how they are to be understood.

FRANK H. HAMILTON.

NEW YORK, 43 W. THIRTY-SECOND STREET.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from May 5, 1874, to May 18, 1874.

ABADIE, E. H., Surgeon.—Leave of absence extended sixty days on surgeon's certificate of disability. S. O. 101, A. G. O., May 8, 1874.

BAILEY, E. J., Surgeon.—Relieved from duty in Department of California, and to report to the Commanding Officer, Department of the Columbia, for duty as Medical Director of that Department. S. O. 96, May 2, 1874.

COOPER, GEO. E., Surgeon.—Relieved from duty in Department of the Columbia, and to report to the Commanding General, Department of California, for assignment to duty. S. O. 96, c. s., A. G. O.

WRIGHT, J. P., Surgeon.—Relieved from duty in Department of Dakota, to proceed to Carlisle, Pa., and, on arrival, report by letter to the Surgeon-General. S. O. 96, c. s., A. G. O.

TOWN, F. L., Surgeon.—Relieved from duty in Military Division of the Atlantic, and to report in person to the Commanding General, Department of Texas, for assignment. S. O. 96, c. s., A. G. O. To proceed to Fort Sill, Indian Ty., and on arrival, report by letter to the Commanding General, Department of Texas, for assignment, so much of S. O. 96, c. s., A. G. O., as directs him to report in person, having been revoked. S. O. 105, A. G. O., May 13, 1874.

TILTON, H. R., Assistant Surgeon.—Relieved from duty in Military Division of the Atlantic, and to report in person to the Commanding General, Department of Texas, for assignment. S. O. 96, c. s., A. G. O.

WEEDS, J. F., Surgeon.—Assigned to duty at Fort Abraham Lincoln, D. T. S. O. 83, Department of Dakota, April 29, 1874.

McLELLAN, ELY, Assistant Surgeon.—To take station at Louisville, Ky., and from that place visit the towns and localities at which cholera prevailed during the year 1873, as designated in instructions given him by the Surgeon-General. S. O. 103, A. G. O., May 11, 1874.

BROWN, J. M., Assistant Surgeon.—Relieved from duty in Department of Texas, to proceed to Philadelphia, Pa., and, on arrival, report by letter to the Surgeon-General. S. O. 86, c. s., A. G. O.

DE HANNE, J. V., Assistant Surgeon.—Relieved from duty in Department of the Missouri, to proceed to New York City, and, on arrival, report by letter to the Surgeon-General. S. O. 96, c. s., A. G. O.

PATZKI, J. H., Assistant Surgeon.—Assigned to duty at Fort Fred. Steele, Wy. Ty. S. O. 65, Department of the Platte, May 9, 1874.

WOODRUFF, E., Assistant Surgeon.—Relieved from duty in Department of Dakota, to proceed to Louisville, Ky., and, on arrival, report by letter to the Surgeon-General. S. O. 96, c. s., A. G. O.

DICKSON, J. M., Assistant Surgeon.—Relieved from duty in Department of the Platte, to proceed to Cincinnati, Ohio, and, on arrival, report by letter to the Surgeon-General. S. O. 96, c. s., A. G. O.

HOLDEN, LEVI H., Surgeon (retired).—Died at Vineland, N. J., on May 12, 1874.

Medical Items and News.

DEATH OF DR. HOLSTON.—At a called meeting of the Zanesville Academy of Medicine, held Saturday, May 2, to take action in relation to the death of its late Fellow, Dr. Jno. G. F. Holston, Sr., which took place at Washington, D. C., May 1, 1874, the following resolutions were adopted:

That we, whose occupation has been to relieve human suffering, are reminded that the time must come when our places on earth shall be vacated. Therefore,

Resolved, That in the death of Dr. Holston, the Zanesville Academy of Medicine loses one of its prominent members, and the profession at large an eminent physician and surgeon of extensive professional and literary culture, ripe experience, and accurate judgment; and society a warm-hearted, genial, and generous member, whose life has been mainly devoted to the good of his fellow-beings.

Resolved, That we attend the obsequies of our deceased Fellow in a body.

Resolved, That we deeply sympathize with the family and relatives of the deceased.

Resolved, That the Corresponding Secretary transmit a copy of these resolutions to the family, the city Press, and the Medical Journals.

C. C. HILDRETH, Chairman.

A. E. BELL, Secretary, pro tem.

DEATH OF JOHN H. GRISCOM, M.D.—The following resolution, presented by Dr. J. G. Adams, was adopted at the last meeting of the Academy:

Whereas, John H. Griscom, M.D., an original Fellow of this Academy, departed this life on the 28th ult., in the 65th year of his age. Therefore,

Resolved, That this Academy do put on record upon its minutes their appreciative sense of the long public services rendered by the deceased, his untiring indus-

try in the pursuit of knowledge, his efforts in the cause of science and humanity, more especially as regards improvements in ventilation and other sanitary measures. In his spirit and intercourse, kind and genial; in his views and influence, highly conservative; in his official trusts, diligent and self-sacrificing, he was an honored member of an honorable profession.

Resolved, That our secretary transmit a copy of this minute to the afflicted family of the deceased, with the assurance of the heartfelt sympathy of the Academy.

(Signed.) JOHN G. ADAMS, M.D.,

ALFRED C. POST, M.D.,

GURDON BUCK, M.D.

THE UNIVERSITY OF OTAGO, NEW ZEALAND, has advertised for candidates to occupy a chair of anatomy and physiology which it has recently instituted. The salary will be £600 per annum, which will commence from the date of embarkation, besides the class fees, which have been fixed at £3 3s. for each student, per term of six months. An adequate allowance will be made for passage-money and outfit. The age of candidates should not exceed thirty, and they must be possessed of qualifications such that home universities would approve of them as competent medical teachers. They must be university men and have a medical degree; a degree in arts besides will be deemed a recommendation. Private practice will not be permitted. —*Med. Press and Cir.*

A MICROSCOPIST was jocosely asked by one of his colleagues if he could tell him anything he did not know about the white blood-cells. He answered at once, "From the terms of your question I think I can mention two things—in the first place they are *not* cells; in the second place they are *not* white."

CONVENTION OF "CONFEDERATE" SURGEONS.—The Confederate Surgeons' Convention, held at Atlanta, Ga., on May 21st, elected Surgeon-Gen. P. Moore, Permanent President, and Dr. Henry F. Campbell, Vice-President at large. The Association was named the Association of the Medical Officers of the late Confederate States Army and Navy. Medical officers of the United States Army and Navy, who resigned to join the Confederates, are made honorary vice-presidents. A committee of three was appointed to confer with the Surgeon-General of the United States Army relative to the archives of the Medical Department of the Confederacy. Richmond was selected as the next place for meeting, in July, 1875.

PROFESSOR BUNSEN'S LOSS.—The valuable manuscripts of Professor Bunsen, of Heidelberg University, the fruits of three years' labor, were accidentally burned a few weeks ago. The Professor was called out by a visitor, who wished to see the laboratory, and when he returned to his room the work of destruction was complete. The rough drafts and the manuscript prepared for the press were all consumed. The cause of the fire is entirely unknown, unless the sun, acting upon the peculiarly constructed window-glass, wrought the mischief.

COLLEGIATE APPOINTMENTS AND RESIGNATIONS.—Professor Edmund R. Peaslee has been elected to deliver the course of lectures on Diseases of Women, at the next session of the Bellevue Hospital Medical College.

Dr. Stephen Smith has been appointed Professor of Surgery in the Medical Department of the University of the City of New York.

Prof. D. Warren Brickell has resigned his position in the Bellevue Hospital Medical College, and has returned to New Orleans.

American Medical Association.

TWENTY-SEVENTH ANNUAL MEETING AT
DETROIT, JUNE 2, 3, 4, AND 5, 1874.

DR. J. M. TONER, OF WASHINGTON, D. C., PRESIDENT.

THE Association held its first day's session in the Detroit Theatre, and was, pursuant to previous adjournment, called to order by the President, Dr. J. M. Toner, of Washington, D. C., at eleven o'clock. The Vice-Presidents, Drs. W. Y. Gaddberry, of Mass.; N. C. Husted, of N. Y.; J. M. Keller, of Ky.; and L. F. Warner, of Mass., were present upon the platform.

A prayer was offered by Right Rev. SAM'L A. McCoskey, Bishop of Michigan.

Dr. WM. BRODIE, chairman of the Committee of Arrangements, welcomed the Association to Detroit in an appropriate address, in the course of which he gave an interesting and detailed account of the growth and prosperity of the city. Among other noteworthy remarks in this connection were the following:

We boast of Detroit as one of the healthiest cities of the Union, its mortality being only two and one-half per cent. for the year 1873. This happy state of health is not only due to her location on the beautiful Detroit River, but to her complete system of sewerage, over ninety-two miles having been constructed since 1835, at a cost of \$1,528,000. Her public-schools system—the establishment of which on their permanent basis, and of which our citizens are justly proud—was eminently due to the efforts of the late Dr. Pitcher, who was your presiding officer at its meeting in this city in 1856. This system embraces twenty-eight school buildings, at a valuation of \$548,000, in which over 12,000 scholars were enrolled for 1873, and education at an actual cost, inclusive of all expenses, of \$10.50 per pupil per annum. Her public library deserves mention as one of her most popular institutions, established by the Constitution of the State, managed by the Board of Education, and supported by court fines and penalties. Its total receipts are \$74,000; its expenditures, \$52,000; and its total number of volumes, 22,935. Detroit is abundantly supplied with water from the Detroit River. Of its purity Prof. Duffield says: "It is impossible to find river water more free from organic impurities." The daily average supply for 1873 was 8,600,000 gallons, being about ninety gallons or three barrels per diem for each inhabitant, at a cost of only \$1.74 per annum. The large surplus of water not directly used by the individual serves to wash the sewers, and adds another reason for the purity of the city and health of her citizens.

The permanent secretary, Dr. W. B. ATKINSON, of Philadelphia, then called the roll, after which Dr. BRODIE announced the following medical gentlemen from the Dominion of Canada as members by invitation: Prof. Richardson, Toronto; Dr. Casgrain, Windsor; Dr. C. B. Hall, Toronto; Dr. Robert Lambert, Windsor; Dr. A. A. Andrews, Windsor; Dr. E. Nesbitt, Sandwich; Dr. George McKieking, Goderich; Dr. F. B. McCormick, Ripon, Ont.; Dr. F. F. Bell, Amherstburgh.

Dr. RICHARDSON responded for his colleagues in a few appropriate remarks.

PRESIDENT'S ADDRESS.

Dr. TONER, of Washington, D. C., then delivered his address, from which we make the following extracts:

I am aware that there has been from the first meeting of this Association a contrariety of opinion as to its

true province and best policy. Some would have it limited in number, exclusive and dictatorial, if not coercive, in its relation to the profession at large. There are those who would have it abandon all semblance of a convention, and devote its time to discussion of scientific facts and the recent discoveries in medicine, to the exclusion of all other questions and purposes.

A few would have it an arena where any and every subject that can enter the mind of a medical man might be introduced, without order or even definite purposes.

Others would be content and feel rewarded for the expense and loss of time in the enjoyment of the social elements so lavishly evoked on all these occasions.

But the arrangement for scientific discussions and the exchange of professional views, with the social reunions which the average judgment of the gentlemen who are in the habit of attending the meeting from year to year has approved, come as near meeting the requirements and securing due consideration to every factor, social, ethical, and professional, that enters into and serves to advance the true interests of the whole profession, and bind it in one harmonious brotherhood, as any general policy that could at present be adopted.

Aggregations of individuals form communities and intercourse establishes society. Common interests and enlightened sentiment, with frequent meetings and exchange of views, evolve dominant ideas, and dominant ideas rule not only societies like ours, but the world.

Twenty-eight years ago this Society was organized, in the City of New York, on a basis to represent the regular profession of the United States. Whether it has always acted wisely, or done the best and all that was possible under the circumstances for the elevation and advancement of the profession, must be impartially judged by our successors.

Of those who find fault I might ask: What organizations or institutions are perfect, or give even general satisfaction? They are not to be found among religious creeds, nor are they to be found in any known code of laws. They do not exist. But the great improvement taking place throughout the world in all the conditions that regulate society and protect rights of the individual, is marvellous. And though absolute perfection is not attainable, we are striving with encouraging success to elevate and perfect as far as possible the art and science of medicine. If I possessed the ability to draw a picture that could correctly represent the status of the profession and its organizations throughout our country at the period when this Association came into existence, and contrast it with one showing our present prosperous condition and numerous well-organized societies, the younger members would scarcely recognize them as representing the same profession.

It is not too much to claim that this Association, by the mere moral support it gives in encouraging the formation of local medical organizations, has done immeasurable good, and added largely to this result.

It fully recognizes the unity of the regular profession throughout the United States. At the same time it has erected a standard of medical excellence and ethical *esprit du corps* never before attained in America, and has persistently and publicly held them up for admiration and adoption. It has drawn with distinctness a line that separates the regular from the irregular practitioner, which will in the future as in the past be firmly maintained; and it is desirable, as far as practicable, to encourage uniformity in the plan and scope of all medical societies which in the sphere of their influence correspond to our civil political divisions; and

further, I think we should continue our efforts to encourage these local medical organizations until every State and county in the United States shall have its medical society, holding proper relations with each other and with this body. The Association is now, and always has been, anxious to bring into its fold the leading physicians from every State, and from every city and village and rural district in the land, and has solicited and still invites original papers on any subject that can advance medical science. It has published annually, from its organization, a volume of contributions and regular and special reports of great value in the different departments of medicine on questions of immediate interest to the profession.

After referring to the advances made in American medicine, he said:

American surgeons can justly claim to have done their part to advance its efficiency.

Their daring and successful operations, as well as their ingenious devices and numerous mechanical appliances, are the admiration of the profession everywhere.

In our cities centre not only dense populations, with great wealth, but all the conditions and institutions most favorable for prosecuting special studies in the most thorough and satisfactory manner. It is in them, as a general rule, that society fosters, and so frequently rewards with princely fortunes, the pre-eminently capable and skillful physicians, as it does men of genius in other callings.

It is true that in great cities pretenders and charlatans also prosper, but where this is a particularly noticeable fact it may, as a rule, be inferred that there is abundant room for physicians of first-class ability. Indeed, physicians possessing the latter qualifications are sure of employment, and are at home and welcome everywhere. Even the best educated neighborhoods and most highly enlightened communities, if not supplied with acceptable physicians, possessed of adequate professional knowledge and well acquainted with the latest improvements in medicine, will patronize the most plausible pretenders to such requirements. The physician is a necessity. He is employed neither as a luxury nor from friendship; but for his actual or presumed skill and ability to prevent, relieve, or cure disease.

Progress is the order of the day—a law of the universe. He who does not constantly keep adding to his knowledge and increasing his resources, must soon fall behind the more enterprising and the better informed of his contemporaries. The physician who does not know that the community in which he lives is keeping a constant watch upon him, and contrasting his knowledge, skill, and success in his profession with those of the best and most successful medical men within the range of their reading or acquaintance, shuts his eyes to an important fact of great interest to himself. The judicious and observing know that time regulates many apparently conflicting professional interests, and sets them working in a manner that in the end promises no discredit to our calling.

It is the judgment of those who watch closely the workings of this Association that questions of a hypothetical, local, or transient character ought not to be introduced here. The time of the Association should be fully employed in scientific discussions and in the consideration of questions of necessary and proper legislation.

The absence of delegates from the Massachusetts Medical Society has been noticeable for several years. I trust that at the present meeting delegates from that old and influential organization may resume their rightful places.

It richly deserves the congratulations of the Association and the profession of the country for lopping off all irregular practitioners who by various pretexts sought to fasten themselves upon it.

The judicial council of twenty-one created at the last meeting, whose duty it is "to take cognizance of and decide all questions of an ethical or judicial character that may arise," will no doubt greatly promote harmony and facilitate the business of the Association.

It is also confidently believed that the change in the plan of conducting the business before the different sections will add to the general interest and efficiency of our meetings. This change may require us to prolong our session to at least four days. Should each chairman of the five different sections occupy the time of the general session allotted to him for an address, which shall review the progress of medicine within the scope of his section, it is not likely they could all be delivered in less than two days. The regulation adopted for the stenographic report and daily printing the remarks of members will make each speaker more deliberate, and perhaps more anxious to have his views fully and carefully stated. With a view to secure more time for our deliberations, I recommend that a regulation extending our sessions to four days be adopted. The hope entertained by some physicians of excluding irregular and unimportant productions from the profession by legislative enactments and penalties is, I apprehend, in our country not to be realized.

The thorough systematic education, the skill and availability of the services of the regular medical man, must instinctively create in the minds of the people an appreciation of his superior claims to their confidence, and thus the profession become a law for its own protection, and which must prove stronger and more enduring than acts of assemblies or rulings of courts.

Medicine has always been more advanced through the fortunate discoveries of the few original observers than it has in centuries of adherence to dominant theories.

I wish, further, to suggest or to inquire whether our influence ought not to be given to the end that all medical institutions created by law or acting under charters should be required to make and publish annual reports of their facilities, their labors, discoveries, and the extent of their operations, to the legislative body that created them.

The principle should obtain, that when a charter issues the institution assumes a public character, and should be held responsible by the public for the manner in which it exercises its privileges, raises and expends its funds, and conducts its business. The public has a right to claim this much, that it may profit by experience, correct abuses, and encourage only the deserving. It has been estimated that there are about 2,400 separate and distinct diseases. The number will probably be reduced as our knowledge of physiology and pathology and of the natural history of diseases becomes more general and accurate.

What seems at first in many cases to be a specific difference frequently disappears as we become more familiar with the range of circumstances and variations that enter into the producing causes, as well as those that may prolong and modify prominent symptoms. Hospitals for the cure and medical treatment of the insane have been provided for most liberally by the general Government and by nearly all the States. Being public institutions, and yet bearing the character of specialties, and possessing unequalled advantages, it seems but natural that the profession should expect reports from them, with record of curative and

cases and detailed accounts of autopsies and microscopic examinations of diseased brain and nerve tissue, of practical value to the general practitioner. A most important step has been taken in this direction by Dr. J. P. Gray, Superintendent of the New York State Lunatic Asylum at Utica, who requested that a special pathologist be appointed as his assistant in that institution. The Doctor's recommendation to this end was unanimously passed by the Legislature, and an accomplished microscopist was appointed to the position. A complete outfit for careful chemical and microscopical examinations and for autopsies, and for taking photo-micrographs of diseased organs and tissues, was provided. The late reports already attest the wisdom of the measure.

If a hospital for the exclusive treatment of cancerous diseases were opened in some of our large cities, where cases could be kept under treatment and careful observation throughout all the stages of the disease, it would supply an urgent want, and do much toward developing and discovering more efficient means for combating this terrible disease. The pathology of this malady is now perhaps better understood than is the power of remedies over it. An institution of this kind has recently been founded in England.

The number and character of the medical works and journals annually published in the United States show that there is a rapidly increasing demand by the profession of the country for the most recent views in medicine, and particularly of the leading histologists and pathologists of the world. Instead of the few, the majority of American physicians are becoming industrious readers and careful students, and demand the latest and most scientific works.

Twenty-five years ago it would have taken eight or ten years to bring new views fairly before the profession for trial that will now be read, revised, tested, confirmed or contradicted within six months, by scores of different observers throughout the country.

The telegraph even has been brought into requisition, and contributes its power to assist practitioners in distant cities to carry on consultations for the benefit of influential or distinguished persons.

The names of patients and their diseases are frequently given in the dispatches of the Associated Press, with the names of the physicians and the special treatment adopted. What more striking evidence of the progress of the age, and of the intelligence of our profession, and of the people who are interested in and avail themselves of the latest inventions and advances in the physical sciences?

There are some hundreds of young physicians of first-class ability, noted for their originality of thought and boldness of investigation, residing in different parts of our country, who are working with the scalpel and microscope and the test tube with the spirit of true philosophers. But where we have ten such we ought to have a hundred. It is from among such that must come the leading medical men of the future.

Young physicians are peculiarly adapted for experimental investigations by having the time, the enthusiasm, and the daring imagination to be original. They are also free from undue reverence for old ideas, and are without preconceived theories—conditions so essential for original experiment and discovery, for which age is found to be largely disqualified.

It is therefore chiefly to the young that the profession must look for its original work and new facts. And while we are deeply gratified and ever ready to award due praise to the retired or deceased physicians, who have fairly won, by earnest study and devotion to medicine, the highest honors of the profession, I feel

it to be a duty to encourage by honorable commendation deserving young men who, by virtue of genius, industry, and force of character, are conquering obstacles to increase the knowledge of our profession and gain recognition and success. Such young men become the teachers of their teachers, the masters of the colleges.

Preventive medicine is now attracting the earnest attention of many of the most profound thinkers in the profession. Within the personal observation and memory of each of us there have been great advances made in the control and prevention of disease. There is much still to be done in this direction. I confidently look forward to the time when epidemics of cholera, yellow fever, and small-pox will be prevented with a certainty just in proportion to the dissemination of the knowledge of efficient preventive measures, and the faithfulness with which the means are applied.

I desire, also, to recommend that this Association take into consideration the question of the desirability of encouraging the formation of an International Medical Congress.

This can be done by uniting and securing the co-operation of the national medical societies of the different sections of the world. The Congress, I would suggest, ought to meet regularly every five years, or oftener, in some one of the different national capitals. The organization should be composed of delegates eminent in medicine, to be appointed from the several national medical bodies, in the proportion of say two members from each body, and an additional delegate for every one hundred active members. The purpose of the Congress should be to confer and consider, from an international point of view, all questions that are promotive of public health, the advance of medical knowledge, and the true interests of the profession throughout the world. The present rapid and frequent communication of all civilized countries with each other makes us all akin, and the advancement of science renders this kind of professional intercourse desirable to the end that frequent and free exchange of all that is known to be new and useful in medicine may be speedily brought to benefit mankind in every clime. The progress of science, the facility of intercommunication, the general and widespread intelligence, the claims of humanity, and the aspirations of the age and of our noble profession demand the formation and support of some such organization.

Should this measure suggested meet the approval of this Association, the steps proper to be taken to secure co-operation in the proposed organization and all the details can be left to a committee.

I suggest that an effort be made to have the first meeting held in Washington City some time during the summer of 1876, while the American International Exposition is being held in Philadelphia.

The departments of the national government in which exist an organized medical corps, the army and the navy, need no special mention or encomiums from me. Their well-conducted bureaus and the highly accomplished *personnel* of the medical staff corps are the pride of the profession of the whole country. Their works speak more fittingly of their praise than could any words of mine. The great army pathological museum and the magnificent medical library which their thoughtful consideration for the profession has created, fully attest their devotion to their high trust and their love for advancement of medical science.

Within a few years a third medical department, known as the Marine Hospital Service, under the immediate direction of the Secretary of the Treasury, has come into existence. It is under the supervision of an

able medical officer, and the purpose is to provide hospital accommodations and medical treatment for sick seamen belonging to the merchant marine of the United States. At most of the ports contracts are made with the local hospitals to receive and treat the sailors.

The government owning but ten hospitals, it consequently makes but few medical appointments. The service is, therefore, small, and may, from its importance, be considered in a formative state.

The medical officers of the army have not yet received that consideration and relief from Congress which you recommended at your last meeting. The committee appointed by you drew up a memorial, which was duly presented to Congress; they also called in person upon the members of the Military Committee of the Senate and House of Representatives, and prepared a bill entitled "A bill to increase the efficiency of the medical department of the army," which, if passed, would place the medical staff upon a footing of equality with the other staff corps. This bill was introduced into the House of Representatives January 6, 1874, read twice, and referred to the Military Committee, who have not yet taken any definite action on the subject.

Meanwhile the action of the American Medical Association and your committee has been heartily indorsed by the general State and county medical societies, almost every one of which has passed resolutions on behalf of their brethren in the army, and forwarded them to their representatives in Congress.

The medical profession of the United States can never be content that the medical officers of the army shall continue to be treated with less consideration in the matter of rank and pay than the officers of other staff corps, or of the medical corps of the navy, and will never cease their appeals to the representatives of the people until justice is done to this deserving body of medical men. I recommend, therefore, that a larger committee be appointed to plead their cause anew; that we may, if possible, secure favorable legislation before the present Congress adjourns, or, if this prove impracticable, that we may bring the matter to the attention of the next Congress so soon as it convenes.

The systematic observations in meteorology that are being made throughout the country, under the direction of the United States Signal Office and the Smithsonian Institution, promise in their results to be of great value in the study of climatology and the causation of disease. I hope to see that system widely extended and its stations multiplied throughout the whole country.

Electricity justly deserves the careful attention which has recently been given to it by a number of medical observers in our own and other countries.

It is well known that electricity is manifested in different forms, as frictional electricity, galvanic electricity, and magneto-electricity. Each of these forms has probably different effects on living organisms, and each should receive special attention from the profession.

It has been found that a current of electricity passed from the extremity toward the centre affects the nerves differently from a current passed in the opposite direction. It is hoped the great power this agent is known to exercise over nutrition may be made serviceable in changing or retarding morbid growths and in reviving lost nervous and muscular strength.

Within the last few years several additions of great therapeutical importance have been made to our *matéria medica*, and it is worthy of note that the most valuable of these are not simple substances existing ready formed in nature, but organic compounds

which we owe to the patient investigation of modern chemistry, and that their medical uses have not been ascertained by the accidental chances of a blind empiricism, but discovered in the course of exact experiments into the physiological effects of various organic substances, undertaken and carried out with all the precautions and refinements suggested by modern science. As examples of the class of experiments from which such results are to be anticipated, I may refer to those of Dr. H. C. Wood, in our own country; in Europe to those of Richardson and Liebreich.

The latter observer has been singularly fortunate in discovering the therapeutical value of two new bodies, which, like chloroform, are chlorine compounds, and which, like it, though in a somewhat different manner, are of singular efficacy in procuring rest and the relief of pain. I refer to chloral hydrate, which has already gone into such extensive use, and to the new anodyne, croton chloral hydrate. Is it not a hopeful sign of the times that we should owe such remedies to that very spirit of exact science which is so often unjustly accused of tending toward nihilism and scepticism in medicine?

The address was listened to with a deservedly respectful attention, and at its conclusion received the hearty approval of the Association.

After the conclusion of the address, DR. PARVIN, of Indiana, moved that the recommendations contained in it of the President be referred to the following committee:—White, of New York; J. D. Jackson, of Kentucky; Bartlett, of Wisconsin; Shippen, United States Navy; and Westmoreland, of Georgia. The motion was adopted.

Announcements of papers to be presented to the Association were made, and were referred to the appropriate sections.

The Committee of Arrangements announced that every morning delegates would be furnished with a full programme of the day's exercises, including the papers to be read in each section.

On motion the delegates from each State were instructed to meet at half-past eight o'clock, Wednesday morning, to select chairmen for their respective delegations.

The Association then adjourned to meet at 9 A.M. on Wednesday.

SECOND DAY—WEDNESDAY, JUNE 3.

In consequence of the want of room in the Detroit Theatre, the place of meeting was changed to the Opera House.

The Association was called to order by DR. TOSER, President, after which the programme of the day was read by DR. BRODIE.

COMMITTEE ON NOMINATIONS.

The following Committee on Nominations was announced:—Arkansas, ———; Alabama, Jerome Cochran; Connecticut, B. H. Catlin; California, G. L. Simmons; Colorado, H. H. Byford; District of Columbia, Johnson Eliot; Delaware, R. R. Porter; Florida, ———; Georgia, W. F. Westmoreland; Illinois, W. H. Byford; Indiana, R. N. Todd; Iowa, J. C. Roberts; Kansas, C. V. Mottram; Kentucky, E. Richardson; Louisiana, ———; Maine, A. Garcelon; Massachusetts, L. T. Warner; Maryland, E. Lloyd Howard; Michigan, Foster Pratt; Minnesota, E. C. Cross; Missouri, Wm. S. Edgar; Mississippi, A. G. Smith; Nebraska, N. T. Anderson; New Jersey, Chas. F. Dishler; New York, J. Marion Sims; New Hampshire, J. F. Carr; North Carolina, ———; Ohio, E. H. Hyatt; Oregon, ———; Pennsylvania, Ben-

jamin Lee; Rhode Island, Joab Kenyon; South Carolina, A. N. Talley; Tennessee, Wm. T. Briggs; Texas, H. W. Browne; Virginia, ———; West Virginia, John C. Hupp; Wisconsin, J. B. Whiting; United States Army, Joseph R. Smith; United States Navy, ———.

PERMANENT MEMBERS.

Dr. F. M. Wilder, of Chicago, Illinois, was elected permanent member. Dr. Charles E. Slocum, of Delaware, Ohio; J. C. Slocum, of Shelby, Indiana; Drs. Nesbitt, Sandwich, Ontario; Bell, Amherstburgh, Ontario; McCormick, Peche Island, Ontario; Scott, Woodstock, Ontario; McLean, Kingston, Ontario; Moore, London, Ontario; Wm. Canilh, Toronto, Ontario, were elected members by invitation.

Dr. R. R. POTTER, of Delaware, introduced a resolution to the effect that in the recommendation and appointment of committees, preference should be given to those who were present. Adopted.

REVISION OF THE CODE OF ETHICS.

Dr. N. S. DAVIS, of Illinois, Chairman of the Judicial Council, then read the following report:

The undersigned committee, to whom was referred the question of a general revision of the code of ethics of the American Medical Association, respectfully report as follows:—Soon after the adjournment of the annual meeting in May, 1873, the chairman of your committee, being desirous of ascertaining how far there existed a desire in the minds of the profession to have the code changed, addressed letters of inquiry to thirty or forty men in different parts of the country who might be supposed to represent the general sentiment of the profession in their respective districts, from twenty-five of whom answers were received. Fourteen expressed an entire approval of the code as it is, and thought it better to attempt no changes. Six were opposed to any general revision, but supported slight changes in some sections, while only five expressed such dissatisfaction as to indicate a desire for thorough revision.

If these correspondents might be regarded as fairly representing the profession, any important changes in the code would be in direct opposition to the wishes of a large majority of those for whose guidance it was framed. Those who have expressed a desire for changes in the present code are readily divided into two classes. The first class appear to look upon a code of ethics in the same light as ordinary by-laws, and consequently regard all in the present code relating to the duties of patients to their physicians, of the public to the profession, and of the profession to the public, as superfluous and useless. They would retain nothing except the rules governing the intercourse of physicians with each other, and a very few of this class object to any *written* rules, claiming that the unwritten sense of *honor* belonging to members of an educated profession is sufficient to afford all needed guidance and control. It seems to us that the objections of this whole class are founded on a narrow and imperfect conception of the real nature and objects of an ethical code. The latter, instead of consisting of a set of rules or by-laws, simply defining the duties and privileges of members of some organized society, should be a concise and full exposition of the relations sustained by a profession to the rest of the community, the mutual obligations imposed by such relations, and the rules governing members in their intercourse with each other. Hence, a code of ethics for our profession must partake, more or less,

of the nature of a moral essay, developing principles for guidance equally applicable to all places and times, instead of a few simple rules applicable to the members of some particular society. It was with this view that Dr. Percival wrote his celebrated essay in the latter part of the last century, and which has been regarded as a standard authority in Europe from that time to the present. The same idea evidently controlled the very able committee appointed by the preliminary convention in 1846, to report a code of ethics for the profession of this country, and who gave us the admirably concise and well-arranged summary of the principles involved by Percival, which constitutes our present code.

To strike out, as some have proposed to do, all relating to the duties of patients, the community, and the public toward the profession, would be to destroy the completeness of the work, and obscure the meaning of what was retained. For the members of any given profession cannot rightly appreciate the relations they sustain to each other without considering at the same time their mutual relations and duties to the community in which they live. After a very careful examination, we are satisfied that our present code of ethics presents the true ethical relations and duties of the profession in a form as concise, as well arranged, and as complete as it is possible to express them. The principles and rules of conduct enumerated are clearly stated, and are equally applicable for the guidance of all who attempt to practise the healing art, whether they are members of any medical organization or not.

The second class, whose members desire alterations in the present code of ethics, do not object to its general scope, but ask for amendments or additions to particular sections only. With only a few and unimportant exceptions, these propositions all relate to two subjects, namely, *specialties* and bestowing professed services by *contract*. Concerning the first of these there seems to be much false reasoning and needless irritation. If *specialists*, or those who limit their practice to some one class of diseases or accidents, are members of the profession, it follows logically that they must be governed in all respects by the same ethical principles as the general practitioners; for no enlightened body of men can consistently have one code of morals for one part of its members and another code for the rest. Whatever may be regarded as derogatory to the dignity and welfare of the general practitioner must be equally so to the specialist, so long as he is recognized as a member of the profession. If the one may not issue cards, hand-bills, etc., calling the attention of those laboring under particular diseases to themselves, neither can the other without violating the principles of both justice and equality.

Then the code of ethics very properly makes no mention of specialties or specialists, but presents plainly the rules necessary for the maintenance of professional character as applicable to all. But we are asked how, then, can those who wish to pursue a special practice make known their position to their brethren and the public? We answer that the title of Doctor of Medicine covers the whole field of practice, and whoever is entitled to that appellation has the right to occupy the *whole* or any part of the field, as he pleases. The acceptance of this honorable title is presumptive evidence to the community that the man accepting it is ready to attend practically to any and all duties which it implies. As all special practice is simply a self-imposed limitation of the duties implied in the general title of doctor, it should be indicated, not by special or qualifying titles, such as *oculist*, *gynecologist*, etc., nor by any positive setting

forth of special qualifications, but by a simple, honest notice appended to the ordinary card of the general practitioner, saying, "Practice limited to diseases of the eye and ear," or "to diseases peculiar to women," or "to midwifery exclusively," as the case may be. Such a simple notice of limitation, if truthfully made, would involve no other principle than the notice of the general practitioner that he limits his attention to professional business within certain hours of the day. Neither could it be regarded as a claim to special or superior qualifications. To give the specialist any privilege beyond this would be to invest him with a special privilege, inconsistent with the equality of rights and duties pertaining to the whole profession. We see no reason, therefore, for recommending any change in the present code of ethics in reference to this subject.

The remaining topic, concerning the bestowal of professional services under specific *contracts* of sufficient importance to require careful attention.

The present code of ethics, while sanctioning a most liberal bestowal of gratuitous professional service to the poor, whether as individuals or in public charitable institutions, and in aid of the sanitary interests of the communities, yet expressly prohibits the bestowal of such services on well-to-do individuals, endowed, mutual benefit, or any kind of money-making institutions, societies, or corporations. It also expressly prohibits all attempts to attract attention and make merchandise of charity by ostentatiously parading before the public notice a proffering services and medicine to the "poor gratis." We see no reason why this is not sufficient so far as relates to the regulation of gratuitous services. To govern the matter of compensation the code simply gives us the following general declaration:—"Some general rules should be adopted by the *faculty*, in every town or district, relative to *pecuniary acknowledgments* from their patients; and it should be deemed a point of honor to adhere to these rules with as much uniformity as varying circumstances will admit." This aim appears to have been to allow sufficient variations in the rate of compensation to accommodate the varying habits and circumstances of different communities, and yet to bind each individual to an honorable compliance with the general rules established by his professional brethren. Such being the correct ethical principle, the difficulty consists in tracing and maintaining clearly its practical application. That the principle laid down in the paragraph just quoted is inconsistent with all contracts or agreements to attend individuals, families, companies, corporations, or any a societies or institutions other than those of a strictly charitable character, for a specified sum per month or year, without regard to the amount of medical services that might be required in the time specified, no one can reasonably doubt. It seems to us equally inconsistent with the ethical rule to enter into a contract with a manufacturing company to attend their employes, or with a school to attend its patrons or scholars, for a fixed sum per annum, to be derived from the levy of a certain percentage on the wages of the employes or on the tuition fees of the students; for however plausible may be the humanitarian idea of securing for the employe and the student adequate medical attendance when sick at the smallest average cost, the practical working of the system violates both the rule that compensation for medical services should be in accordance with the kind and amount of services rendered, and that every individual and family should be free to choose their own medical attendant without dictation or indirect restraint.

These objections do not apply to a certain kind of contract service, such as that required in connection with the medical staffs of the army and navy, nor to the hospital tax on sailors in the marine hospital system, for reasons too obvious to require mention. On other subjects requires a few moments' attention. There is a class of public charitable institutions, such as county almshouses, orphan asylums, etc., supported by public taxation. In many of the States the public authorities having control of such institutions have annually asked for bids from the profession, offering to award the contract for professional services to the one who should bid for the lowest pecuniary consideration.

While as charitable institutions any member of the profession might offer his services to such of the poor inmates as might ask for them gratuitously, yet the idea of asking members of the profession to bid against each other for the pay for public professional services is repugnant to every feeling of professional honor, and often productive of great injustice to the sick poor.

The public authorities in all such cases should fix such just rate of compensation for the necessary medical services as they may deem best, and then appoint the best medical man who is willing to accept the compensation proposed. And we have no doubt but that a proper attention to this subject on the part of the profession would secure the necessary change.

It is, however, very desirable to so manage all our pecuniary relations with the public, and especially with municipal and legislative authorities, that we avoid creating the impression on the public mind that the profession and its social organizations are little better than mere trades-unions, having for their chief object mutual pecuniary protection. After carefully reviewing the whole subject, your committee do not recommend any alteration in the present code of ethics. On the contrary, we desire to express the opinion that if every medical school and society would supply each graduate as he left the school and each member initiated into the society with a printed copy of the code, accompanied with the injunction that it be carefully studied, it would be productive of much good, directly to the profession and indirectly to the community.

N. S. DAVIS.

DETROIT, June 24, 1874.

After a little discussion the report was unanimously adopted.

AMENDMENTS TO THE PLAN OF ORGANIZATION.

The following amendments to the plan of organization proposed at the last session of the Association, were read by DR. DAVIS, of Illinois:—

THE following amendments to the plan of organization are to be acted upon:

By DR. N. S. DAVIS, Illinois:

Strike out the second paragraph of Article II, and insert the following:

"The delegates shall receive their appointment from permanently organized State medical societies and such county and district medical societies as are recognized by representation in their respective State societies, and from the medical department of the army and navy of the United States."

Also, strike out the fourth paragraph of same article, and insert:

"Each State, county, and district medical society, entitled to representation, shall have the privilege of sending to the Association one delegate for every ten of its regular resident members, and one for every additional fraction of more than half that number.

"The medical staffs of the army and navy shall be entitled to four delegates each."

By Dr. P. Pinco, of Massachusetts:

Art. II., second paragraph, after "Army and Navy," insert "and the Marine Hospital Service of the United States."

By-laws, section 6, after "the chiefs of the bureaus of the army and navy," insert "and the supervising surgeon of the United States Marine Hospital Service."

By Dr. E. L. Howard, of Maryland:

Art. IV. Strike out second clause of first paragraph and insert:

"They shall be nominated by the Judicial Council, and shall be elected by vote on a general ticket."

By Dr. A. S. Maxwell, of Iowa:

"Resolved, That in view of the many and important duties imposed upon the nominating committee, the medical society of each State and Territory that elects delegates, be requested, when selecting delegates, to nominate one member of such delegation as their member of the nominating committee, and also designate the mode of filling vacancies."

By Dr. A. M. Pollock, of Pennsylvania:

Art. VI., first paragraph, strike out the word "five" and insert "ten."

By-laws, Art. 5, first paragraph, strike out "five" and insert "ten."

Dr. REYBURN, of the District of Columbia, asked if it was intended by the first amendment to exclude Territorial representation.

Dr. DAVIS said that when this Association was formed there were but few local organizations, and but few existed for the first few years, and therefore, to make the Association a success, the basis of representation was made broad. Now the Association has grown in strength and abuses have crept in. It has now been thought best to avoid endless discussions here. It has been found that now an endless variety of institutions are represented, some of them utterly irresponsible; consequently there has been a loud outcry for a stricter basis of representation, and therefore we wish to recognize none but representatives of organized State, Territorial, district, and county societies, and local societies which are recognized in their respective State organizations.

Dr. WOODWARD asked how this would work where there were more than one worthy society in one place.

Dr. DAVIS—All local societies recognized by their own State organizations could be admitted.

Dr. BUSEY, of Washington, asked how they could limit representation in this way, when reputable local societies could be multiplied in all large cities, and offered the following proviso:

Provided, however, that the number of delegates from any particular State, Territory, county, city or town shall not exceed the ratio of one in ten of the resident physicians who may have signed the code of ethics of this Association.

Dr. DAVIS approved of and seconded the adoption of the proviso, but he thought there was no such danger as the gentleman apprehended.

Dr. WOODWARD, D. C., said that in the District of Columbia the representation could be unlimited.

Dr. BUSEY said that now this had been brought down to one in ten.

Dr. QUIMBY, of New Jersey, opposed making the representation too limited.

Dr. LILLIE, of New Jersey, said that all trouble had come from local organizations and men not recognized by the State organizations. He instanced the system in his State, and said he was directed to urge the passage of the amendment.

The proviso was adopted.

The report and resolution were adopted by a large majority.

SECOND PROPOSED AMENDMENT.

Dr. ATKINSON moved that this be so worded as to limit the marine department to one representative.

Dr. BUSEY objected on the ground that an irregular practitioner might be appointed.

Dr. DAVIS thought there was too much political influence in the Marine Hospital Service to admit of its recognition, and moved that the amendment be laid upon the table indefinitely. Carried unanimously.

THE THIRD PROPOSED AMENDMENT.—On motion of Dr. REYBURN, this was laid upon the table without debate.

THE FOURTH PROPOSED AMENDMENT.—This was opposed by Dr. KELLER, and on his motion was tabled with significant approval.

THE FIFTH PROPOSED AMENDMENT, on motion of Dr. ATKINSON, was laid on the table without debate.

ARMY MEDICAL STAFF RANK.

Dr. KELLER, chairman of the Committee on Rank of the Medical Staff of the Army, read the following report:

Your committee have the honor to report that immediately after the adjournment of the St. Louis meeting they took steps to ascertain the status of the medical staff of the army under existing laws, and conferred with a number of the medical officers as to the best method of securing for them that equality with the other staff corps in the matter of rank which it is undoubtedly just and right that they should enjoy.

Your committee then drew up a memorial to Congress setting forth the facts of the case, and presenting the draft of a bill which, if it should become a law, would afford the relief asked by the medical corps without injury to any other branch of the public service. This memorial was printed, and copies forwarded to each member of the American Medical Association and to the various State and county medical societies, with a letter requesting their co-operation.

In response to this appeal the several local societies have passed resolutions endorsing the action of the American Medical Association and of your committee, and asking favorable legislation by Congress. These resolutions have been forwarded to the respective Senators and Representatives.

Shortly after the commencement of the present session of Congress your committee waited upon the military committees of the Senate and House of Representatives, presented the memorial, and urged the adoption of the bill by which it was accompanied. The bill was accordingly introduced into the House of Representatives, January 6, 1874, read twice, and referred to the Military Committee, by whom, we regret to say, no action has as yet been taken on it.

Notwithstanding this failure to secure prompt legislation by Congress in behalf of our brethren in the army, your committee are of opinion that by continued exertion our object can probably be attained during the next session of that body. The present session has, as it happens, been an unfortunate one for urging claims of the medical staff. In consequence of the financial panic of last fall the utmost economy in all administrative matters has been attempted, and at the time your committee presented its memorial to Congress a very considerable reduction in the army had been proposed and was under consideration. So far as your committee can judge, it is now very improbable that any such reduction will be made, but the fact that it has been under consideration was no doubt the

chief reason why the bill introduced January 6th has not yet been acted upon. We therefore recommend the appointment of a new committee to memorialize Congress at its next session, and think it desirable that it should be composed of one member from each State, as provided in the following preamble and resolutions, the adoption of which are respectfully recommended:

Whereas, We have learned with regret that Congress has not as yet acted favorably on our memorial in behalf of the medical corps of the army; and whereas it is our opinion just and right that the rank of the medical officers of the army should be fully equal to that of the officers of the other staff corps, or of the medical corps of the navy, which we are informed is not the case under existing laws; therefore,

Resolved, That a committee of one from each State and Territory be appointed by the President for the purpose of memorializing Congress on this subject, and of securing the co-operation of the several State and county medical societies for the same purpose.

J. M. KELLER, Kentucky,

Chairman of Committee.

JOHN A. MURPHY, Ohio,

N. S. DAVIS, Chicago, Ill.

H. F. ASKEW, Wilmington, Del.

J. M. TONER, Washington City.

Surgeon WOODWARD, of the army, on behalf of the medical department of the United States Army, thanked the committee for the report, and concurred with the views expressed in regard to the effect of the panic upon the action. He explained the action of the present law upon the rank of army medical officers.

He therefore offered the following amendments to the resolutions. After the word "territory" insert the words "with power to fill vacancies," omit the words "by the President" and add the following:

Resolved, That Dr. J. M. Toner, of the District of Columbia, be chairman of said committee, and that the other members of the committee be appointed by the President.

Unanimously adopted.

The Catalogue of the Army Medical Library was accepted with thanks, and the following letter was read:

WAR DEPARTMENT, SURGEON-GEN.'S OFFICE,
WASHINGTON, D. C., April 11th, 1874.

DR. J. M. TONER, President of the American Medical Association, Washington, D. C.:

DEAR SIR:—By directions of the Surgeon-General, United States Army, I have the honor to forward, for presentation to the American Medical Association, a copy of the catalogue of the library of this office, in three volumes, royal 8vo., and to call the attention of the members of the Association to the character of the collection and to the deficiencies which still exist in it. Since the printing of this catalogue a large number of foreign medical theses and pamphlets have been added to the library, making the total number of its titles about 65,000; but large as this may appear, it is not more than one-third of what our national medical collection should contain. In order to place the medical writers and teachers of this country upon an equality with those of Europe in regard to facilities for consulting the literature of their profession.

The catalogue now presented is an alphabetical one of authors, and only a sufficient number have been printed to supply the principal libraries and medical journals; hence it is impossible to supply copies to individuals. But a catalogue is now in course of

preparation, arranged according to subjects, of which it is hoped that a sufficient number can be printed to supply those who need such a work. It is very desirable that, during the coming year, the deficiencies of the collection, especially in American medical literature, should be filled as far as possible, in order that the subject catalogue may present a good bibliography of the subject, and to this end the assistance of physicians throughout the country is especially requested as regards the completing the files of American medical journals, transactions of medical societies, announcements of medical colleges, and reports of hospitals, asylums, boards of health, etc., etc. These medical pamphlets cannot be purchased, and the only prospect of obtaining them is from the garrets, closets, and shelves of physicians who may have preserved them, and may be willing to part with them in consideration of the importance of the object for which they are desired.

Very respectfully, your obedient servant.

J. S. BILLINGS,

Assistant Surgeon United States Army.

REPORT ON BAY COUNTY DELEGATES.

The Judicial Council, through their secretary, reported the following decision in reference to the case of the disputed Bay County delegations. By the constitution this decision is final.

MR. PRESIDENT—The case of the Bay County Medical Society, referred to the Judicial Council for adjudication, would respectfully report that they have declined to receive the delegates from both societies on account of irregularities.

S. N. BENHAM,

Secretary.

ANNUAL ADDRESS ON PRACTICAL MEDICINE.

DR. N. S. DAVIS, President of the Section of Practical Medicine, Materia Medica, and Physiology, read the following address:

MEMBERS OF THE ASSOCIATION—By an amendment of the constitution of this national organization, adopted at the annual meeting in 1873, it becomes my duty on the present occasion to report to you "the more important advances and discoveries of the past year" in the department of Practical Medicine, Materia Medica, and Physiology.

To judge correctly concerning the improvements and discoveries made in any important department of science or art in a single year, requires a minute knowledge both of the preceding condition of such science and of its entire literature for the year under consideration. Hence, the task involves much labor, and its proper performance needs the exercise of sound judgment; for it is not every novelty that constitutes a discovery, nor every new phraseology in the expression of ideas or facts that constitutes an actual advancement.

Perhaps the chief improvements or additions to our knowledge in the department of physiology during the year ending April 1st, 1874, are such as relate to the functions of the brain and nervous system. The experiments of Fritsch and Thitzig, Nothnagel, Fournier, Ferrier, Dupuy, Carville, Bartholow, and others, for the purpose of determining more definitely the functions of particular parts of the brain, have attracted much attention. The novel methods adopted by these experimenters, consisting in some instances in the injection of distinctive substances, colored with aniline, into the substance of the brain, and in others in the application of electric and galvanic-electric action to limited portions of the cerebral hemispheres, and the striking results that followed, were thought by many to have brought a new era in the development of cere-

bral physiology, and to have overthrown many of the opinions hitherto regarded as well founded. Up to the time of these recent experiments it was supposed that the gray matter of the cerebral periphery, being the seat of mental perception, was not amenable to direct excitation by stimuli. But when Ferrier laid bare the surface of the convolutions, and by applying his blunt electrodes induced with readiness and apparent uniformity certain muscular movements, according to the convolutions touched, it appeared to demonstrate not only sensibility of the cerebral surface to stimuli, but also the special localization therein of motor functions. By the subsequent investigations of Dupuy, as detailed in his inaugural thesis, it is shown that the faradic currents used by Ferrier could not be restricted to the peripheric layer of the brain, but they readily penetrated to the striated matter and central ganglia, and therefore produced their effect on muscular movements by direct excitation of these deeper-seated parts. M. Carville, in repeating the same methods of investigation, more especially with the animals experimented on under the influence of anaesthetics, obtained results confirming the views of Dupuy. Very recently Dr. Bartholow, of Cincinnati, availed himself of an opportunity to perform a limited number of experiments on the brain of a patient, a large part of whose skull had been removed by disease in such a manner as to leave a considerable extent of cerebral surface bare, including portions of both hemispheres.

The mode of experimenting differed from that of Ferrier, chiefly in the use of fine needle electrodes penetrating the brain substance, instead of blunt ones resting on its surface. The results in producing muscular movements corresponded closely with those obtained by Ferrier on animals. And when during the third experiment the faradic current was rendered more intense, decided epileptiform convulsions ensued. While the results of these few experiments on the human brain correspond closely with those obtained by Ferrier, yet they are still more amenable to the objections made by Dupuy and Carville, because in making a subsequent *post-mortem* examination Dr. Bartholow found his needle electrodes had penetrated from one to one and a half inch into the cerebral substance. The whole history of experimentation involving the injury or mutilation of animals, for determining the functions of any part of the nervous system, shows that conclusions must be drawn from them with great caution. From a careful review of all these recent and highly interesting experiments, their combined results appear to confirm the previous views concerning the functions of different portions of the brain, instead of overthrowing them. And if they have added anything to our physiological and anatomical knowledge, it is in indicating more definitely the exact points or localities in the periphery, where the striated fibres forming the medium of communication between the central ganglia—as the corpora striata and optic thalami—and the gray matter of the convolutions touch the latter.

We had regarded these results of previous physiological experiments in connection with many pathological phenomena as sufficient to indicate clearly a primary centre for ordinary sensation in the optic thalami, to which impressions from all points of the body are transmitted by one set of nerve filaments, and from which they are transmitted to some point in the periphery by some of the white fibres intervening between these bodies and the gray matter of the convolutions, when the impressions are mentally recognized, and the resulting volition is sent from the same part by another set of white fibres, first to the central ganglia represented by the corpora striata, and from thence to

whatever set of muscles are required to obey the mandate of volition. Instead of indicating any new functions in the convolutions, or spinal organs of muscular sense, the recent experiments have simply indicated more directly the particular convolutions in contact with the conducting fibres communicating through the common centre, with particular sets of muscles. The observations of Dr. Eichorst (see Virchow's Archiv) on the degeneration and regeneration of cut and injured nerves are interesting and important. They were made on the nerves of rabbits, and appeared to establish the fact that cut and injured nerves first exhibit an accumulation of granular matter, increasing the bulk which appears to arise from a breaking up or degeneration of the medullary matter of nerve. The sheath or schwann and the perineum become swollen from serous transudation, while the axis cylinders remain but little changed. During the second week these exudative and degenerate changes gradually disappear, and the process of regeneration becomes visible in the form of delicate and slender threads running into and extending from the injured end of the nerve. This reparative action is observable at the end of the second week, and continues several weeks before it becomes complete. Dr. Eichorst made no observations in regard to the time required for the nerve function to be restored. But from the slowness of the reparative process, as well as from other recently observed facts, it is rendered probable that those cases of apparent speedy restoration of function after injury or excision of nerves, reported by surgeons, have been instances in which the parts received nerves from other sources. While I would not discourage investigations in any direction, or in any degree undervalue the importance of a correct physiology of the nervous structures entering into the human body, yet I am strongly impressed with the idea that we are attributing too much to nerve influence, and too little to the influence of properties inherent in all living structures. We have come near to the standpoint of referring all impressions, healthy and morbid, to a primary reception by some part of the nervous system, and as a consequence of regarding all vital actions as in some way dependent on nervous influence. In this we are confounding nerve *sensibility* and nerve *force* with properties that are inherent in living organic matter, and are as clearly appreciable in the primary germinal cell, or granule of bioplasm, as in the most highly organized nerve structure. I do not allude to vitality or the abstract principle of life, for it is doubtless beyond human comprehension. Imparted primarily by the Creator, to matter in certain modes of combination, and perpetuated by parent to offspring throughout the whole domain of organic nature, both vegetable and animal, it stands in its relation to the human mind as an ultimate fact, incapable of further analysis or explanation.

But when matter is thus endowed with vitality it possesses certain properties that can be studied and comprehended as readily as we study the properties of inorganic matter. It is as easy to demonstrate that the germinal cell of the ovum or the acorn possess a susceptibility to the presence of certain exterior agents, as heat, moisture, electricity, and a peculiar affinity by which it elects and combines with certain atoms of matter and rejects others, thereby effecting determinate changes that we call growth, as it is to demonstrate that an acid will unite with a base, or that the presence of a second acid will cause the rejection of the first and the formation of a new compound. Susceptibility and vital affinity are properties common to all living organic matter, whether in the primary germinal specks of bioplasm or in the most complex structures of the

human body. And they exert a controlling influence in all that relate to molecular changes in assimilation, nutrition, disintegration, secretion, and as a consequence in the evolution of a disease. These properties are capable of being modified or acted upon directly by all those pervading forces, sometimes styled unponderable agents, such as electricity, heat, light, etc., and by the presence of many alimentary and medicinal agents. They are in no sense derived from the nervous structures, and can be modified only indirectly by nerve influence. Every system of physiology which does not recognize these elementary properties of all living matter as distinctly as it does the special functions of each organized structure, will be found defective. Not only will it be defective as a branch of science, but as the basis or point of departure for the study of pathology, it will continue to involve us in doubt, obscurity, and false conclusions.

Materia Medica.—The past year has not been made notable by the discovery of any new and valuable article of the *Materia Medica*, or by new applications of old remedies of such importance as to be worthy of special mention. What we most need, however, in this department, is not the addition of new articles or new applications of old ones, but a more complete knowledge of the composition and properties, with a more exact appreciation of the *modus operandi*, of such as are already on the official list. The progress of organic and analytical chemistry, and their application to the investigation of the composition and properties of medical agents, is constantly separating out the active principles and presenting them for use in more convenient and reliable forms; but most of our methods of testing the effects of medicines on the various functions of the human body are extremely defective. So true is this, that the most diverse opinions still exist concerning the action of many of the oldest and most frequently used articles of the *Materia Medica*. And not a few of them—like opium, quinine, alcohol—are commonly regarded as capable of exerting directly opposite effects by simply altering the dose. That is, we are told that in small doses they are stimulant or tonic, and in large doses sedative or narcotic, but at what point in the progress of increasing the dose the action becomes reversed, no one appears able to point out with exactness. Perhaps in no other department of medicine do we find opinions and conclusions derived from investigations so partial or incomplete; and the adherence to names and classifications involve so much confusion. It is to this condition of our *Materia Medica* that we owe many of these apparently contradictory modes of practice, which have done so much either to create scepticism both in and out of the profession, or to fasten the theory that the type and character of diseases change with the cycles of time. The idea that the special type and character of diseases have undergone marked changes, and are far less active or sthenic now than in the earlier part of the present century, has become very general both in and out of the profession. And this is alleged as a reason for the change in practice from depletion and antiphlogistics to nourishment and so-called stimulants. But if we analyze more closely the development of opinions and modes of thought, as presented in the medical literature of the last half century, we shall be forced to the acknowledgment that the idea of change in the character of diseases has followed rather than preceded the changes in the modes of practice, and that it really has no other appreciable facts on which to rest. In other words, it will be found to have been a simple theoretic idea, suggested to avoid the difficulty

and scepticism arising from such various and apparently contradictory modes of practice.

We say *apparently contradictory*, for it is not certain that a more careful review of the *modus operandi* of the remedial agents used would not show the most diverse in appearance to have really reached the same end by different routes. For example, on the assumption of the chronic physiologists that alcohol is respiratory food, acting as a stimulant to the organic functions and sustaining the temperature of the body, nothing could appear more opposite than to treat one case of fever or acute disease with artificial sedatives, evacuants, and alteratives, and another case of the same disease with alcoholic liquids and nourishment. But when we turn from the theoretical assumption to the results of positive experimentation we find the ingestion of alcohol to be followed by a reduction of temperature, a retarding of capillary circulation and molecular change, and a diminution of nerve sensibility. In other words, we find the *assumed* stimulant to be a positive and universal *sedative* to organic and molecular changes, and anesthetic to nerve sensibility.

Hence the practitioner who plies his patient freely with wine, whiskey, or brandy is as certainly holding him under the influence of a powerful sedative as was his ancestor who bled and phlebotomized, or his contemporary who gave veratrum and alteratives; and we need resort to no supposable change in the type of disease to understand why all, if wielding their weapons with equal skill, arrive at very similar results. As already intimated, there is no other department of medicine that so urgently needs a thoroughly critical and experimental revision as our *Materia Medica*. The work should be carefully planned and persistently pursued until the erroneous phraseology is corrected, and the mass of speculations and mere assumptions are replaced with positively observed facts.

Practical Medicine.—In the department of Practical Medicine, as in the case of *Materia Medica*, the past year has revealed no striking discoveries either in regard to the nature of sickness or the method of treatment; yet it has been characterized by a genuine progress that is worthy of careful study.

History is said to be ever repeating itself. The human mind is ever tending to extreme views in all departments of study, and to hasty generalization from facts insufficient in number and imperfectly observed. And in no department of literature and science are these tendencies more strikingly illustrated than in the history of practical medicine.

The pendulum of professional opinion and practice has swung from one extreme to another with almost as much regularity and celerity as if moved by the force of gravity. During the first half of the present century professional practice had reached the extreme of depletion and evacuants, when, checked by its own abuses, the return wave carried us in the short space of three decades, first to conservatism or expectancy, and then to full stuffing and so-called stimulation; until wine, brandy, and indiscriminate nourishment were made the instruments of abuses no less injurious to the human family than blood-letting and evacuants in their palmist days. This last swing of the professional pendulum has just reached its widest divergence from the perpendicular, and one of the most gratifying evidences of progress in practical medicine the past year consists in the plain indication to be seen in various quarters that the pendulum has fairly commenced its return motion. The constantly increasing importance attached to fresh air, pure water, and frequent ablutions in the sick room; the more careful adjustment of the quantity and quality of food to the

capacity of the digestive organs for acting on it; the rapidly increasing condemnation of the indiscriminate use of alcoholic and other anæsthetic and narcotic agents; the occasional unshattering of the long neglected lancet, with here and there a bold, outspoken advocacy of its judicious use; and above all, the better appreciation of the fact that a retardation of tissue metamorphosis and elimination is by no means equivalent to assimilation and nutrition, either in health or disease, are marks of a genuine progress that can be easily recognized in the literature of practical medicine during the past year. And happy would it be, both for the profession and the public if the return wave of thought, investigation, and practice, now fairly begun, could be so guided by a higher mental discipline, the adoption of more patient and complete methods of observation, and the adherence to a more rational induction, as to turn it steadily upward at the true meridian line, instead of allowing it to roll steadily on, until it again breaks upon the reefs and shoals of its own excesses. But was there no good reason for hoping for such a result. On the contrary, evidence of the same tendency to extremes and hasty generalizations are as visible in the field of practice to-day as at any former period. Very recently attention was directed anew to the importance of noting the variations of temperature in disease, and straightway there appear diagrams marking the variations of temperature in the progress of diseases with as much apparent fixity and certainty as the thermometric lines are drawn over the topographical map of a continent, and the practitioner looks upon his pocket thermometer as his chief instrument in diagnosis and prognosis. That *temperature*, if studied in close, careful connection with the co-existing indications of the state of mutual disintegration and elimination, is of great importance in a chemical aspect, is certainly true. It was the subject of my inaugural thesis in January, 1837. It was again the subject of a careful series of investigations by me, more especially in its relations to certain kinds of food and drink, in 1850, the results of which were embodied in a paper read to this Association in May, 1851, and published in the *Northern Medical and Surgical Journal* for that year. Those investigations fully disclosed the important fact that the temperature of the body varied from one degree to two degrees Fahrenheit with each ordinary meal, invariably rising during the active period of digestion and then gradually declining until the next ingestion of food, thereby establishing precisely the same facts that were again proved experimentally by Dr. C. E. Buckingham, of Boston, as published in the *Boston Medical and Surgical Journal* for January 1st, 1874. It was in the same paper read to this Association in 1851 that the first direct experimental proof was given of the power of alcohol when in the human system to directly reduce its temperature. That the temperature of a body is altered by every change in the arrangement of its molecules, being increased as those become more compact or denser, and decreased as they are rarefied or rendered less dense, is a well-known law of physics. As a rule, those processes by which new material is digested, assimilated, and added to the tissues evolve caloric heat, while those by which the cells and atoms of the tissues are redissolved and eliminated through the skin, lungs, and kidneys absorb or render the sensible heat latent, and therefore reduce the temperature.

When these adverse processes balance each other, the ordinary standard of temperature is maintained, subject to such daily variations as accompany the active stages of digestion. Thence it is plain that a given degree of temperature in any stage of disease is

a simple physical fact, the correct interpretation of which will depend entirely on the careful noting of the coincident state of the processes of injection and elimination; just as the dulness elicited by percussion denotes the simple physical fact of increased density, while the question whether such density depends upon tubercular deposits, hepaticization, or pleuritic effusion, will depend altogether upon the history of the case and the coincident facts. If we use our clinical thermometer for the same purpose that we use the instruments for percussion and auscultation, that is, for the establishment of a physical fact to be interpreted by a careful appreciation of preceding and accompanying phenomena, it will be of great value. But if we endeavor to make its markings into arbitrary rules to guide our practice, as has already been too hastily attempted, it will lead us into mischievous errors at every step. Another striking exemplification of the fact that our own day is as prolific of partial observations and hasty inferences as any that have gone by, is found in the application of the microscope to the study of etiology and pathology. Through its prolific revelations one army after another of poisonous germs are found preying upon the human race, until not only the air, earth, and water, but even the blood and the bowels, literally swarm with them. From syphilis the cholera and from throat disease to cancer we have little else than microscopic germs enumerated as essential causes of disease. Dr. A., in some part of Europe, announces that he has discovered in the dissections of cholera patients certain germs which, by diligent cultivation, multiply and develop rapidly, and a large part of the medical world at once leaps to the conclusion that these are the veritable causes of that dire disease; and instead of patiently extending observations to ascertain whether the same germs are not to be found in the serous discharges from mucous surfaces in any form of disease, after exposure to atmospheric air, they immediately give loose rein to imagination for the purpose of explaining how these extraordinary germs, hatched on the banks of the Ganges, could be propagated and distributed around the globe.

For this purpose they are made to travel with caravans, sail on ships, ride on railroads, and when there is neither caravan, ship, railroad, nor canal, they are made to percolate through the soil, receiving reinforcements now and then from some luckless wight perambulating the country with *cholera*, and dropping his dejections just in the right place to supply the needed link in the chain of connection. But just as we have our maps lithographed, our literature filled with satisfactory explanations, and our warehouses filled with materials for disinfecting the dreaded dejections, the tantalizing word comes from a thousand sources that the supposed cholera germs are not by any means peculiar to the dejections from that disease, but may be readily cultivated as a post-partum growth in any serous evacuation from the alimentary canal. From the tenor of these observations let no one infer that I undervalue the microscope as an aid in the study or investigation of medical topics. Its use has literally opened to us a wide and most important field of knowledge, and when rightly used is capable of adding much more. My object is simply to attract your attention to what has appeared to me the strongest barriers in the way of genuine progress, both in the science and art of medicine, namely, incomplete observation of facts, deductions from inadequate premises, and the constant use of more theoretical assumptions or suppositions as though they were demonstrated facts. It is the indulgence of these practices

that actually keeps one-half of the professional observers busy in correcting the errors and disproving the assumptions of the other half, and fills our literature with endless contradictions. Almost every problem connected with medicine is complex, requiring for its proper solution a careful observation of many elements, and their exact relations to each other. This is pre-eminently true of the problems involved in the study of etiology, or the causes of disease. To demonstrate the true relation of cause and effect in the origin and spread of diseases requires not only many observations concerning all the elements entering into the problem, but it requires these observations to be made coincidently in several distinct localities. And when the causation of epidemics is involved, the observations should have preceded for a considerable time the actual appearance of the disease, and be continued a like period after it has ceased to prevail. Indeed, if we would make genuine and reliable progress in the study of the causes and modes of propagation of diseases of every kind, we must no longer depend on chance observations, individual enterprises, or irregular and temporary expedients, but we must devise a complete and permanent plan or system of observation, covering the whole country, rendering available all the aid to be afforded by chemistry, microscopy, meteorology, and other branches of general physics, and pursue it with fidelity for a series of years. The appliances needed for such a work, even to the inclusion of atmospheric currents and terrestrial electricity, are available at the present day. What is needed is the wisely devised plan, the individual workers to man it, and the central executive person to maintain it in operation and cause the results to be annually gathered, carefully scrutinized, and communicated to the profession at large. And is not this national representative body exactly the central executive power that we need? Is not the Section on Practical Medicine, Materia Medica, and Physiology the place to devise the plan, to choose the workers, to designate the localities, and to annually gather in and digest the fruits? Many have asserted that the American Medical Association is a failure, and many are apparently looking anxiously for its early dissolution. But it has appeared to me that it has just reached the stage of development and the degree of perfection in its organization necessary for entering upon a career of prosperity and usefulness hitherto unknown in the history of scientific and professional organizations. With all ethical matters in the hands of a judicial council, with our strictly representative character improved, and the organizations of the sections more complete, we are really just prepared for efficient service in every department of the broad domain of medicine.

May we hope that during this session of the Association every member will attach himself permanently to some one of the sections, choosing the one embracing departments of study most congenial to his own tastes and opportunities, and that each section, in addition to the hearing of reports and volunteer papers and discussing them, will carefully plan definite methods for investigating some important topic connected with each branch of medicine assigned to it.

Such a course, pursued from year to year, would rapidly diffuse a more philosophical spirit of investigation, check excesses and hasty generalizations, foster co-operation, uniformity, and persistence in researches, and give to this Association such a character as would rally to its support the earnest workers in the profession from all parts of the country, thereby rendering its existence not only perpetual, but also ever increasing-

ly useful to the profession it represents and to the great family of man.

SYPHILIS AND PROSTITUTION.

Dr. S. D. Gross, chairman of the Section on Surgery, next delivered an address upon the progress of surgery, in which he treated of the history and character of syphilis and its influence upon the public health. It was an elaborate and able attempt to prove the unity of the syphilitic poison and to establish its influence upon all the so-called hereditary diseases. The position taken was in many respects original and radical, and as a contribution to the discussion of the general subject was interesting and suggestive. The question of the control of prostitution was discussed, but without any definite conclusion as to the best course to be pursued.

Dr. J. MUNION SIMS, in rising to thank the author for this paper, expressed the opinion that the term, legalizing prostitution, was so obnoxious to the moral and religious sentiment of the community, that no attempt to have distinct laws passed, bearing upon the question, could ever be successful. He suggested that the only feasible plan was to place the matter in the hands of the health boards, who could have all the necessary power, and could exercise that power in a quiet and inoffensive manner to the end desired. Such health boards could be empowered to cause house visitation, and to force those infected with the disease to be sent to suitable hospitals, the same as in cases of small-pox and other contagious diseases.

It was suggested that a committee, with Dr. Gross as chairman, be appointed to carry out the objects of the paper.

The Association then adjourned until 9 A.M. the day following.

THIRD DAY—WEDNESDAY, JUNE 6.

The Association met at nine o'clock. Dr. Grant, of Ottawa, Ont., and Dr. Murphy, of Chatham, Ont., were admitted as members by invitation. The arrangements for the return of the delegates to their homes by rail were announced.

REPORT ON THE PRESIDENT'S ADDRESS.

The Committee on the President's Address reported as follows, through Dr. White, of Buffalo, the chairman:

Your committee, to whom was referred the recommendations and suggestions contained in the President's Address, would respectfully report as follows:

We are fully in accord with the President concerning the propriety and desirability of establishing at some central position a physiological and pathological laboratory.

In view of the growing sense of the importance of carefully recorded facts and observations, we are fully impressed with the desirability of the publication of annual reports of the progress and discoveries of all chartered medical and sanitary institutions.

We also recognize the importance of concerted action on the part of the profession, and agree with the President in urging the formation of a complete system of State and local medical societies.

We would also recommend an extension of time of the session of one day, making the length of the session four days. This is done in view of the fact that, although the arrangement of the sections under the present circumstances is admirable, they occupy more than half of the time of the meeting, causing a lack of time for the proper and deliberate consideration of legisla-

tive matters. When, in connection with this, there is taken into consideration the fact that the over-generous hospitality of those who entertain the Association is apt to occupy much time, it will be seen that the time for the discussion of the papers is inadequate.

We also look with much favor upon the President's recommendation of the organization of an International Medical Congress, and would move the adoption of the following:

Resolved, That in view of the lack of time in which to properly transact the business of the Association, an extension of one day is deemed advisable.

Resolved, That the President appoint a committee of five, of which he shall be chairman, to elaborate a plan for the organization of an International Medical Congress, and report at the next meeting.

Your committee had also prepared a resolution in regard to memorializing Congress concerning the rank of the medical staff corps of the army, but find that they are anticipated by Dr. Keller. They would, therefore, simply recommend on the part of the members of this Association continuous personal application to the representatives in Congress from their several districts in regard to this important subject.

The report was accepted.

THE DEATH OF DR. HENRY MILLER, OF KENTUCKY.

Dr. WHITE also offered a preamble and resolutions, written by Dr. Gross, in regard to the death of Henry Miller, of Kentucky, an ex-president of the Association, and made some remarks eulogistic of the character of the deceased. The resolution was adopted, and it was moved that Dr. White be appointed to draw up a memoir. Dr. White declined, and Drs. Gross, Keller, and Gaillard were appointed a committee on the subject.

MONUMENT TO DR. McDOWELL.

Dr. KELLER brought forward the subject of a monument to Dr. Ephraim McDowell, of Danville, Ky., the father of ovariectomy. He said that the Boyle County (Kentucky) Medical Society and the Kentucky State Medical Society had taken steps toward the erection of a monument to Dr. McDowell, and offered the following resolution:

WHEREAS, A most laudable effort has recently originated in the Boyle County Medical Society of the State of Kentucky, and in the Kentucky State Medical Society, to create a fund for the erecting of a statue, or some other suitable monument, in honor of Dr. Ephraim McDowell, the father of ovariectomy, English writers to the contrary notwithstanding, who lived in the town of Danville, in the State of Kentucky, and who performed in that town the first ovariectomy, in the year 1809;

Resolved, That the American Medical Association most earnestly endorse the action of said county and State societies, and as urgently commends the object to the generous consideration of the medical profession of the world.

Dr. Keller favored the resolution in a few words, and hoped for an expression in full on the subject.

Dr. WHITE also favored the resolution, and it was adopted.

PAPER BY DR. PARVIN, OF INDIANAPOLIS.

Dr. PARVIN, from the Section on Obstetrics and Diseases of Women, read a paper on Hemorrhage of the Uterus.

Thanks were tendered for the paper, which was referred to the Section on Obstetrics.

ABOUT DR. PALLER'S PAPER.

Dr. WHITE moved the suspension of the rules to allow Dr. Pallmer's paper on Gynecology, which had been crowded out, to be read.

The chair (Dr. TONER) ruled the motion out of order, as the paper had been referred to the Section on Obstetrics.

A gentleman appealed from the decision of the chair, but on its being stated that the paper had been referred to the Section on Obstetrics, and had not been reported back to the general session, the appeal was withdrawn and the regular order was proceeded with.

Dr. Talley, of the Section on Medical Jurisprudence, being absent, his paper was made a special order for this morning.

WASTE OF LIFE.

Dr. A. N. BELL, of Brooklyn, chairman of the Section of State Medicine and Public Hygiene, read a report on the subject above indicated.

Dr. Bell's paper was accepted, and referred to his section. A vote of thanks was tendered for it.

REPORT OF THE DELEGATE TO EUROPE.

Dr. ATKINSON read the report of Dr. Seguin, the delegate of the Association to European medical bodies, as follows:

Mr. President and Members of the American Medical Association:—You sent me as a delegate to the British Medical Association, and to other kindred European societies for the year 1873-74.

Ill-health did not permit me to attend other meetings than those of the British Association in London, and of the French Association for the Advancement of the Sciences in Lyons.

By both societies I was received for your sake as the most worthy among you could have been, and allowed the most cordial hearing.

I took this opportunity to advocate, with slight variations, in London and in Lyons, a theme of great importance. I mean the question of harmonizing our means of observation and of record, and of instructing therein mothers and nurses.

The British Medical Association ordered the printing of my lecture, and the Section of Medicine of the French Association for the Advancement of the Sciences voted the nomination of a commission to arrange the preliminaries of an international agreement on this subject. The motion was firmly supported by Prof. Vercueil, president of the Section of Medicine, and by Prof. Morey, of the College de France, and carried.

At this point I ask the concurrence of the American Medical Association, thinking that we must not now remain behind in a question in which we were ahead last year.

This question is of incalculable interest.

Our methods and instruments of observation are discordant in results and in scales; our clinical tables differ from nation to nation, from one hospital to another, and are almost ignored in private practice; family physicians are helpless to supply their share of the advancement of science, because they do not educate mothers to be their clinical assistants, and mothers and nurses remain a prey to the vilest quackeries because we do not teach them better.

As soon as the object of this communication shall be attained, the observations of physicians will become comparable at a glance, and their record be as positive as those of the operations of the chemist, the physicist, and the dynamist.

Moreover, women will be more useful when they form a higher estimate of their functions in the sick

chamber; and when they know that diseases are natural deviations from natural laws, they will cease to look for supernatural means of restoring natural health.

These considerations could be much enlarged. To save time I cut them short, and conclude by asking the American Medical Association to form an international commission of physicians of high standing, speaking the European languages, and despatching to go to Europe this summer, to charge them to represent the American Medical Association before the British Medical Association, the German and French Association for the Advancement of Science, and other kindred societies; to promote interchange of ideas, and particularly to co-operate with them in any plan, scheme, or organization which would have for its direct object the uniform establishment and propagation of the methods and instruments of positive observation. And, finally, to invite them to report on the progress of this work at the next meeting of this Association.

The report was accepted and ordered printed in the minutes, and its recommendations adopted.

GENERAL BUSINESS.

DR. ATKINSON read a communication from the librarian of the Association at Washington. The report was received.

Dr. Atkinson also offered a resolution for the exchange of the published report of the transactions of the Association with other associations, the editors of medical journals, and the library of Congress. Carried.

Dr. Woodward, from the Committee on Nomenclature, reported progress, and asked to be continued. Granted.

A RESOLUTION OF CENSURE.

Dr. WILSON, of Michigan, offered the following preamble and resolution:

WHEREAS, Dr. Bartholow, of Cincinnati, O., in his zeal for scientific research, has recently made a series of experiments with electricity upon the brain of a patient, by inserting needles into the substance thereof, and passing currents from these to different parts of the body, causing thereby pain, convulsions, and probably hastening death; and,

WHEREAS, We are ever ready and willing to accord the greatest praise and honor to the original investigator in any part of the domain of medicine, yet these experiments are so in conflict with the spirit of the profession, and opposed to our feelings of humanity, that we cannot allow them to pass unnoticed.

Resolved, That in our opinion, no member of the medical profession is justified in experimenting upon his patient, except for the purpose and with the hope of saving said patient's life, or the life of a child *in utero*.

The resolution was referred to the Judicial Council without debate.

DR. MYERS EXONERATED.

Dr. DAVIS stated that the matter referred to the Judicial Council in regard to Dr. William H. Myers, of Indiana, had been considered, and that the council decided that Dr. Myers was in good standing. Accepted and adopted.

A MEDAL FOR MEMBERS.

Dr. ASKEW moved a resolution that a die suitable for a medal, with a likeness of Dr. Davis on one side, and the name and date of organization of the Association on the other, be struck, and furnished to members. Adopted; and Doctors Tonner, Keller, and Woodward were appointed a committee to carry out the resolution.

MISCELLANEOUS.

Dr. A. M. POLLOCK, of Pittsburg, moved the appointment of a committee of fifteen, to confer with the Philadelphia Society, in regard to the meeting in Philadelphia in 1876. Adopted.

The following committee were appointed under the resolution:

Drs. Pollock, Pittsburg; Altie, Lancaster; Green, Easton; Curwin, Harrisburg; Lyons, Williamsport; Gillite, Franklin; Lee, Franklin; Hoebstock, Pottsville; King, Pittsburg; John Loman, Johnstown; Eugene Smith, Michigan; N. C. Husted, New York City; E. Lloyd Howard, Baltimore; J. H. Wheeler, Nashua, N. H.; L. F. Warner, Boston.

Dr. BRODIE presented the plate on which was engraved the card of membership when the Association met in Detroit in 1876. It was accepted for the archives of the Association, and a vote of thanks was tendered to Dr. Brodie for it.

Dr. DAVIS, by request, made some explanations in regard to the by-laws and the relation of the sections to the general session.

Dr. BRODIE called on Hon. G. V. N. Lathrop for some remarks. He was greeted with applause, and made a brief response.

The Association then adjourned until nine A.M. Friday.

FOURTH DAY—FRIDAY, JUNE 5.

The Association was called to order at the appointed hour by Dr. J. M. TONER, the President.

On motion, Dr. EDWARD W. JENES was added to the delegation for Foreign Societies.

Dr. J. W. BENNETT, of Brookhaven, Miss., sent a communication containing medical reports from Canton, China, showing the progress of Western medicine in the East.

THE SALARY OF THE PERMANENT SECRETARY.

After some discussion the sum of \$500 was appropriated as the salary of the Secretary for the year.

The following gentlemen were appointed a committee to digest a plan for an international medical association: Drs. A. M. TONER, N. S. DAVIS, Alfred Stillé, Austin Flint, J. S. Billings.

OFFICERS AND COMMITTEES.

The following officers were elected for the ensuing year:

President—Dr. W. K. Bowling, Tennessee.

Vice-Presidents—

1. Dr. William Brodie, of Michigan.

2. Dr. J. J. Woodward, of United States Army.

3. Dr. H. W. Brown, of Texas.

4. Dr. H. D. Didama, of New York.

Treasurer—Dr. Casper Wistar, of Pennsylvania.

Librarian—Dr. William Lee, of the District of Columbia.

Committee on Library—Dr. Johnson Elliott, of District of Columbia.

Assistant Secretary—Dr. Will. Walling, of Kentucky.

Committee of Arrangements—Drs. Edward Richardson, chairman; Lawrence Smith, Robert Gale, James Holland, Henry Bullitt, J. M. Keller, D. W. Yandell, Lewis Rogers, R. C. Hewitt, all of Louisville.

Committee on Prize Essays—Drs. J. A. Octobry, L. P. Yandell, J. D. Jackson, all of Kentucky; Thomas Phillips Parvin, T. M. Stevens, both of Indiana.

Committee of Publication—Drs. F. G. Smith, Wm.

B. Atkinson, D. Murray Cheston, Casper Wistar, Alfred Stillé, all of Pennsylvania; William Lee, of District of Columbia; H. F. Askev, of Delaware.

The committee also report the following nominations for chairmen and secretaries of sections for 1865:

1. Practice of Medicine, Materia Medica and Physiology, Dr. Austin Flint, of New York, chairman, and Dr. J. K. Bartlett, of Wisconsin, secretary.

2. Obstetrics and Diseases of Women and Children, Dr. W. H. Byford, of Illinois, chairman, and Dr. S. C. Busey, of District of Columbia, secretary.

3. Surgery and Anatomy, Dr. E. M. Moore, of Rochester, New York, chairman, and Dr. T. S. Lattimer, of Maryland, secretary.

4. Medical Jurisprudence, Chemistry and Psychology, Dr. Jerome Cochran, of Alabama, chairman, and Dr. G. A. Moses, of Missouri, secretary.

5. State Medicine and Public Hygiene, Dr. H. I. Bowditch, of Massachusetts, chairman, Dr. H. M. Baker, of Michigan, secretary.

Members of Section—Drs. J. Cochran, of Alabama; D. A. Linthicum, Arkansas; T. M. Logan, California; R. G. Buckingham, Colorado; B. H. Catlin, Connecticut; L. P. Bush, Delaware; F. Howard, District of Columbia; — Nottingham, Macon, Georgia; H. A. Johnson, Illinois; W. H. Myers, Indiana; A. Y. Fields, Iowa; D. W. Stormont, Kansas; J. D. Jackson, Kentucky; S. M. Bemiss, Louisiana; S. Fitch, Maine; E. L. Howard, Maryland; H. I. Bowditch, Massachusetts; H. M. Baker, Michigan; A. B. Stuart, Minnesota; A. G. Smythe, Mississippi; D. F. Dean, Missouri; J. H. Peabody, New Hampshire; J. W. Parsons, New Hampshire; E. M. Hunt, New Jersey; A. N. Bell, New York; Wm. Clendenin, Ohio; H. Bettenger, Oregon; A. M. Pollock, Pennsylvania; E. M. Snow, Rhode Island; R. A. Kinlock, South Carolina; J. H. Van Deman, Tennessee; D. R. Wallace, Texas; J. L. Cabell, Virginia; A. T. Woodward, Vermont; H. P. Strong, Wisconsin; John Frisell, West Virginia.

Committee on Nomenclature—Drs. A. Sager, of Michigan, chairman; R. W. Hazlett, West Virginia; C. V. Mowtram, Kansas; John H. Collender, Nashville, Tennessee; D. V. Dean, Missouri; W. H. Cumming, Atlanta, Georgia; Alonzo Garelon, Maine; J. H. Wheeler, New Hampshire; W. W. Mayo, Minnesota; W. M. Chambers, Illinois; G. Sutton, Indiana; B. A. Vaughan, Mississippi; Geo. Mitchell, Ohio; J. J. Woodward, United States Army; N. M. Dodson, Wisconsin; L. P. Yandell, sr., Kentucky.

Judicial Council—Dr. A. N. Talley, South Carolina, for two years; J. R. Bartlett, Wisconsin; R. H. Gale, Kentucky; J. B. Johnson, Missouri; J. R. Bronson, Massachusetts; B. W. Catlin, Connecticut; Franklin Staples, Minnesota; W. V. Briggs, Tennessee, in place of the seven whose terms expire at this meeting. The rest of the present council continued.

Special Committees.—Dr. H. R. Storer, chairman of a committee to report on American as compared with foreign winter cures, continued.

Dr. John Morris, of Baltimore, special committee on the use of pessaries.

Dr. John A. Oetzelony, of Kentucky, special committee on cystic degeneration of the kidneys.

TREASURER'S REPORT, ETC.

The report of the Committee on Publication was read. The treasurer reported that the volume of transactions of last year was of much smaller size than formerly. A surplus of volumes remained, which he asked to be allowed to distribute. The balance on hand in the treasury was \$1,938.48. The reports were accepted, adopted, and ordered entered on the minutes, with the exception of that portion relating to their resignations. Adopted.

RESIGNATIONS REFUSED.

DR. SMITH, chairman of the Committee on Publication, and Dr. Wistar, treasurer of the society, tendered their resignations, but the society declined to receive them, and they were continued in office for another year.

DEATH OF DR. MENDENHALL, OF OHIO.

It was announced that a telegram had been received that Dr. George Mendenhall, one of the former presidents of the society, died last night. The following gentlemen were appointed a committee to report at the next meeting concerning Dr. Mendenhall's death: Drs. Howard, Murphy, Richardson, Heighway, and Bartholow.

RESOLUTIONS OF THANKS.

DR. VAN DEMAN, of Chattanooga, Tenn., moved the adoption of the following resolutions:

"WHEREAS, In view of the fact that the American Medical Association is now about to adjourn, it is appropriate that they show some manifestations of their gratitude and thankfulness to this City of the Lakes for their kindness to said association, to the several railroads for the courtesies extended, and to the several officers and committees for their efficiency and untiring energy in making our stay profitable and pleasant among them; therefore

"Resolved, That our most profound esteem and grateful thanks are due, and are hereby extended to His Excellency Governor Bagley, His Honor Mayor Moffat, Mrs. David Thomson, Hon. James F. Joy and lady, Mrs. Wm. Pitts, Hon. E. A. Brush and lady, Hon. Philo Parsons and lady, Dr. and Mrs. Stewart, Dr. and Mrs. Brodie, and Mrs. Wm. B. Wesson, whose hospitable hearts have made us as welcome to their homes as the doors of their mansions have been opened wide; to the many citizens who have shown us so many kind attentions; to the several railroads for their courtesies extended to our members; to the medical brethren of Detroit, who have contributed so much to make our stay pleasant in their beautiful city, to the several members of the press of this city and their respective reporters, who for correctness of reports and faithful performance of their duties cannot be excelled anywhere; and last, though not least, our honored president, Dr. Toner; the efficient secretary, Dr. Atkinson; the several standing committees, and particularly the Committee of Arrangements, and their wide-awake chairman, Dr. Brodie, for their earnestness and familiarity with their respective duties, we recommend to future committees, and officers of like character.

"Resolved, further, That we will ever hold in grateful remembrance our visit to Detroit; and may we in our future meetings, in whatever locality we may be called together, be as hospitably entertained and as well received, and carry home with us the feeling manifested at this meeting, that the American Medical Association knows no South, no North, East or West; all meeting under one flag, the banner of a united country, to do

PLACE OF NEXT MEETING.

The names of the officers and committees were ordered to be printed in the published minutes. Louisville was fixed as the place for holding the next meeting, and the first Tuesday in May was selected as the time.

battle against one common enemy, 'the ills that human flesh is heir to.'"

Dr. DAVIS, in seconding the resolutions, said that he especially desired to praise the preparations made by the Committee of Arrangements for the proper transaction of business, in the selection of proper rooms for the meetings of the sections, and the announcement daily of the order of business.

MISCELLANEOUS.

Dr. A. N. TALLEY, of South Carolina, was expected to read a paper at 10.30, but he announced that he had been unable to do so, owing to ill-health. He was permitted to send the paper to the Committee on Publication, or to prepare it in time for the next meeting of the Association.

Dr. KELLER moved that Drs. S. D. Gross of Philadelphia, N. S. Davis of Chicago, J. M. Toner, Washington, J. Marion Sims, New York City, and John Morris of Maryland, be a committee to consider Dr. Gross's paper on syphilis, and report at the next meeting. Adopted.

Mrs. ELIZA S. LEGGETT presented to the society a book written by her father more than a hundred years ago, and a pamphlet, showing that that gentleman was the first to introduce the doctrine of Jenner into this country, and also presented the lancet with which the vaccination was made. Accepted with thanks.

PAPER ON SURGERY.

It was announced by the President that a paper had been received from Dr. Paul F. Eve, of Nashville, Tenn., on surgery, "What the West has done for Surgery." It was referred to the Committee on Publication.

THE NOMINATING COMMITTEE.

A brief discussion took place concerning the work of the Nominating Committee. It was suggested that they should report before the last day of the meeting, so that the officers may be elected when the attendance is larger. Dr. SIMS thought that the work of the committee was very large and important, and could hardly be commenced too early. It should also be finished early. Dr. WOODWARD, U.S.A., thought that the committee were most competent to decide as to their times of meeting. They would doubtless transact their business as rapidly as possible. A motion to instruct the Nominating Committee in regard to this matter was laid upon the table, it being suggested that the attention of the Association had been called to the matter, and that this would probably prove sufficient.

OBJECTION TO DR. BARTHOLOW.

Dr. HOWARD moved to substitute Dr. Carson for Dr. Bartholow, on the committee to prepare suitable resolutions on the death of Dr. Mendell, stating that there were reasons which it was unnecessary to name for not placing the latter's name on the committee.

Several members objected, and a lively debate arose. Dr. KELLER moved that the committee be instructed to report this matter for publication in this year's volume of the transactions. Carried.

Dr. Howard's motion was then adopted, though a loud volume of "noes" was heard when the question was put.

THE CANADIANS.

Dr. HALL, of Toronto, Canada, offered a resolution expressing the thanks of the Canadian delegates for the reception which had been tendered to them by the Association. He felt that himself and his associates

had derived very great benefit from the meeting. They had become aware that medical science had advanced to a very high point in the United States, and the result of the meeting had been to increase the liberality of all the delegates, who had learned to respect each other, and to labor more mutually for the good of the profession. Dr. Hall expressed the good will which Canadians and Englishmen feel towards the Americans, and especially to men engaged in similar professions. He spoke very fully of the peculiar differences between American and Canadian institutions, and of the different forms of government in Great Britain and the United States, alluding to the good-looking Queen who governs the former, and to the rather grim-looking soldier who rules over the latter. In conclusion, Dr. Hall trusted that they might next year see a large number of the members of the American Medical Association at the meeting of the Canadian Society.

Dr. RICHARDSON, in seconding the resolution, said that he could not allow the opportunity to pass to express his thanks for the honors and courtesies he and his friends from Canada had received. He had not felt that he was a Canadian or a stranger. Both by members of the Association and by citizens of Detroit, they had been received with such friendliness that they felt that no words of appreciation could be extravagant.

Dr. N. S. DAVIS, of Chicago, expressed the good feeling which the American members entertain towards their Canadian brethren. The friendly contact between the two would send the delegates to their homes, he said, with that magnetism which would do more good to their patients than they receive from pills and powders. He had himself been in attendance at the meeting of the Canadian Medical Association, and had received the kindest and most hospitable treatment. He rejoiced that the profession to which he belonged contained such ornaments to medical science as are now to be found in Great Britain, Canada, and the United States, and that the science has no boundaries save the desire to benefit the human race.

The resolution was adopted.

REPORTS FROM THE SECTIONS.

The minutes of the various sections were reported to the Association, and referred to the Committee on Publication.

A WELCOME TO LOUISVILLE.

A hearty invitation was extended by Dr. Richardson, of Louisville, to members of the American and Canadian Associations, to attend the next meeting at Louisville, where they would be greeted with a genuine Kentucky welcome.

THE ROLL CONFIRMED.

Dr. BRODIE read the last names on the roll, and moved that the roll be confirmed. Adopted. The total number of members in attendance was announced at 427. [Applause.]

MISCELLANEOUS.

Dr. O'NEILL moved that it be the duty of the permanent secretary to prepare at each meeting a list of the members and publish them early in the session, for the use of committees. Adopted.

Dr. H. B. BAKER gave notice of an amendment to the constitution, that the officers of the several sections be elected by the sections themselves after the sections convene.

A resolution, of thanks to the janitor, pages, etc., was adopted.

Dr. BRODIE, in behalf of the citizens of Detroit,

expressed the great pleasure and satisfaction which they felt in the meeting, and their hope that they might have the pleasure of meeting them again.

VALEDICTORY.

DR. TONER then delivered his valedictory as follows:

GENTLEMEN: Your labors are brought to a close, and we are about to adjourn the twenty-seventh meeting of the American Medical Association. Before putting the motion that shall at once terminate the session and my official relations to this body, permit me once more to thank you for the courteous and efficient manner in which you have supported and assisted me in conducting the business that brought us together, and congratulate you for the philosophic, thorough and intelligent manner in which you have viewed and discussed the different questions that have been presented before us.

I am quite sure that this meeting will be conspicuous in our annals, and long remembered by all who have participated in its profitable deliberations, and have partaken of the unbounded hospitalities of the people of Detroit. The character of the work done by us must serve to make this Association more extensively known throughout the world, and its purposes and aims better understood, both by the people and the profession of the United States.

I am confident we all feel more than rewarded for our attendance by the new ideas we have gained, and by the actual increase of our professional knowledge, and by the cementing of old friendships, and the formation of many new and agreeable acquaintances. The question now before us is that the American Medical Association adjourns to meet in Louisville, Ky., on the first Tuesday in May, 1875.

The Association then adjourned.

NOTE.—In the preparation of the foregoing report we are largely indebted to the *Detroit Free Press* and the *Detroit Tribune*, both of which papers contained very full synopses of the proceedings.—Ed.

Progress of Medical Science.

COMPLETE ABSENCE OF THE UTERUS.—At a recent meeting of the Swedish Medical Society, Dr. Lamm narrated the following interesting case: A servant-girl, 25 years of age, consulted him for amenorrhœa. On bimanual examination through the vagina and rectum, no trace of a uterus or its rudiments could be found, but at about the normal level of the os there was a long, thin, firm band crossing the pelvis. There was a vagina, but instead of gradually enlarging as it ascended, it became smaller, somewhat like the finger of a glove; its length was about 9 centimetres. There were no rugæ, and the mucous surface was drier than usual. All the external genitals, together with the clitoris, were normal. The pelvis also was well formed, and the breasts and nipples were fully developed. Menstruation had, naturally, never taken place, nor had she experienced any of its molimina. Though she was subject to headaches, no periodicity was noticeable. Another strange feature of this case was, that the ovaries were found lying in the inguinal canals, and were about the size of plums. One could be replaced, the other could not. After hard labor the ovaries became swollen and painful; but these attacks did not seem to be in any way connected with the phenomena of menstruation.

INTESTINAL DUST.—At the last meeting of the Paris Academy of Medicine, Dr. Laboulbène, of Necker Hospital, made an interesting communication on the above. He stated that he had had the opportunity of observing six cases in which the patients, who generally fed almost exclusively on vegetables, evacuated with fecal matter a fine broken dust, which cannot be mistaken for biliary gravel, or the crystals of ammonia or magnesia sometimes evacuated by typhoid patients, or the fecal concretions found in the vermiform appendix. Chemical analysis of this dust had shown that it always contained a large proportion of silica. The presence of the dust thus introduced into the body had been the cause of gastralgia, constipation, and nervous phenomena, ending sometimes in hysteria and convulsions. Gentle purgations and animal food had put a stop to the disease.—*The Lancet*.

SUCCESSFUL LIGATION OF FEMORAL ARTERY AND VEIN.—Dr. E. P. Bennett, Danbury, Ct., writes: "Ligation of the femoral artery and vein having so generally been followed by gangrene, and consequent loss of life or limb, the following case may be of interest to the profession, and of vast importance to those who may be so unfortunate as to meet with an accident in which these vessels may be severed. A gentleman by the name of Olmstead, in the adjoining town of Redding, while engaged in skinning the head of a creature, was so unfortunate, in consequence of the slipping of the knife, as to completely sever the femoral artery and vein at about the middle of the thigh. A person with him at the time had the presence of mind to immediately cord the limb, so as to completely suppress the hemorrhage until I, with my son, arrived. I immediately cut down to the wounded vessels and put a ligature around both ends of the artery and vein. The wound was then dressed in the usual manner, and the limb was enveloped in a warm covering, and bottles of warm water applied to the limb, which soon regained its normal temperature, and the gentleman recovered without any further trouble. The ligatures from the vein came away in a few days and from the artery in the usual time. In the earlier part of my practice I was very cautious about ligating veins, for fear of phlebitis; but of late years I have often ligated veins, and thus far have never had any trouble from so doing."

LOCAL TREATMENT OF PULMONARY CAVITIES BY INJECTIONS THROUGH THE CHEST-WALL.—A noteworthy advance in the therapeutics of pulmonary diseases has been recently made in Philadelphia, by Professor Pepper. It has occurred to him, in view of the uniform failure attending the ordinary methods of treatment of pulmonary cavities in the stage of softening, that the morbid process might be more effectually combated by injecting powerful remedies directly into the diseased tissues through the chest-wall. He reports three cases in which this new procedure has been accomplished with perfect impunity, and in one of the cases with decided amelioration of the symptoms. In the first case reported there were manifest physical signs of a superficial cavity in the subclavicular space on the right side, containing some fluid. The operation is described as follows:

"On February 20th the No. 1 needle of Dieulafoy's aspirator, with the syringe attached, was introduced to the depth of about one inch in the second interspace on a line with the right nipple. He complained merely of a slight sensation of tingling and numbness, extending down the right arm. There was no cough

excited and not a drop of blood followed the puncture.

"February 24.—The same needle was introduced at the point of the original puncture to the depth of one and seven-eighths inch, and was followed by the escape into the vacuum of a few drops of offensive pus. The needle was very tightly bound by the tissues through which it passed, but some motion could be imparted to its free end, indicating that it was in a free space. Three or four minims of a mixture composed of liq. iodinii comm. gtt. ij. to f. i. of tepid water were then injected through the cannula by a hypodermic syringe.

"The operation was followed by loose, rattling cough, and the expectoration of about three fluid drachms of fresh, frothy blood. He was immediately put to bed, and the cough and hemorrhage soon stopped. His temperature in the evening and the following morning was only 99° F."

On February 28, six minims of iodine solution, of double the former strength, were injected at the same point and in the same manner.

On March 5, ten minims were injected at a point one-eighth of an inch nearer the sternum. March 8, it is recorded: "The patient is brighter and more cheerful than for months past. There is no hectic irritation, the temperature never rising above 99° or 99.8°. The pulse ranges about 84. His breathing is so much relieved that he has walked up three flights of stairs without much dyspnea. The cough is but little troublesome and only a few white frothy sputa are raised. Auscultation shows that many of the râles formerly heard over the right apex have disappeared. There has also been some increase in flesh. All internal medication has been discontinued."

In the other two cases the method pursued was the same, but not continued sufficiently long to accomplish any decided result. In the second case the needle was introduced in the second intercostal space, on the left side, about one inch outside of the line of the left nipple. In the third case the point of insertion was one-half inch outside the line of the right nipple, in the second intercostal space.

Local anesthesia by freezing was employed before puncturing. At the first puncture it is recommended to use the aspirator for the purpose of evacuating any fluid contained in the cavity. Afterwards a simple capillary cannula may be used. As the puncture is made the patient is directed to take a full inspiration.

The only point claimed to have been gained by these experiments is "the possibility of puncturing superficial pulmonary cavities and injecting into them small quantities of dilute solution of iodine." The fact of such treatment being admissible suggests an innovation in the treatment not only of pulmonary *emphysema*; but, as hinted by the writer, of superficial indurations or caseous infiltrations of the lung tissue; also, "of certain cases of severe hemorrhoptysis, especially when the hemorrhage proceeds from a well-defined seat of disease."

In an appended note reference is made to some reports of a recent paper in the *Berliner Klinische Wochenschrift*, by Prof. Mosler, on the "Local Treatment of Cavities in the Lung" by injecting certain remedies through the chest-wall, leaving the cannula in. These reports were seen by Professor Pepper after his paper had been prepared. The coincident investigations of so eminent an authority as Prof. Mosler are a further evidence of the importance of the subject.—*Philadelphia Medical Times*, March 14, 1874.

tled, "Experiments concerning the Effects of Lactic Acid upon Animals, by C. Heitzmann." The article is as follows:

"Lactic acid has been discovered in the urine of patients suffering from rickets and osteomalacia by Marchand, Ragsky, Lehmann, Simon and others. C. Schmidt demonstrated the same in the fluid from long bones in mollities, the bones having been metamorphosed into globular cysts. Interested in these statements Heitzmann instituted a series of experiments in the beginning of April, 1872, regarding the effect of lactic acid upon the bones of living animals, administered both internally and by subcutaneous injection. The animals selected were 5 dogs, 7 cats, 2 rabbits and 1 squirrel. As early as the second week of the experiments on dogs and cats, it was obvious that whether the medicine were injected subcutaneously or given by the mouth, while the supply of calcareous salts was diminished in consequence of the medicine, a swelling occurred at the extremity of the diaphyses of the long bones and at the junction of the ribs with the cartilages. This enlargement developed regularly until the fourth or fifth week and was immediately followed by curvatures of the extremities. Catarrhs of the conjunctival, bronchial, gastric and intestinal mucous membranes, with emaciation and spasms of the limbs, were accompanying phenomena.

Microscopical examination of the epiphyses showed a condition similar to that found in the epiphyses of rachitic children.

A continued administration of the acid was followed by diminished swelling of the epiphyses of the long bones, and the curvatures of the extremities were, to a certain degree, lessened. After a steady use of the acid for four or five months, however, there was a marked repetition of the catarrhal symptoms and softening of the long bones, which became flexible like willow-twigs.

A microscopical examination of the bones of those animals which had been using the lactic acid for from four to eleven months longer, gave an appearance similar to that found in the bones of those who have died of mollities.

No tumefaction of the epiphyses occurred in the three rodents. One died at three months and the other at five after commencement of the treatment, with symptoms of inanition. In the bones of these animals no marked indications of rachitis or mollities were visible. After eleven months of lactic acid treatment the squirrel is now drawing near his end.

These experiments demonstrate that by continued administration of lactic acid to carnivora, rachitis, primarily, and afterwards mollities ossium, may be artificially induced."

THE USE OF IODIC ACID BY HYPODERMIC INJECTION.—For some time the hypodermic syringe has been used to introduce fluids into the centre of glandular tumors. Lately Dr. Luton, of the Rhénus School of Medicine, has drawn attention to the remarkable success he has had in the dispersion of glandular and other tumors by the use of iodic acid thus applied. Goitres have been so treated, the solution he uses being about one-fifth acid, the balance water. A sharp local action at once occurs, but he has seen no inconvenience follow, and the resolution of the tumor has finally been effected without suppuration.—*Med. Press and Circular*.

A TELL-TALE STRAW.—The *Medical Times* says:—"Among the prizes at a recent homeopathic Commencement was a hypodermic syringe."

LACTIC ACID.—In the *Pharmaceutische Centralhalle für Deutschland* for Nov. 20, 1873, is an article enti-

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, June 15, 1874.

THE MEETING OF THE ASSOCIATION.

THE American Medical Association held its last Annual Meeting in Detroit. The proceedings of the same, which we present in full elsewhere in our columns, prove it to be a notable one in respect to many changes for the better which have been made in its organization. We venture to say that no more successful session has been held since the old-time period when the Association, as such, was looked upon with becoming and reverential awe by all those who sought an authoritative guide in medical propriety, and who realized the ultimatum of a decision on all matters connected with medical ethics. The changes which have been wrought for the better have been in the main those which have been so repeatedly insisted upon in these columns. It is not our purpose to claim any credit for originality; in fact it would be hard to make suggest itself to any one who had studied the subject with any attention whatsoever. The main cause for congratulation with ourselves is, that we were evidently on the right side, all doubts to the contrary being set aside by the remarkably smooth working of the new plan. If any one had any doubts as to the practical working of a judicial council, they have but to review the proceedings of the organization from the first day to the last, to notice the absence of all the usual quarrels that were heretofore so rife in open session, and to appreciate the readiness with which the Association accepted the decisions of said council as final. It is certainly saying a good deal on the first trial of its work, that no complaint was entered against the council by any one, and the promise for the future is certainly proportionately encouraging as its machinery becomes the more perfectly understood.

To such as have been acquainted with the difficulties

attending the discussion of vexed questions in ethics in former times, the impossibility on many occasions of referring the matters in dispute to a competent tribunal, it was refreshing to see how unnecessary debate was at once checked by a prompt reference to the council. In fact, if the duties and powers of the council are properly understood and appreciated, it will be next to impossible in future to disturb the harmony of the meeting, or detract from its dignity as the representative medical association of the country. The strictly executive business is now wholly confined to the council; matters of general interest are taken care of in the morning sessions, while the strictly scientific element is developed by the various sections.

In regard to the new arrangement for the meetings of the sections, we are warranted from the experience of the last session of the Association in saying that the said changes were for the better. In the practical working of the plan, however, there was more difficulty than in that of the council, or in that of the morning session. As a beginning, however, the results were as good as could have been anticipated. The material was abundant, but the trouble was there was not enough care taken in selecting the proper papers before their presentation. In the main the subjects presented were of practical interest, but the cases which were an exception to this were not so few as we should like to have seen. If the chairmen of the different sections, who were representative men in their departments, had taken the pains to look over the papers, and with the sanction of a sub-committee accepted or rejected the same, the sections would not have been compelled to stultify themselves by receiving papers much less wasting valuable time in listening to them. In one or two instances the sections could not recommend these papers for the transactions, simply because it was perfectly apparent that the said papers were unworthy. The only way out of the dilemma that was at all promising was the reference of the papers to the medical journals. We are not so badly disposed towards our fellow-men as to think this action was a reflection upon medical journalism, and so we view it in the light of a grim joke. Some of these papers may be published. If they are, however, we will pity the authors, and will sympathize with the journals for their scarcity of good "copy." Whenever a section, actuated by every principle of ordinary courtesy towards an author, is willing to strain a point to be obliging and conciliating, and so plainly dodges the question of a recommendation of a paper, as was apparent in more than one instance, the case is a hard one for the section, and is perhaps a little disagreeable to the author—at least to one who is at all impressible. All these little difficulties could be obviated by a little care on the part of the chairmen of the sections in soliciting papers in the first place from responsible gentlemen, men who have a reputation to keep, and in asking contributions from such as they know are able to make a reputation. Even such a course would not

be absolutely trustworthy until the papers offered were submitted to a competent sub-committee for their impartial judgment. As a rule all the papers to be presented, or at least the majority of them, could be examined before the meeting, in fact, engaged months beforehand. If this could be accomplished, and we see no practical objection to it, it would prevent would-be writers from springing their productions upon sections, and gaining more of a hearing before them than they could obtain even from their personal friends at home.

Another plan to obtain good papers would be to have them recommended by the societies at home. If this were the case, we could have promised beforehand that at least one paper from New York would not have been presented *in extenso* before any section.

The question of delegateship was settled in a very satisfactory manner by the passage of the amendment proposed last year. Now we have the whole matter in a nutshell. The delegates are chosen from every society recognized by the respective State Societies, with the proviso that such representation does not exceed ten per cent. of all the residents in a given district. All institutions are very properly ruled out. This is a measure which we have advocated for years past, and it is becoming for us to endorse it *in toto*.

Laying aside the exceptions already mentioned, the papers presented to the sections were exceptionally good, and the discussions were carried on in a becoming spirit. The social element was a success, largely due to Dr. WM. BRODIE, of Detroit, whose personal efforts in this direction called forth the thanks of all present.

The address of the President, Dr. J. M. Toner, of Washington, was a model in its way, reviewing the progress of medicine in this country, and offering such suggestions for the improvement of American medicine as his extensive knowledge of its resources entitle him to offer. The determination to make the meeting a success in every way was equalled by his capacity and resources. The next meeting will be held in Louisville, Ky., and should be very largely attended.

Reviews and Notices of Books.

A CLINICAL HISTORY OF THE MEDICAL AND SURGICAL DISEASES OF WOMEN. By ROBERT BARNES, M.D., London. With one hundred and sixty-nine illustrations. Philadelphia: Henry C. Lea, 1874. 8vo. pp. 791.

It is difficult to understand the *raison d'être* of another work on the Diseases of Women, in view of the many excellent treatises which have been written during the past ten years. Yet we think Dr. Barnes's book will take and maintain a popular position along with its elder compeers. The title is a happy one in so far as an attempt is made to differentiate it from other recent books on the subject; but as really a distinctive feature, and indicating the mere character of the volume, or as containing more case histories than its fellows, it

is misleading. The work is strictly clinical only so far as it may embody the results of a large experience, and not one whit more so than Thomas's and other practical works on the same subject; it is constructed on the same principles as these, and with no better claim for a clinical basis. The pathological portions are particularly valuable, "the rich mines of pathological material in the museums in the College of Surgeons and of the London hospitals" having been explored. Full and fair expositions of the various opinions held on many unsettled subjects in gynecology are given, and here, as indeed throughout the book, familiarity with the whole literature of this department of medicine is shown. Dr. Barnes is not only a practitioner of exceptionally large opportunities which he has used well, but he has kept himself informed of what has been said and done by others, and he has in the present volume judiciously used this knowledge. Experience and good sense have led him to generally moderate views in therapeutic procedures, and we do not find his teachings in the direction of rash or extravagant surgical interference, which has been the characteristic of a certain school of gynecologists, and which, we believe, has been more destructive of life than is generally admitted, and has certainly entailed long, and often permanent, ill-health on its victims.

The arrangement of the book is good. There are several excellent diagnostic chapters, which we would particularly recommend to the student and practitioner, as those on the significance "Of Leucorrhœa," "Of Hemorrhagic Discharges," "Of Dyspareunia, including Vaginismus," "Of Sterility," etc. These are truly treated of clinically. The chapters on displacements of the uterus are among the best in the volume, and to our mind very sound. We give the following quotation, with regard to the true *modus operandi* of the Hodge pessary, which is too little understood by practitioners, and leads to many failures which would be avoided if its true theory of action were more generally appreciated:

"The Hodge or lever pessary answers most of the indications with the least amount of drawbacks. It is of essential importance to bear in mind what is too often forgotten, namely, that it is a lever. A lever must be freely movable. The lever-pessary, to act properly and safely, must float in the pelvis. It is simply held in the vagina. It should not take any bearing upon the walls of the pelvis; to make it do so would be to degrade it to the level of the old ring-pessaries, and to sacrifice its principle of action. This is what happens if too large an instrument is used. Then the vagina will be put on the stretch, its elasticity will be impaired, leverage lost, and the pessary pressing unduly may cause inflammation and ulceration" (p. 567).

Dr. Barnes thinks that chronic metritis may be followed by substantial, if not complete recovery. He says:

"Appealing to the same evidence which proves the cure of acute metritis, we cannot absolutely deny the curability of chronic metritis. Pregnancy is, if I may trust my own observation, not infrequent. It sometimes takes place, no doubt, whilst the uterus is still in an imperfectly restored condition. But the value of this test of return to functional work is strong. . . . Now if, as Scanzoni himself asserts, there is no such thing as chronic metritis absolutely limited to one part of the organ, of course when we have hypertrophic induration of the cervix, about which there can be no doubt, before us, we must infer that the body of the uterus is similarly affected. Now it is a fact beyond dispute that pregnancy is not uncommon in cases of very advanced,

even extreme, hypertrophic elongation of the cervix. I have notes of many such cases. We are driven, then, to conclude that the hypertrophy resulting from chronic metritis may either be so far cured that the uterus can resume its highest function, or that the persistence of the hypertrophic change is not an absolute bar to this resumption of function. Practically, whichever alternative we adopt there is a cure. . . . I think, then, we may conclude that the uterus hypertrophied under chronic metritis may be restored, at least sufficiently for the resumption of its duty. If the morbid hypertrophic matter can be removed by gestation, why not by other means. . . . If we can establish a reasonable presumption that the condition is curable by any means, surely we need not despair of finding other means that may accomplish the same end" (pp. 445-6).

We can strongly recommend Dr. Barnes's work to the gynecological student and practitioner.

A PRACTICAL TREATISE ON THE DISEASES OF CHILDREN. By J. FORSYTH MEIGS, M.D., and WILLIAM PEPPER, M.D. Fifth edition, revised and enlarged. Philadelphia: Lindsay & Blakiston, 1874. 8vo, pp. 1,008.

THE modest duodecimo volume of some 300 pages, published in 1848, has in successive editions been gradually enlarged until, in the present edition (the fifth), it has become a portly octavo of over 1,000 pages. It is now one of the completest and most trustworthy treatises on the diseases of children in any language. The fifth edition has been subjected to careful revision; several important articles have been rewritten, and many new ones have been added, as those on Pulmonary Emphysema, Pneumothorax, Affections of the Tonsils, Retro-pharyngeal Abscess, Malarial Fevers, and Scrofula. Besides giving the large experience of its authors, it manifests a full knowledge of what has been most recently done in the department of diseases of children, both in this country and elsewhere; and in this part of their task the authors have shown fairness and judgment. The practical aim of the book has been generally well sustained; and whilst the essentials of etiology, pathology, and morbid anatomy have not been overlooked, adequate space has been given to the discussion of the treatment of the different diseases, which, as a rule, has been ably, and, as we think, happily indicated.

Cholera infantum is still retained in the section on "Diseases of the Stomach and Intestines," which we regard as leading to a wrong notion of its pathogeny, and tending to strengthen the false theory of its being a local and not a general disease; and though what is said of its causes and pathology would indicate that the authors do not wholly share this error, still we think they fall into as grave a mistake in taking a much too limited view of the morbid nature of this affection, if one not altogether wrong. The conditions under which cholera infantum occurs, and the symptoms of the chronic and more common form of the disease, show a much closer pathogenetic relation to camp diarrhoea than to malignant cholera. Whatever may be the causal factors, they produce the same result, and the disorder becomes essentially one of malnutrition; and upon the recognition of this view depends, we believe, the success of treatment. Our authors, looking upon it as essentially a choleraic disorder, naturally fail, if our notion is a correct one, in giving suitable prominence to the most important therapeutical indications.

Chapter IV., on Diseases of the Nervous System, is

remarkably complete, and generally on a level with our advancing knowledge of this class of disorders.

The rapid sale of the last editions of this work, since the valuable collaboration of Dr. Pepper has been secured, shows the estimation in which it is held by the profession.

Correspondence.

THE MEETING AT DETROIT.

[SPECIAL CORRESPONDENCE.]

DETROIT, June 4, 1874.

So much will probably be said of the scientific part of the meeting of the Association that we have been tempted to say a word or two upon the social element. In the first place the attendance was unprecedentedly large. Dr. Brodie informed us that there were 427 delegates present by actual count. When it is considered that each delegate pays five dollars for the honor, we think we can calculate that the *Transactions* of the Association have a fair share of appearing "on time."

On looking over one of the morning papers, which by the way gave very full reports of the proceedings, we learned that a number of noted medical men were present. This notice was hardly orthodox, as it is well known how disagreeable it is for modest medical men to be paraded before the public as "distinguished and successful" practitioners. The fact is it is undignified to allow it, is in direct violation of the Code, and more, it is none of the business of the public. We are all successful practitioners, only you and I are better than others. But what is the use of invidious distinction when the papers say that we are all equally distinguished and successful? In what we have to say we shall stick to facts, and if they prove suggestive to others, we leave to them the responsibility of working them up.

The medical men in Detroit were pleased to see so many really distinguished medical men. When we say this much we speak with authority, and not as the scribes (reporters).

Dr. Brodie, the chairman of the committee of arrangements, was particularly pleased to see that the meeting was a success. He worked hard enough for it, however. He was hither and thither and everywhere, and appeared to be anxious to get at some other place in the mean time. We hope the unpoetical comparison will be forgiven, but he reminded us of a pea on a hot shovel bobbing here and there without being able to get hot enough. The worst of it was he kept every body hot about him. There was no end to entertainments: five or six receptions were crowded into one evening, setting aside lawn parties, boating excursions, parades, and exhibitions of the injection properties of the fire engines (very suggestive to spray producers). As to the victualling part of the entertainments there was just the same fault to be found. If there could be said to be such a possibility as having too much of strawberries and cream, chicken salad and coffee, we would mildly suggest that the possibility was very nearly approached. We believe that the question at these entertainments was, whether strawberries were made for man, or man made for strawberries, and we know that a good many had to give up the conundrum. We were forced to go with the majority, who

were in favor of man as an enveloping rather than a developing being.

A noticeable feature in these entertainments was the absence of spirituous liquors, a custom which deserves commendation, despite the radicalism of one of the members of the Association, who believes alcohol was created for no purpose whatsoever. There was no vote taken on this question, as nothing was opened for discussion. We should like to have heard the views of the gentleman who read that paper on hydrophobia before one of the sections.

There was a good deal of talk in regard to the Presidency, and from the first it was understood that the "coming man" should be a New Yorker. Drs. Sayre, of New York, Moore, of Rochester, and White, of Buffalo, were named, but there was such a want of settlement, such a lack of agreement as to the individual man who should be pressed, by the New York delegation, that the whole affair fell through, and the successful candidate was chosen from Nashville. New York will have it next time—so say the know-nothings. The election of Woodward, of the army, was considered to be a deserved compliment to his corps. Speaking of the army, we hope that the modesty of Dr. Billings, of Washington, will not be outraged by a reference to his presence at the meeting. If we had to count up the number of gentlemen who were introduced to him we should have to give it up; and if we were to ask him how many of these gentlemen, among other trivial matters, asked him about the spare copies of the Medical and Surgical History of the Rebellion, we imagine he would have to give it up also. We are frank to confess that we were one of the number to ask him, not for ourselves alone, but for "our suffering fellow-men," for the "good of the profession," "good of the army," and other likely reasons, when he informed us that there were some spare copies, but only for such as had desirable books for exchange. The time for getting these histories of the war, for nothing, seems to have passed.

We saw many gentlemen from New York at the Russell House, which might be considered the headquarters.

Primus inter pares was Dr. J. Marion Sims. He still bears a rather youthful appearance, and while he is as enthusiastic on his specialty as ever, he has the same modesty concerning his real merits as he had when he made his first successful operation for vesicovaginal fistula. We heard him describe it for the first time in New York, and we can speak with authority. He was chosen a member of the Nominating Committee from New York. Dr. Sayre is always at a meeting of the Association. He came up with a paper on fractures, and maintained, among other things, that it was possible to make union of a fracture of the thigh perfect. And like him, when once he said it, he stuck to it, the Surgical Section to the contrary notwithstanding. Foster Jenkins, of Yonkers, was also there, mostly as a looker on; but he being a book-worm, and having quite a collection of rarities in his library, was quite interested in Billings' account of the Surgeon-General's library. We have no doubt that there will be some exchanging going on. We hardly believe that he has a Medical History of the Rebellion, as yet. Dr. Garrish, of New York, was also present, and had a paper on hydrophobia—a subject to which he has given his special attention. If we had the newspaper at hand in which his remarks were printed at length, we would quote. Dr. Bulkley, the rising dermatologist, was present with two papers. Dr. Brodie introduced him, on one occasion, as a "sealy" doctor. We imagine he must have had in mind his capacity for

weighing things properly. If so the pun was tolerable.

Dr. White, of Buffalo, took part in the discussions, and maintained his reputation as an easy speaker, as did also Dr. Moore, of Rochester, who was often seen in earnest conversation with his colleagues on a subject which is now interesting him very much—that of fractures. Dr. Parvin, of Indiana, had an instrument for excision of uterine fibroids, which he exhibited to his section, and afterwards explained in detail to some friends. It is an ingenious affair.

Speaking of new instruments, a great deal of humor centered around the description of one by a delegate. He was too modest to make his remarks in open session, and was only forced to explain by the immaturity of friends. He styled the instrument the Compound Back-action-Auro-retro-Micro-spectroscopic Speculum, and insisted that by its use a diagnosis of piles, ulcer of stomach, and congestion of the brain could be made out in one sitting or lying, as the case might be. He had a sketch of the instrument, showing the passage of light from the aural to the anal speculum, but he experienced a great deal of difficulty in making his hearers understand how the light could be made to penetrate the brain of an ordinary patient, and how, in case the colon became impacted, the beam of light could be made to reach the diaphragm without refraction. The different explanations offered, and the number of suggestions made to improve the instrument, were, from the nature of the subject, and the end claimed, an unalloyed source of pseudo-scientific amusement. The exhibition of the drawing and the description were as entertaining as the affair was novel. The more there were to listen to the description the merrier it became, and each went away vowing to improve upon the grand principle. The fundamental difficulty, however, was, that no one understood the real use of the instrument except the inventor.

Dr. Dunglison, of Philadelphia, was also present as a delegate, and a boarder at the Russell House. As all are aware, he is the rising medical lexicographer, the able editor and reviser of the *Medical Dictionary*. If he were asked how to get a dictionary, and in the same way as Billings is asked to get the History of the Rebellion, he deserves to be pitied. We mean to say in the way of a hint for a presentation copy. Dr. Dunglison came to the Association in quite an important function, as correspondent of the *Med. Times and Gazette* of London. When we were informed of it we almost wished we were on patronizing terms with him, in the hope that he might mention our name among the distinguished ones present.

Dr. Gross, of Philadelphia, read a very important paper on syphilis, and we think that the ground taken, that the disease was the *foons et orio* of everything else, was novel enough to claim attention. Very few agreed with him on that point, but he can afford to stand alone, for a while at least. Dr. Davis, of Chicago, was there, and why not? It has been said that he runs the machine of the Association. The fact is, he can't help it, because the majority have a fashion of following him in any important move. Who is to blame?

The President, Dr. Toner, was a universal favorite. We expected to see a statistic as venerable in years as in experience; but one finds it difficult to reconcile his well-preserved appearance and genial manner with that of an incorrigible book-worm, who has his house in Washington packed in every conceivable corner with books. One reason, perhaps, for this promiscuous distribution of books is that he is still a bachelor. But we are drifting too much towards mere gossip, and must close.

SEPTICEMIA BY AUTO-INFECTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I have been tempted to send you a report of the following case by reading Prof. Barker's article on "Puerperal Septicemia and Pyemia." I regret exceedingly that I have kept no accurate report of the case; but, imperfect as it may be, I think it will be extremely interesting, and may assist in arriving at the proper pathology of certain cases of septicemia by auto-infection.

Samuel C—, a medical student of mine, aged 29, of stout and robust frame, with no hereditary predisposition, was taken sick about the 24th of September, 1873, with typhoid fever, modified, or rather complicated, with malarial features. About the twelfth day of the disease he had a most alarming intestinal hemorrhage, which was entirely controlled by fl. ext. ergot in drachm doses. From this time until about the 12th day of October his convalescence was more rapid than is usually the case. Diarrhea had ceased, tongue natural, no tympanites, pulse normal, and temperature 99°. I had intended not to visit him after the next day. In the night, however, I was called to see him at 11 o'clock, to relieve a violent pain in the calf of the left leg. I ordered an anodyne liniment, and the leg enveloped in hot flannels. I saw him again at 5 A.M., and discovered phlegmasia alba dolens, apparently caused by clot between the saphenous opening and the common iliac vein. The veins up to the saphenous opening were corded and painful; the leg enlarged about two inches in circumference, and exquisitely painful when the leg was moved by himself. Under the influence of quinine, potass. chlorat., and tr. ferri chloridi, he gradually improved for two or three days. During this time he seemed to be doing remarkably well, except the suffering with his leg. The temperature at no time exceeded 101°, and his other symptoms natural. Rather suddenly his whole condition changed for the worse; and, judging from the symptoms, we (I was assisted in the case by Asst.-Surg. P. Middleton, U.S.A.) thought he had a relapse of the enteric fever. His condition was decidedly typhoid; a profuse diarrhea, fearfully offensive; wasting perspirations, tympanites, low delirium, etc. We began then to fear septicemia. Up to this time the thermometer had not aided us, as the range in relapsing typhoid and septicemia is almost identical. We did not fully satisfy ourselves until the temperature was 106½°, and then we knew that we had a case of septicemia. The treatment had been quinia, averaging 30 grs. per day, mur. tr. ferri, potass. chloratis, and from 8 to 16 ozs. whiskey. All through the attack beef-tea, milk-punch—in fact the most nutritious diet. Three days before he died he raised himself in bed and became livid—was almost fatally asphyxiated by a clot passing through the heart, which eventually became a pulmonary embolus. He from this time rapidly sank, and died on October 30th.

The conclusions I draw from this case are the following: Here was a stout, healthy man reduced by enteric fever and profuse intestinal hemorrhages; his blood in a state of hyperinosis, which resulted in a venous thrombosis from inopexia. There is no doubt in my mind that the fever and the hemorrhage were the sole agents which brought about this state. Trousseau, in his article on "Dothinenteria," mentions such a case in a niece of his. Now, there are three terminations of a venous thrombosis: 1st, Fatty metamorphosis, and subsequent absorption of the clot, accompanied by recovery; 2d, the clot may become de-

tached, and cause death by asphyxia, or the consequences of pulmonary embolism; and, 3d, by disintegration of the clot, producing a septic poison, and, of course, septicemia.

In my patient's case absorption had partly taken place, as was proved by the diminution in the size of the leg, and the corded and knotty condition of the veins. There is no doubt but that he was nearly asphyxiated by a clot passing through the heart, and becoming a pulmonary embolus. The sad sequel certainly proves a septic poison from disintegration of a clot, which is to me conclusive evidence of a case of septicemia by auto-infection without phlebitis. No autopsy.

W. B. RODMAN, M.D.

FRANKFORT, KY., May 22, 1874.

DISLOCATION OF HIP IN A WOMAN SEVENTY-THREE YEARS OF AGE.

TO THE EDITOR OF THE MEDICAL RECORD.

THIS letter contains a record of a case of very great interest, a dislocation of the leg in a woman 73 years old. Except the case reported by Gauthier (88 years), this is, so far as I know, the oldest person in whom the accident has occurred.

Yours truly,

FRANK H. HAMILTON.

SIR:—Sarah Hamilton, at 86, widow, white, American. For a number of years she had been living alone in a small house in the village of South Salem, Ohio. Having fallen while in the act of walking across her room-floor, and finding herself unable to arise, her outcries brought in her neighbor. I was called immediately to see her (morning of December 8, 1872), and on entering the room I found her in the sitting posture, her left leg extended, while her right leg was flexed upon the thigh, and at the same time thrust under the popliteal space of the opposite fellow. Knowing her advanced years, and the slightness of the cause for present injury, intercapsular fracture of the neck of femur flashed across my mind. Wishing to avoid, as far as possible, further injury to soft parts at seat of fracture, I put her injured limb in a more favorable position before moving her. Judge of my surprise, upon putting my hand under lower third of femur, to feel distinct crepitation there. Now I resigned myself to a case of multiple fracture. But in this I was happily disappointed, for upon careful examination, after putting her in bed, I found the fracture just above the condyles of the femur the *only one*. Put her limb in almost the straight position, laying it on a well-padded double inclined plane, raised enough merely to fit popliteal space; short splints at point of fracture, fearing to use a perineal band, on account of thinness and age of subject; made extension with four-pound weight and pulley; counter-extension by weight of body. At end of fourth week union had made considerable progress. On the sixtieth day I removed the splints, and found firm union. No excoriation about the limb or body. Still fearing an accident, I retained the weight and short splints a week longer. During the treatment of this case I called in my friend W. H. Willson, M.D., of Greenfield, Ohio, who examined the fracture before bony consolidation took place. While I was examining for intercapsular fracture, I found the head of the femur of this right limb resting on the body of the pubes, pushed far up toward anterior inferior spinous process of right ilium.

She now told me that thirteen years previous she had fallen down a flight of steps about three feet

high, and the result was a luxation of the head of the bone. No attempt at reduction had been made, her medical attendants being uncertain at the time of the nature of the injury. "Often," she said, "I would push that lump down in my groin, and it would move my whole leg." For the years that I had known her she always walked with her right foot so strongly everted that it formed a right angle with the left; and I often wished to examine into the nature of the injury, but never had an opportunity until now. She was unable to walk for six months after she suffered the dislocation.

On March 28th, 1874, Dr. W. H. Willson and myself again met and re-examined this patient very carefully. Though in her eighty-eighth (88) year, we found her health good and disposition cheerful. By a most rigid physical examination we satisfied ourselves beyond a doubt that an ancient luxation existed here, with head of femur on body of pubes, resting near the anterior inferior spinous process of right ilium.

We also made the following measurements:—Right limb, injured: from anterior superior spinous process to external malleolus, 30 inches; left limb, sound: between same points, 31½ inches. Shortening of right femur, as near as could be ascertained by measuring from top of greater trochanter to external condyle, as compared with opposite fellow, ½ inch; the dislocation occurring in her seventy-third year.

Respectfully submitting the above report, we remain
Your obedient servants,

P. J. KLINE, M.D.,
Portsmouth, Ohio.

W. H. WILLSON, M.D.,
Greenfield, Highland Co., Ohio.

To Prof. F. H. Hamilton, N. Y. City.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from May 19, 1874, to June 4, 1874.

SURGEON-GEN. MOORE, and Assistant Surgeons **J. J. WOODWARD** and **J. S. BILLINGS**.—Directed to attend the annual meeting of the American Medical Association, and on its adjournment to return to their proper stations. S. O. 118, A. G. O., May 28, 1874.

BILL, J. H., Surgeon.—Assigned to duty as Post Surgeon at Fort Wood, N. Y. H. S. O. 94, Mil. Div. of the Atlantic, May 9, 1874.

FRYER, B. E., Surgeon.—Assigned to duty at Fort Wadsworth, N. Y. H. S. O. 94, c. s., Mil. Div. of the Atlantic.

FILTON, H. R., Assistant Surgeon.—Assigned to duty at Fort Sully, Dakota Territory. S. O. 94, Department of Dakota, May 12, 1874.

MIDDLETON, P., Assistant Surgeon.—Assigned to duty at Fort Duncan, Texas. S. O. 72, Department of Texas, May 12, 1874.

STEINMETZ, WM. R., Assistant Surgeon.—Granted leave of absence for three months. S. O. 120, A. G. O., June 1, 1874.

CORRECTIONS.—In the last No. of THE MEDICAL RECORD (June 1), we inadvertently stated, in a paragraph on page 304, bearing the caption of "College Announcements and Resolutions," that Prof. Edmund R. Penrose had "been elected to deliver the course of lectures on Diseases of Women at the next session of the Bellevue Hospital Medical College." We ought to have said that Dr. Penrose had been regularly appointed Professor of Gynecology, in said College. Under the same caption we also stated that "Dr. Stephen Smith had been appointed Professor of Surgery in the Medical Department of the University of the City of New York." We should have said that Dr. Smith had been appointed "Professor of Clinical Surgery and Surgical Jurisprudence." Dr. Alfred C. Post is Professor of Surgery in the Medical Department of that University.

Medical Items and News.

POISONING BY HYDROCYANIC ACID.—The extent to which cyanide of potassium is used in the various arts makes it important that those who use it should be acquainted with some of the dangers to which they are exposed. A French photographer, Bourdon, was recently taking some scenes at Fontainebleau. Working in the laboratory one morning, his fingers became blackened by nitrate of silver, and he attempted to remove the stains by rubbing them with a piece of the cyanide of potassium. In doing so a small piece became impacted under his nail, and came in contact with a small excoriation. Severe pain ensued, and then an attack of vertigo. Thinking that vinegar might give him relief, he poured some over the wound. The result, however, was most disastrous, for the cyanide was immediately decomposed, and free cyanic acid was liberated. The vertigo increased to an alarming degree, and was accompanied by rigors and lividity of the face. Unfortunately he was alone and could not communicate with his friends, so that he remained in this condition a number of hours, entirely unable to move or speak. Medical advice was obtained, and he rallied sufficiently to give some account of his singular attack, but the poisonous action of the acid had already progressed too far, and he died on the following night.—*Gaz. d'Alle Clin.*, April, 1874.

CHLORAL POISONING CURED BY STRYCHNIA.—A man who had taken an overdose of the hydrate of chloral, for the purpose of self-destruction, was recently taken into a hospital in Berlin. The amount of the poison was 34 grammes, or about 370 grains. He lay in a heavy sleep, respiring deeply, with congested face, and a pulse of 100. As there were no symptoms that were regarded as immediately threatening, the treatment was confined to cold applications to the head. An hour and a half later the face became livid, the pupils were widely dilated, the pulse fell to 92, the temperature rose to 103.4, and respiration became intermittent. The pneumogastries were then faradized, and the normal respiration returned. Half an hour later symptoms of collapse set in, the pupils became contracted, the face grew pale, and the heart almost ceased to beat. A hypodermic injection of ½ grain of strychnia was then given. The beating of the heart was materially strengthened, and the pupils were dilated. These favorable symptoms, however, lasted but a short time, and the face again became livid, the heart-beats were fainter, and the pupils did not react. At this time about ¼ grain of strychnia was administered hypodermically. The action of the heart was again restored, but the respiration was labored. It was necessary to resort to faradization, which was kept up at intervals during the night and part of the next day. On the same afternoon the patient had recovered his consciousness. Notwithstanding the large quantity of chloral taken, there were no gastric symptoms, which was explained on the ground that the patient had eaten largely of rye bread before taking the poison. This case is illustrative of the value of strychnia in poisoning by chloral. Liebreich was the first to show the physiological antagonism between the two substances. It is noteworthy that faradization played an important but secondary rôle in the case.—*Berl. Klin. Woch.*, 1, 1874.

THE REPORTS OF THE SECTIONS OF THE AMERICAN MEDICAL ASSOCIATION have been crowded out of the present issue, and will appear in our next.

Medical Department of Life Insurance.

MORTALITY OF CONSUMPTION AND PARALYSIS.

COMPILED FROM THE RECORDS OF A LIFE INSURANCE COMPANY.

By ISAAC L. KIP, M.D.,
OF NEW YORK.

DURING a period of ten years, from 1858 to 1868, the total number of deaths from all causes was 1,448, of which 144 were under 25 years of age, 508 between 25 and 35, 615 between 35 and 50, 162 between 50 and 60, and 19 over 60. The deaths from consumption represented a total of 265, or a little over 18 per cent. Thirty-nine of the number were under 25 years of age, 135 were between 25 and 35, 80 between 35 and 50, 10 between 50 and 60, and one over 60. It will thus be seen that more than half of the deaths from consumption occurred between the ages of 25 and 35, whereas nearly two-thirds of the deaths from other causes (705 out of 1,183) occurred after the 35th year.

Continuing the investigation among the deaths from consumption, we find that in 60 instances—nearly 23 per cent.—the disease appears to have been hereditary, as ascertained by the data given in the original applications for policies. In one instance both parents and a brother had died of consumption; in another, both parents; in ten instances, a parent and a brother or sister; in twenty instances, a parent; in eighteen instances, a brother or sister; in nine instances, two or more brothers or sisters; in one instance, two aunts. Of the remaining 205 cases, six had previously had "spitting of blood;" four, "bronchitis;" two, "slight cough;" one, "asthma;" one, "pneumonia;" one, "chronic diarrhoea."

The deaths from "apoplexy" and "paralysis" numbered in all 135, or nearly 13 per cent. of the deaths from all causes. Eight were under 25 years of age, 49 between 25 and 35, 100 between 35 and 50, 33 between 50 and 60, and 5 over 60. The only evidence of anything like an hereditary character in the disease lay in the fact that the same or allied diseases had carried off one or more members of the family in sixteen cases (over 8 per cent.). In 55 instances the height and weight were recorded. Arranging these in the form of a table, together with the averages, according to the American standard, we obtain the following:—

N. of individuals involved.	Height.	Average weight, American standard, lbs.	do, lbs.
1	4 ft. 11 in.	100	—
1	5 ft.	152	—
0	5 ft. 1 in.	—	120
1	" 2 "	86	125
1	" 3 "	150	130
3	" 4 "	138	135
9	" 5 "	141	140
12	" 6 "	151	143
18	" 7 "	152	145
14	" 8 "	156	148
14	" 9 "	158	155
9	" 10 "	159	160
7	" 11 "	177	165
2	6 ft.	185	170
1	6 ft. 1 in.	152	—
2	6 ft. 2 in.	205	—

In seventeen instances (20 per cent. of the entire number) the weight exceeded the 20 per cent. usually allowed for deviations from the standard. In only one instance did the weight fall below the 20 per cent. allowance in the other direction. The general average, however, was somewhat above the standard.

ON THE PROTECTIVE VALUE OF VACCINATION.

By ALBERT MULLER, M.D.,
WALDHEIM, GERMANY.

(Translated * by Normand Smith, M.D., of New York.)

IN consequence of the small-pox epidemics which have infested Germany for the past few years, the old controversy over the advantage of vaccination, which the scientific medical world justly regarded as settled, has been again revived. In spite of all the statistical proofs which have been repeatedly adduced, the opponents of vaccination, mostly laymen, dispute anew the advantages of the same, and by continued agitation have made it necessary to review the question once more. If the alleged proofs adduced by the other side are too gratuitous and too unworthy of criticism to demand again and again a serious refutation, the whole controversy has, on the other hand, accomplished this much, viz.: it has shown that the small-pox statistics, although very copious, present defects which offer occasion and opportunity for objection. Now if a question, in itself scientific, attains such increased practical importance that the legislature takes it in hand, and proposes to decide it in accordance with the opinion of the large and influential majority of the physicians and of the public—which it would be virtually doing should it sanction the contemplated introduction of compulsory vaccination—it is desirable that the basis for this legislative action be made perfectly sure and secure against any reasonable doubt. It is hoped that the following communication will contribute somewhat to this.

A very nearly all the statistics that have been made up to the present time are defective, because they are almost entirely *mortality statistics*, and give only unsatisfactory information in regard to the liability to contract the disease.† They limit themselves to giving only an approximate estimate of the *morbidity*. The effect of vaccination on the prevalence of the disease thus remains almost entirely undiscussed, or—like the question of its influence upon the mortality of the disease—it can be tested only by the small fraction of patients who furnished the material for observation.

If statistics of this kind be derived from hospitals, or if they include only certain strata of the population, doubts may be justly raised whether the numbers thus obtained can, without further restrictions, lay claim to general availability, or whether they should not be applied only to the particular epidemic from which they have been taken. For the purpose, then, of removing as far as possible the objection that the general correctness of the numbers obtained ought not to be trusted, because no account had been taken of the number of cases of sickness which did not result in death, we should endeavor to obtain a complete general view of some one epidemic, in order to study the effect of vaccination on morbidity as well as mortality. Besides, it is necessary at the same time to

* From the "Archiv der Heilkunde," 18ter Jahrgang, 2tes Heft, 1874.

† The Germans use the term "morbidity" to convey this idea of liability to contract the disease, and we shall take the liberty of using it here in that sense.—TRANSL.

ascertain as accurately as possible the number of persons living in the place at the time of the epidemic, and what proportion of them had been vaccinated. It is only in this way that we can obtain a direct and pretty sure opinion as to how great has been the protection of vaccination. Dr. R. Flinzer, whose excellent paper (*The Small-Pox Epidemic in Chemnitz and Environs in 1870 and 1871*) I received while writing this article, appears to have fully accomplished this object. He bases his communications on more extended and comprehensive statistical calculations than I have been able to make.

With these facts in view I endeavored to obtain a comprehensive survey of the small-pox epidemic which prevailed in the city of Waldheim in 1872, and lasted until April, 1873. This was possible only by inquiring from house to house, and then only after the city authorities had given their sanction to the undertaking. By my advice two lists were drawn up in the month of March of the present year, one of which included all those who had been attacked with the disease, together with the name, sex, age, dwelling, information as to how they had caught the disease, occupation, proof of vaccination, time and result of the attack, condition of dwelling, and mode of life; while the other specified the number of persons in each house who had or had not been vaccinated, the number of doubtful cases, and the number of persons revaccinated at a given period (beginning of 1873) of the epidemic. The objection may be raised that material obtained in this way is not reliable; nevertheless the sources of error are not so great as would at first appear. In the first place, owing to the limited proportions of the field, it was possible in most of the cases to establish the correctness of the information given in regard to the sickness; and in this way I have been able to exclude the doubtful cases, allowing only such to be recorded in which a distinct eruption was present. But even laymen learn to recognize a distinct eruption during an epidemic; and I am convinced that the eruption of other diseases is very seldom mistaken for variola. The information regarding vaccination can lay claim only to an approximate correctness; since, however, the two lists in part control one another, and it is found, upon comparison, that the two almost exactly agree in those parts which are common to both, we can assume that no important mistakes have occurred. Nor is there any reason for supposing that incorrect information was wilfully furnished.

I have also been able, through the kindness of the district physician, Dr. Leonhard, to make use of the statistical reports of the city, as well as of its burial permits. These also served as a control upon a portion of the cases. The following are the results obtained according to the above-mentioned plan:—

From January, 1872, to April, 1873, inclusive, there were in the little town of Waldheim 250 cases of small-pox (including the mildest cases), *i. e.* about 5 per cent. of the population.* Among these were 124 who had been vaccinated (including those who had had small-pox before), and 126 who had not been vaccinated, or whose vaccination was unsuccessful.

Waldheim had towards the end of 1872, not including the house of correction and the garrison, a population probably of about 5,200 souls (after the census of 1871, 5,145). Among these were 4,713 who had either been vaccinated or had had the small-pox (= 93.2 per cent. of the population), and 342 (= 6.8 per cent.) who had either not been vaccinated at all, or in whom

the vaccination had been unsuccessful.* To these figures were added those of each category who had died up to the time of making up the lists.

Of the number still remaining to complete the estimated number of the population, a part may be found among the children just born, and hence not included in the calculation, while the remainder, for reasons not ascertained, could not be traced; at all events they do not change the result, because they are in all probability distributed on both sides, according to their proper percentages.

According to this, 2.6 per cent. of those vaccinated (124 out of 4,713) and 36.8 per cent. of those not vaccinated (126 out of 342) took sick. The proportion in Chemnitz, according to Flinzer, was 1.61 per cent. of the former, and 57.22 per cent. of the latter.

It must not be forgotten that the number of those vaccinated was almost 14 times larger than of those not vaccinated. If vaccination afforded no protection against small-pox, and we were to assume that those who have been vaccinated are attacked as often as those who have not been vaccinated, then in the present case 1860† persons ought to have taken the disease. This enables us, therefore, to calculate the injury which the neglect to vaccinate is capable of causing. The following table gives a survey of the progress of the epidemic:

TABLE I.
Number of Individuals Sick.

The epidemic is remarkable from the fact that its rise was very rapid, attaining, as it did, almost its full force within a month; while its decline, though at first equally rapid, was afterwards slower.

The following combination (Table II.), according to age and with the separation of the vaccinated from the unvaccinated, confirms in general the well-known experience that the first years of life contribute the greatest number of small-pox cases,—obviously because the majority of the unvaccinated are included in this age. During the first 5 years there were 100 cases (= 40 per cent.), of whom 88 were unvaccinated, which is about 26 per cent., taking 342 as the whole number. Vaccinated children, though seldom attacked, do sometimes take the disease, but generally very lightly; this I am able to affirm from personal experience.

* In Chemnitz (Flinzer), 85.5 and 14.5 per cent.

† That Waldheim had a somewhat better ratio for the vaccinated than Chemnitz, is not remarkable, since vaccination was practised diligently there until within a short time, and the age was a little younger than in Chemnitz, and before the year 1872.

* 5,200 - 1254.68 = 1.61 per cent.

* Flinzer gives 5.6 per cent. for Chemnitz.

Some will be inclined to maintain that these vaccinations must have taken imperfectly. From between the 10th and 15th years onwards the number of cases of small-pox among the unvaccinated diminishes, while among the vaccinated the number of cases increases, and, with a certain amount of variation, attains its maximum between the ages of thirty and forty. From this we see that the protection afforded by the first vaccination diminishes from between the 10th and 15th years onwards, which confirms the expediency of re-vaccination. These, however, are well-known and sufficiently demonstrated facts.

The protecting influence of vaccination comes out in still bolder relief when we examine the mortality rate. Out of 250 patients, 65 died (= 26.4 per cent.; 1.3 per cent. of the entire population). They are distributed according to age and according as they were vaccinated or not, as follows:—

TABLE III.

Age.	NUMBER OF DEATHS.			PERCENTAGES.		
	Vaccinated.	Unvaccinated.	Total.	Proportion of deaths to cases of small-pox.	Ratio, where they had been vaccinated.	Ratio, where they had not been vaccinated.

In the first 13 years all the deaths were of unvaccinated persons, with one single exception during the first year, where the cause of death was not ascertained by a physician, so that it is not positively known whether small-pox should be considered as the cause or not.

During the first five years it is universally true that about one-half of the unvaccinated patients die; in the first year, even two-thirds. Among the vaccinated patients the first fatal case occurs in the 14th year; the remaining 9 occur among 91 cases of sickness in which the ages were between 16 and 70. These, too, cannot all be laid to the account of small-pox, for one of them, judging from the appearance of the body, was a case of diphtheria, and in two others a secondary pneumonia was the immediate cause of death. In order to place these numbers in the right light, we must make a comparison between Table II. and the first part of Table III. The last part of Table III. gives the percentage reckoning, and invariably compares the corresponding lines of both tables with one another, *i.e.*, the total number of deaths with the total number of patients, the fatal cases among the vaccinated with the number of sick persons who had been vaccinated, etc. A few of the percentage calculations are inclosed in parentheses because they seem worthless, owing to the smallness of the fundamental numbers. The mortality of the unvaccinated for the epidemic of this place amounts to 43.6 per cent.; of the vaccinated, 8.8 per cent.

In Chemnitz the total mortality amounted to 6.9 per cent., making 0.73 for the vaccinated, and 9.16 for the unvaccinated—a very low figure. My calculations correspond more closely with those of Thomas (Arch. d. Heilk., 1872, 2 u. 3 H.), who obtained 4.3 for the vaccinated, and 42.1 for the unvaccinated; and with those of Siegel (the same Archives, 1873, 3 H.), who found 8.1 for the former, and 35.5 for the latter. It shows that the epidemics of Leipzig and this place were very much alike as regards virulence. In the epidemic at Hamburg (Knecht, Archiv für Dermat., 1872, III. H.), 33.1 per cent. of the unvaccinated and 1.5 per cent. of the vaccinated died between the ages of 10 and 20 years. The calculation for the remaining ages is wanting. In the Leipzig Hospital, according to Wunderlich's report (Archiv. d. Heilk., 1872, III. H.), of those who had never been vaccinated and of doubtful cases taken together, 65.1 per cent. died; of those vaccinated, or who had already had small-pox, 8 per cent. It should be observed, in this connection, that the numbers obtained from hospital records do not give a true picture of the whole epidemic. Keeping this in view, we see that Wunderlich's mortality rates for the unvaccinated are too high. They are estimated, for instance—namely, from all the reports of the Leipzig epidemic—at an average of 47.6 per cent.; in fact, it should be placed at a still lower figure, since it is necessary to remember that Thomas's observations also were chiefly among the lower classes.

Another argument, often brought forward, but never proved, against the protective power of vaccination, is the assertion that, in considering the fact that the unvaccinated get sick and die oftener than the vaccinated, we should not lay the blame to vaccination or non-vaccination, but attribute it chiefly to poverty, to insufficient nourishment, and poor dwellings—in short, to social misery, since it is a fact that the unvaccinated always belong to the miserable and poverty-stricken class. In other words, it is maintained that the class to which the vaccinated belong is far less likely to contract any disease, small-pox included, than that to which the unvaccinated belong;

and the small-pox mortality is proportionately no greater among these last than is the mortality incident to any other form of disease. Let us see how much this assertion is worth. We have in Waldheim a progressive system of assessment, according to which those liable to taxation can be arranged in convenient groups.

Among about 5,200 inhabitants there are 1,491 liable to be taxed. Of these

	Thalers.	Thalers.	Class.
80 return an income of over	1,000.		1st.
124 " " from 500 to 999.			2d.
467 " " " 200 to 499.			3d.
820 " " less than 200.			4th.

If we calculate from these figures, which represent the number of taxable people, the probable number of the inhabitants belonging to each class, we have—

278 of the 1st Class,

433 " 2d "

1629 " 3d "

2860 " 4th "

The 250 cases of sickness may be divided among the different classes, as follows:—

In Class I. there were 5; in Class II., 24; in Class III., 55; in Class IV., 166. Table IV. shows the same thing, with additional details.

TABLE IV.

Number of Inhabitants.	Class.	Number of sick.	Per cent.	Average per cent.	Variation from the average.	Vaccinated.	Unvaccinated.	Related to each other as
278	I.	5	1.8	4.1	-2.3	5	..	..
433	II.	24	5.5		+1.4	20	4	5.1
1629	III.	55	3.3		-0.8	33	22	3.2
2860	IV.	166	5.8		+1.7	66	100	2.3

It follows, then, from the previous table that the lowest taxable class gets sick the oftenest, and the first class the most rarely. It will also be noticed that the third class comes next in order to the first, as regards the disposition to sickness; while the second class surpasses the average almost as much as the fourth does. Then, if we examine this striking ratio of the second class somewhat more carefully, we see from the lists that only the four unvaccinated persons (all of whom, by the way, died) were under six years of age, while all of the remaining vaccinated persons were more than 14 years old, viz., 7 between 14 and 20 years, 2 between 21 and 30, 7 between 31 and 40, 3 between 41 and 50, and 1 was 59 years of age. In other words, they had all reached the age when, according to universal consent, the protective influence of the first vaccination is only very weak, or has altogether disappeared; they fall sick almost as often as the last class on the list (notwithstanding they belong to families who are in comparatively good circumstances), and obviously because the first vaccination afforded them insufficient protection or none at all—for it must be borne in mind that, up to the present time, revaccination has been seldom performed among the better families of the middle or burgher class. The first class occupies the most favored position of all as regards susceptibility to contract small-pox, the number of cases having been considerably under the average, and the five cases mentioned having been of a mild type.

Those belonging to this class have all been vaccinated, and the greater part of them also revaccinated; and, besides, they avoid coming in contact with small-pox patients as much as possible.

The figures in the 3d class come very near to the average; that is, about $\frac{1}{3}$ of the population belonging to this class take sick. The unvaccinated take the disease oftenest; they constitute $\frac{2}{3}$ of all those taken sick. It should be specially noted that the vaccinated persons of this class do not get sick oftenest than the vaccinated of the 1st class, the average for both being about $\frac{1}{3}$ of those belonging to each class.

The 4th class, which includes workmen as well as the scum of the population, contributes absolutely and relatively the largest share; about $\frac{1}{3}$ of those belonging to this class are attacked by small-pox. The reason of this can be seen from the ratio of the vaccinated to the unvaccinated (sick persons), which is as 2:3. While the number of the vaccinated in all the other classes exceeds that of the unvaccinated, here the ratio is the inverse: out of 166 sick people only 66 had been vaccinated. The 66 vaccinated persons constitute here also only a little more than $\frac{1}{3}$ of all those belonging to the class, but not more than in the 1st and 3d, notwithstanding the difference in outward circumstances; the comparatively large number of sick people is chargeable chiefly to the unvaccinated. This observation receives further support from the following calculation: Among the population at large the proportion of the vaccinated to the unvaccinated was about as 15:1; accordingly the 4th class would have had about 2,670 vaccinated persons, and 190 unvaccinated. Of the former 66 took sick, i.e., 2.5 per cent.—exactly the same ratio as was found for the vaccinated, taken as a whole. Among the 190 unvaccinated there should have been 70 cases (36.8 per cent.); in point of fact there would probably be 100, because in this class the above-mentioned proportion of 15:1 is not correct, but has been changed, to the disadvantage of the unvaccinated. It must not be forgotten that the agitation against vaccination has always found adherents in this class of society; that, moreover, every attention to health, vaccination included, is grossly neglected. The morbidity per cent. for the vaccinated in the remaining classes is, in the 1st, 2.0; in the 2d, 5.0; and in the 3d, 2.2. Here, also, for reasons already discussed, the 2d class only exceeds the normal per cent., while among the rest, the different taxable classes, strange to say, give proportions approximately the same. Hence it follows that indigent and limited circumstances do not exercise any considerable influence on the frequency with which the disease is contracted. Whether other diseases are affected by the conditions just mentioned, I shall not attempt to decide. It is certain, however, that vaccination exercises a very decided influence on the tendency to take small-pox.

The mortality of the individual classes corresponds closely with the morbidity. In the 1st it is = 0, in the 2d it amounts to 25 per cent.; in the 3d, 18.8; in the 4th, 30.1, as will be seen from an examination of the following table:

TABLE V.

Class.	Number of Inhabitants.	Number of deaths from small-pox.	Vaccinated (of the deaths).	Unvaccinated (of the deaths).	Percentage of the sick.
I.	278	..	..	..	..
II.	433	6	4	2	25.00
III.	1629	10	8	2	18.18
IV.	2860	50	7	43	30.1

Again, we find that it is among the unvaccinated that the high mortality rates occur; and among the last class on the list no more persons die of small-pox (notwithstanding their unfavorable circumstances of life) than in the other classes, if they have only been vaccinated. In the 4th class, 10 per cent. of the vaccinated died, of the unvaccinated 43 per cent.; in the 3d class, 6 per cent. of the vaccinated, 34.3 per cent. of the unvaccinated; in the 2d class, 10 per cent. of the vaccinated and unvaccinated taken collectively.

These figures show most convincingly how great an influence vaccination exerts on morbidity and mortality in small-pox, and on the other hand how little both are affected by external circumstances.

The 250 cases are distributed among 110 houses (about $\frac{1}{2}$ of the whole number), but not uniformly in all quarters of the city. Among 47 houses there was only one case; among 31, there were two cases; among 13, three; among 6, four; among 5, six; and in one house there were eight cases, and in another eleven. The houses with the largest number of cases (from 4 upwards) are all situated in the thickly settled parts of the city, where the epidemic was the fiercest; more than the half of them are in one long street. The unvaccinated constitute almost always the majority of cases in a house; and where there are more sick persons who have been vaccinated, they are always, without exception, adults. It is in the thickly settled parts also, that the large majority of deaths occur, and almost all of them were among the *unvaccinated*, whose mortality here amounts to 50 per cent.

In this connection I could give many more interesting details, if I were not afraid of making this report too extended.

Finally, allow me to make a few remarks on the intended introduction of compulsory vaccination. I do not belong to those who admire this plan, principally because it appears to me very inconsistent that on the one hand we should give every man unlimited freedom to take care of his health according to his own judgment (this has been secured by the privilege accorded to all physicians of practising medicine as they choose), while on the other we attempt to compel him to use a certain remedy for a certain disease.

They say that this is done in order not to allow the innocent—i.e., the vaccinated—to suffer with the guilty. But are the vaccinated really in such great danger?

Surely only when they are vaccinated unsuccessfully or not revaccinated at the right time. All small-pox statistics prove this. Whom, then, do they wish to protect? Those who will not allow themselves to be vaccinated? Strictly speaking, however, they have no right to do it. From the stand-point of public hygiene, compulsory vaccination cannot be recommended so long as there is a preventive against small-pox which is accessible to every one at all times. For this last, ample provision should of course be made.

At most, then, there might be some question about the advisability of vaccinating infants. But here compulsory vaccination would not help matters, for we could not compel children to be vaccinated immediately after birth, and yet, unless we did so, they might catch the disease before the proper period for vaccination arrived. The difficulty of enforcing compulsory vaccination would probably result in its shipwreck; at all events, it will never satisfy the expectations of its advocates. The small-pox calamity teaches rather than the unrestricted liberty of carrying on any business may react in an injurious and unexpected manner upon the field of practical medicine. The same rule cannot be applied to all cases—and compulsory vaccination is

certainly not the best means for counteracting this injurious influence.

ON THE WASTE OF LIFE BY PREVENTABLE DISEASE.*

By R. BRUDENELL CARTER, F.R.C.S.,

OPHTHALMIC SURGEON TO ST. GEORGE'S HOSPITAL.

IN this dilemma [the selection of a topic] I was reminded of the accession to political power of a party leader who has recently declared himself plainly with respect to the want of improved legislation for the protection of the public health, and it occurred to me that in such a conjuncture it might not be unseemly if I were to invite your attention to certain sanitary questions which may soon afford occupation to the Legislature. On these questions the members of our profession should, I think, by virtue of superior knowledge, claim to be the guides of public opinion; and, in order to assert this claim, and to endeavor to show that it is well founded, I propose to address you to-night upon "The Waste of Life by Preventable Disease."

In order to do this profitably, it seems necessary, in the first place, to surround the phrase "preventable disease" by some kind of definition. In a certain wide sense, we may say that every disease is preventable; for, if we were all to live in strict accordance with the dictates of reason and physiology, there can be little doubt that we should, in most cases, die only of natural decay. But the diseases which I have now in my mind, and to which I think the word "preventable" may most properly apply, are those that depend, if not for their existence, at least for much of their prevalence and of their severity, upon the acts and defaults of the community, rather than upon those of the individual. We know, only too well, that every large aggregation of human beings is attended by a liability to outbreaks of epidemics of various kinds; and that, as the aggregation increases in its density and in the number of its units, this liability increases also, not merely in a direct, but in a quadrate or cubic ratio. Now to these epidemics, which have, if not their causes, certainly the conditions of their most dire activity, in the accumulated waste and excretions of many persons, the quality of "preventableness," if I may coin a word for my necessity, must attach in a peculiar manner. It is manifest, I think, that a community might be so ordered that its members should neither do nor suffer harm by virtue of their close proximity to each other; but it is also manifest that the stringency of the necessary precautions would have to be calculated (and this is a point apt to be overlooked) not upon the mere ratio of density of population, but upon the higher ratio of the increasing proneness to disease. In England, at this time, there are many persons who spare neither expense nor trouble in their endeavors to secure the health of themselves and of their families. There are many who take little heed of such matters, and there are some who sacrifice health to foolish or vicious indulgences. But all alike are exposed to innumerable causes of sickness from which they are powerless to shield themselves, and concerning which the careful have no advantage over the careless, except such as may be due to a greater personal power of resisting morbid influences. Typhoid fever, like death itself, comes with the same step to the huts of paupers and to the palaces of kings.

* An extract from the annual oration delivered before the Medical Society of London, and printed in full in *The Lancet*.

The ordinary channels of contagion, so far as we are acquainted with them, are such that all classes and ranks are about equally liable to the invasions of disease. The landlady who receives linen from an infected house and diffuses the infection not only among the inmates of her customers, but also among the cottages of her workpeople, or among those that fringe the water-cours, into which her drainage is led. The school-keeper who, on the outbreak of scarlet fever in his establishment, scatters his pupils far and wide over the land, spreads contagion not only in the households to which they immediately proceed, but also among the families of domestic and other dependants. So much is this the case, so much is it a matter of constant experience, that infectious maladies may be "caught," as the phrase is, we know not how, that personal caution as to health is distinctly discouraged by the familiar knowledge that it may so easily be rendered nugatory. But we know also, on the other hand, that many of the conditions which foster contagious diseases, and many of the channels through which they spread, are fully under the control of the community, and that really the only practical question with regard to the exercise of that control is whether the balance of advantage is distinctly on one side or the other. People in general have no conception, have not even a conjecture, of the annual amount of pain and loss which, in various ways, epidemics inflict upon the community. They see that the restraint of epidemics, to be effectual, must be accomplished at the cost of some restraint of personal freedom; and, while they are not sure that the desired end would, after all, be attained, neither are they sure of the extent or character of the advantages which restraints on freedom might entail. Now the diseases of which I wish to speak to-night as being preventable, are those only against the propagation of which the community is powerful, whilst the individual is almost absolutely powerless; and these, for all practical purposes, may be taken to correspond with the class called "zymotic" by the Registrar-General. The mortality from this zymotic class may form the basis of an estimate of the ravages of preventable disease amongst us, and may serve to show the magnitude of the evils which, for want of proper sanitary legislation and administration, we, as a people, are condemned to endure. There are two members of the class, however—namely, rheumatism and diarrhoea—which it is doubtful whether I ought to include; since they are, both of them, in great measure attributable to the want either of personal or of parental care. But the mortality directly produced by rheumatism, and registered under that head, is altogether insignificant; and the inclusion of diarrhoea may, I think, fairly be balanced by the exclusion of phthisis, which produces a far larger number of deaths, and which, as Drs. Buchanan and Bowditch have shown, is clearly capable of being much diminished by those public sanitary measures which serve to dry the soil beneath and around habitations. I think therefore that I shall not be far wrong in assuming that the known facts about the zymotic class will be sufficient for the purpose that I have at present in view—that is to say, that they will furnish us with grounds for rational conjecture concerning the amount of disease which might be prevented, almost, if not altogether, by the intelligent and well-directed action of the State. Concerning the possibility of such prevention it is not necessary that I should argue before this assembly; neither shall I enter upon the question, which in the present state of knowledge is insoluble, whether the diseases of the zymotic class are always produced by infection, or

whether they some times originate, and so with the operation of unknown influences. It is part of the common stock of medical knowledge that they at least exist subject to conditions; and that, if the conditions were unfulfilled, the diseases themselves must disappear.

A statement expressed only in figures, when it deals with numbers larger than those of which we have habitual practical experience, gives rise to but faint conceptions in the mind. But, even when thus stated, the mortality from the zymotic diseases is startling. Taken collectively, during five successive quinquennial periods, from 1847 to 1871, these diseases, in the period from 1847 to 1851, destroyed the lives of 512,261 persons, out of a total mortality of 2,024,367, or occasioned one death in 3.94. From 1852 to 1856 they destroyed 472,640, out of 2,082,346, or one in 4.4. From 1857 to 1861 they destroyed 375,085, out of 2,168,087, or 1 in 5.78. From 1862 to 1866 they destroyed 560,015, out of 2,397,532, or one in 4.28; and from 1867 to 1871 they destroyed 562,487, out of 2,476,731, or one in 4.4. During the whole 25 years they caused the loss, in round numbers, of two millions and a half of lives, out of a total mortality of eleven millions, or one death in 4.48, the exact figures being 2,482,508, and 11,153,963. If we add another half million of deaths for another five years, we arrive at the result that three millions of people, a number approximately equal to the population of London, are killed by zymotic diseases in the course of each generation.

The mortality thus produced, however, is not the whole of the evil which I have to describe, and it may be doubted whether it is even the worst part of it. Let us first consider the question of prevalence. On this part of the question I have referred to the Reports of the London Fever Hospital, and I have examined the proportion of deaths to admissions in that institution during the nine years from 1863 to 1871. There were in all 27,332 cases, chiefly made up by typhus, enteric, and scarlet fevers, but including 1,192 described as febricula, in which there were no deaths, and 4,117 of "other diseases," such as small-pox, measles, a few cases of pneumonia, and some others; the total, therefore, not unfairly representing the zymotic class as a whole. Among the 27,332 patients there were 4,490 deaths, or almost precisely 1 in 6; while, in the case of typhoid fever taken alone, the proportion of mortality was very nearly the same. There were 3,652 cases of typhoid, and 611 deaths, or 1 in 5.94. It may be assumed that the careful attendance and good nursing of the hospital would diminish mortality, and, on the other hand, that the cases admitted would be severe. If we set one of these conditions against the other, we shall perhaps be right in regarding the mortality of 1 in 6 as a fair representation of what usually occurs; so that, in order to obtain a notion of the prevalence of zymotic diseases, we must multiply by six the deaths laid to their account by the Registrar-General. This would give about 600,000 cases a year, or 18,000,000 cases in a generation. My own impression, however, is that this estimate is far too low, because, when we include mild cases of the exanthemata occurring among the better classes, I do not think the total mortality from zymotic disease is nearly so much as 1 in 6. Probably 1 in 12 would be a good deal nearer the truth. It has come to be regarded as customary that every person should pass three or four of these diseases, and parents so little expect their children to escape measles, and whooping-cough, and scarlet fever, that it is made a matter of congratulation when these occur in a family at some

not specially inconvenient season. The estimate of prevalence, therefore, certainly does not err on the side of excess, and I suspect that it errs very much on the side of deficiency. Still I do not hesitate to adopt it, because I think it entitles me to assume that each of the 600,000 cases which certainly occur annually may be regarded as possessing a character of at least moderate severity, and as having a corresponding period of duration.

According to the proportions existing at the last census, in 600,000 persons there would be 292,280 males and 307,720 females. Of the males, 154,909 would be 20 years old and upwards, and 137,371 would be under 20 years old. The females of 20 or upwards would be 172,324, those under that age 135,693; so that, including both sexes, there would be 327,223 adults, and 272,767 children or young persons. Dr. Buchanan has been good enough to furnish me with a conjectural estimate of the duration of illness in the chief diseases of the zymotic class, reckoning it, of course, from the first appearance of the symptoms to the time when the ordinary duties of life may be resumed. I cannot venture to oppose my own small experience to his; but his estimate appears to me to be low. He sets the duration of typhus and of relapsing fever at five weeks, that of enteric fever at six weeks, that of febricula at three weeks, and that of scarlet fever at four weeks; or an average of four weeks and a half for each case. Let us apply this to the numbers already stated, and first to the 154,909 adult males. We cannot place the lost earnings or productiveness of each patient at a smaller sum than one pound per week, nor the cost of his maintenance, medical attendance, and nursing, at less than another pound, making the total loss and cost for each male adult nine pounds per illness, or £1,349,181 in all. In the case of adult women we may perhaps estimate the total loss and cost at six pounds per illness, or £924,454; and in the case of children and young persons at one pound per illness, or £172,767. We have here a total sum of £2,596,402 to represent what would be the immediate and direct annual pecuniary cost and loss by zymotic disease to the community if it fell upon the wage-earning classes alone. The greater cost of its incidence upon the bitter classes cannot be estimated from any data known to me. The illness of the Prince of Wales disturbed the whole current of English society, and the value of such a life as that of the Prince Consort, or, coming to more recent times and to our own sphere, the value of such lives as those of the Rev. Charles Butler and of Dr. Peter Allen transcends my humble powers of expression. The money cost, whatever it may be, falls partly, of course, upon the relatives of the sick, partly upon the members of clubs and benefit societies; partly, and very largely, upon the rates for the relief of the poor. The one hundred thousand premature interments must cost at least £2 each, and they raise our money total to £2,796,402 yearly. Besides the mortality and the cost of sickness, we must also take cognizance of the considerable percentage of imperfect recoveries. It is my lot, at two hospitals, to see a large number of children suffering from eye disease, and especially at the Royal South London Ophthalmic Hospital, around which there is a poor and densely crowded population. My inquiries as to the origin of the malady are constantly followed by the reply—"Ever since he had the measles." In the Irish Census return for 1871 it is stated that out of 6,347 blind persons living in that country, 526 had lost their sight from small pox, 31 from measles, 34 from scarlatina, and 99 from fever, or 690 in all; so that more than one-tenth of the existing blindness was due to

zymotic disease. Enteric fever, scarlet fever, small-pox, and measles all entail upon some of their victims an indefinite period of broken health or of impaired usefulness; of which Bright's disease after scarlet fever, or a consumptive tendency after enteric fever, or blindness produced by small-pox, may be cited as extreme examples. In cases of a less marked kind they often leave a protracted feebleness that may be communicated to offspring. The miscarriage of pregnant women is common in typhus, still more common in relapsing fever, and occurs occasionally in all zymotic maladies, so that it seems reasonable to suppose that the fetus in utero may habitually be more or less injured in such cases. Here, of course, we have no very firm ground under our feet, and no data upon which to found any numerical conclusions. But the experience of every one in this room will bear me out when I affirm that the evils thus referred to are terribly real in their character, and terribly large in their extent.

The mention of affections of the eye reminds me that some of the most important of the preventable diseases would almost, or altogether, escape notice if I were guided in my enumeration of them by the mortality returns alone. There are some, and these not the least formidable, that either do not kill at all, or that do not kill immediately, or in any proportion to their prevalence. When people, especially children, are crowded together under unnatural and insanitary conditions of living, they are prone to suffer from a very grievous malady, known as contagious ophthalmia; and the wisdom of the Poor-law Board during the last few years has developed this malady in workhouses and pauper schools in a manner to which previous English experience affords no parallel. The precise facts with regard to its prevalence are known only at Gwydyr House; and I have been credibly informed that, when a member of the late House of Commons gave private notice of his intention to move for returns showing the truth, he was told that his motion would be opposed with all the strength of the Government, and he was induced, as a matter of party allegiance, to refrain from bringing it forward. I heard this without surprise, for the truth was far too bad to bear the light. I have been able to obtain, from a private source, a copy of a report made to a Government inspector by the medical officer of one of the schools. It states, among other curious matters, that, of 1,662 children in the school in question, only 182 had escaped ophthalmia; 163 had suffered from one attack of the disease, 151 from two attacks, 110 from three, 75 from four, 54 from five, 58 from six, 22 from seven, 25 from eight, 7 from nine, 11 from ten, and 204 from more than ten attacks. Concerning the ultimate results of these attacks I have no information; but an analogous condition of things once existed in Irish workhouses, and there the facts have been made known. During the thirteen years from 1849 to 1862, 118,835 cases of epidemic ophthalmia occurred in these workhouses. Among them, sight was partially injured in 1,925 cases, one eye was destroyed in 1,270, and both eyes were destroyed in 517; so that 1 in 32 of those who were affected suffered permanently in a greater or less degree. This proportion would give only 28 permanent sufferers among the children mentioned; but, in another part of the school return from which I have quoted, I find it said that, out of 1,195 children, 347 had "granular lids after ophthalmia;" and I have no doubt that, in all or nearly all of these, sight would eventually be greatly impaired, and that in many it would be wholly lost. The preventable diseases that

do not kill immediately, although they perhaps do more than any others to cripple and destroy usefulness, to sap the powers of life, and to produce degeneracy of offspring, belong chiefly to the ethetic class. There are well-known differences of opinion with regard to whether the legislation that would diminish these diseases would not be a greater evil than the diseases themselves. For my own part, in this case, as in most others, I should say "*Salus populi suprema lex*;" but I have no desire to enter at present upon a much debated question, which lies beyond the limits within which I propose to confine myself. There is no difference, among those who are acquainted with the facts, on the essential point that the legislation in question, where it has been carried into effect, has diminished the prevalence of disease in a very great degree; and there can be no doubt that a still further diminution would be the result if similar legislation were extended to places in which it has not yet been enforced.

(To be continued.)

THE VEXED QUESTION OF FEES.

By A MEDICAL DIRECTOR.

It has always appeared to us that the action of some County, and even State, Medical Societies in binding their members not to make examinations for Life Insurance Companies at a less rate than five dollars for each case, was one of very doubtful wisdom. If it be conceded that, in a given portion of the State, the current value of a visit to a sick person in comfortable circumstances is two dollars, upon what ground, it will be asked, do the physicians in this district base their claim to be remunerated at the rate of five dollars per examination. With the ordinary blank forms for medical examination in use among the great majority of companies, the time spent by the average medical examiner is not more than fifteen minutes. Hence these physicians cannot claim increased compensation on the ground of more time being required for an insurance examination than for an ordinary visit. Perhaps some will say: "More skill and experience are required to make a good examination for life insurance than to treat a case of sickness." Very true; but the action of the society compels even the inexperienced beginner to make the same charge for his services as the old and skilled examiner, whose services are cheaply secured at five dollars an examination.

Another argument, brought forward by some, is, that the examination of candidates for life insurance now and then places the physician in such a peculiar position, that he cannot serve the insurance company rightly without detriment to his interests as a private practitioner; and that for this reason he is fully justified in charging a uniform fee of five dollars for every examination. This argument, which strikes us as being thoroughly sound, holds good only for the country districts and small towns; in the large towns and cities it will rarely apply, as the examiner will not often be called upon to examine one of his own patients. But here the cost of living constitutes another element which has to be taken into the account, and which in certain places justifies the examiner in charging more than his brother practitioner in the country. While the country examiner, then, bases his claim to a fee of five dollars on the ground that his interests as a private practitioner are injured to at least the extent of the difference between that amount and his ordinary fee in practice, the city examiner feels that he is fully entitled to it on the ground of the excessive cost

of living. Both, in our judgment, are right; but why should they seek to secure these ends by so questionable a measure as a County or State Medical Society resolution, so framed as to outlaw all those who do not comply with its provisions? If an insurance company is imbecile enough to employ quacks, eclectics, and ignoramuses, no resolution passed by a State or County Medical Society will bring that company to its senses. If, on the other hand, the company is in the hands of enlightened men, who will listen to reason and who know that the best interests of the company depend upon the hearty co-operation of their medical examiners, the action of the society—partaking as it does of the nature of a strike—will only serve to disgust them with physicians as a class, and so probably put off, instead of hastening, the day of increased compensation.

At the present time there seems to be a universal desire among all the prominent life insurance companies to correct abuses, and to place all the branches of the business upon a solid, honest footing. If the fees now paid to medical examiners are insufficient, let an appeal be made, in proper terms, to the associated companies, and, if the reasons given are clear and satisfactory, the chances are that the appeal will be listened to.

Miscellaneous.

THE INSURING OF "UN-FOUND" LIVES.—At a recent meeting of "The Institute of Actuaries," in London, Mr. George Humphreys, M.A., read a paper on the practice of the "Eagle Life Insurance Company," with regard to the insurance of lives classed as "unsound." He gave full details of the rates of mortality prevailing amongst this class of lives, in the Eagle Company, during an experience of sixty-three years.

From June, 1808, till June, 1871, the Eagle Company insured 3,147 lives which they classed as "unsound," and added an average of six years to each life upon accepting the risk, and charged the premiums accordingly. These 3,147 cases Mr. Humphreys classified as follows: Gout, 418 cases—average age added to each life on entering, 4 years; hernia, 481—average age added, 3 years; organs of respiration affected, 284—average age added, 7 years; obesity, 45—average age added, 6 years; intemperate habits, 119—average age added, 7 years; family history and want of robustness, 579—average age added, 6 years; miscellaneous affections, 1,120—average age added, 6 years. Total, 3,147 cases; and average age added in each case, 6 years.

Although the additions to each age were made on no fixed principle when adopted, yet Mr. Humphreys found that, on the whole, the ordinary surplus had been realized on this class of business. The average duration of the entire 3,147 policies was ten years each; and of the policies in the case of hernia, twelve years each. Mr. Humphreys ascertained by this examination that hernia affected the duration of life very little. One of the most remarkable features in the investigation which Mr. Humphreys had made was, that most of the lives died from wholly different causes than those of the specified "unsoundness" on their being insured.

Any efficient medical examiner ought to be able to say what probable damage the life has sustained from rheumatism, ague, hernia, and other diseases not absolutely fatal, and how many years, in all likelihood, that particular life has been abridged by the attacks.

Original Lectures.

LECTURE UPON GENERAL THERAPEUTICS OF THE NERVOUS SYSTEM.

By E. C. SEGUN, M.D.

PART II.

(Phonographically reported for THE MEDICAL RECORD.)

CLASS B.

SUB-CLASS II.

Depressants and Anæsthetics.

- (a)—Cerebral depressants. { Cold, bromides of potassium and calcium, opium, hydrate of chloral, food, etc., chloroform, ether, etc.
- (b)—Spinal depressants. { Conium, bromide of potassium, cold and food.

(a). Cold is to be employed in the same manner as when we wish to produce an anæmic condition of the brain. The inclination to sleep experienced by persons exposed to severe cold, such as encountered in the Arctic regions, is an illustration of the effect which cold can produce upon the nervous system.

The India-rubber bag sometimes employed in making applications of ice diminishes the intensity of cold applied, and is inferior to the bladder ordinarily employed (*vide supra*).

Bromide of Potassium has usually been spoken of as acting through the blood-vessels, and causing their contraction and consequently anæmia of the parts they supply. Dr. W. A. Hammond and many others speak of the remedy as acting in this manner.

There has been some doubt expressed as to whether Kbr. is true hypnotic.

At present, perhaps, this is to be regarded as an unsettled question. For my own part, judging from my own experience and the testimony of others regarding Kbr., I have been led to conclude that, when given in sufficient doses, it acts very powerfully as a cerebral depressant. In health, I admit that no narcotic effects are obtained from a few doses of the medicine, but in cases of cerebral irritation, and insomnia from a variety of causes, its action is sure and immediate. In delirium tremens, for example, in such cases as are not complicated by degenerative liver and kidney disease, in the so-called sthenic cases, Kbr. given in doses of $\frac{3}{4}$ i. or more every hour, until $\frac{7}{8}$ iij. or $\frac{3}{4}$ iv. have been taken, will, conjointly with semi-darkness and quiet, cut the attack short by producing sleep. In 1866-67, while house physician to the New York Hospital, I had the opportunity of thus treating a series of cases of this disease with very satisfactory result. I say this while perfectly aware that several medicines seem to shorten the duration of delirium tremens, and that it is, under certain conditions, a self-limited disease.

In certain forms of insomnia seen in connection with fevers, the bromide of potassium may fail to produce sleep, because (?) of the continued influence of a blood-poison in keeping up the morbid state.

In the insomnia and delirium of pneumonia I have also seen speedy relief procured by $\frac{3}{4}$ iij. or $\frac{3}{4}$ i. doses of Kbr. In the simpler (?) conditions of sleeplessness caused by anxiety, over-exercise of the brain functions, emotional disturbance, this remedy usually acts well. Perhaps the most convincing proof of the action of Kbr. upon the cerebrum is to be had from observing the effects of the long-continued use of large doses of the remedy. A condition called "bromism" is set up,

characterized by stupor, deficient memory, aphasiiform speech, tottering gait, loss of facial expression, salivation, mucous irritation, papular skin disease, etc. Although we see this result more often in the course of the treatment of epilepsy, yet it may be developed in persons not having this disease. The mental state of brominized persons is not unlike that of patients with dementia.

Hydrate of Chloral is, in my opinion, the best medicine that can be employed for producing sleep. It does not intoxicate, or disturb the digestive organs, as opium does. When chloral succeeds, and it almost invariably does succeed, it produces a calm sleep not followed by any special disturbance of the system.

I would have you bear in mind that this remedy is a much more direct hypnotic than opium, and yet that it does not possess the power of preventing the perception of pain. Hence a rule to follow is to give chloral in cases of insomnia not connected with pain. The physicians to insane asylums in Europe and in this country have found in chloral an invaluable agent for giving rest to patients suffering under mania in any of its forms. They have also testified to the very great safety attending the use of the medicine, many patients getting large doses of it nightly for months and years. Chloral may also be used in the cases where (*vide supra*) bromide of potassium is indicated, and the two may be given together. If you are to choose between these two drugs, use Kbr. if in addition to the cerebral irritation there exists some physical excitement (spinal irritation); chloral in cases of pure cerebral disturbance. The theoretical view, that Kbr. acts by causing anæmia of the brain, leads to the withholding it in cases of cerebral anæmia and mal-nutrition. This I believe to be an error, since in my experience the occasional giving of Kbr. (and chloral hydrate) in such cases has in no way hindered the good effects of restorative medicines.

The dose of hydrate of chloral may be, for adults, 15 gr. or $\frac{3}{4}$ i. In females, especially, it is well to try a small dose on your first trial. A scruple dose I believe to be a perfectly safe one for a man. The doses of $\frac{3}{4}$ iij. and $\frac{3}{4}$ i. should be used in cases of acute mania, or severe delirium.

The conjoint use of bromide of potassium and chloral is very satisfactory. A drachm of Kbr. may be administered in the afternoon, followed at bedtime by grs. xx. or xl. of chloral.

Concerning the use of opium and its constituents in diseases of the nervous system I believe that I need say very little. I would have you always bear in mind the exceedingly unpleasant way in which this remedy affects very many females, producing insomnia and, later, vomiting and constipation. For these susceptible individuals (a few males must be included) some of the liquid compound preparations of opium, McMunn's elixir, the liquor opii comp., may be substituted for morphia or simple opium. In a very large number of cases of nervous disease we seek to relieve pain by the use of morphia. In such cases it is best administered hypodermically, in the form of strong solution of the sulphate, or acetate, or muriate. I must admit that my own patients seldom receive any but the sulphate of morphia injections, in the shape of Magendie's solution (16 gr. to $\frac{3}{4}$ j.), $\frac{1}{4}$ x. of which are equivalent to $\frac{1}{2}$ gr. morphia sulph. I am, however, in the habit of adding a little atropia, $\frac{1}{100}$ or $\frac{1}{200}$ grain to each hypodermic injection, for the purpose of remedying the nauseating and constipating effects of the morphia. My solution of atropia is composed of atropia gr. j., distilled water 3 v.; $\frac{1}{4}$ j., containing $\frac{1}{100}$ grain atropia. I have employed this combination since 1867 with great satisfaction.

Food is a depressant, because it remedies the morbid irritability produced in the brain in cases of exhaustion, whether from hemorrhage or over-work.

Sometimes the effect of food is very marked indeed. Many of you have doubtless experienced a sensation of exhaustion, accompanied by headache, perhaps severe, which has been entirely relieved by taking a good meal. The headache perhaps has been made to disappear, even before the meal was completed, and you have felt immediately refreshed, and that without wine or other alcoholic stimulant.

In many cases of delirium and mania the effects of the persistent giving of nutritious food are evidenced by rapid improvement and cure.

b. Spinal Depressants. — Conium is the type medicine of this class, and seems to be the direct antagonistic of strychnia. It acts by paralyzing the spinal motor centres, from the nucleus of the third nerve down. This remedy can be used with benefit in spasmodic affections.

In small doses it produces a paretic condition of the spinal axis, indicated by partial ptosis, strabismus, or double vision, weakness of the knees; and the arms may become slightly paretic. These symptoms appear within an hour after the medicine has been taken. By the administration of larger doses, almost complete akinesis is obtained, which may last for half an hour or an hour, but is not dangerous.

The remedy should be given only once a day, and in many cases to the extent of partially paralyzing the patient.

A reliable preparation is the English *succus conii*, which may be administered in doses of from $\frac{1}{2}$ j to $\frac{1}{2}$ vj once a day. An equally good form of conium is Squibb's fluid extract. I usually prescribe this, and give it in doses of $\mathcal{M}$ xl. or $\frac{1}{2}$ j. Dr. John Harley, of London, has done much to give us a clear notion of the action of this remedy, and he has found it useful in chorea, epilepsy and other spasmodic diseases; he points out the necessity of obtaining the physiological effects of this and other drugs when we wish really to do good in affections of the nervous system. In epilepsy I have employed the fluid extract of conium in combination with Kbr., in epilepsy, with good results.

Bromide of potassium also acts directly upon the spinal cord as a depressant. It lowers the activity of the motor tract (though in a lesser degree than conium) and diminishes reflex excitability. Its use is consequently indicated in all affections in which reflex action is abnormally great, and in many such we obtain immediate and permanent good results from its administration. In various forms of convulsions, the eclamptic attacks of children, of pregnant and parturient women, Kbr. does good. Morbid excitement of the lumbar part of the spinal cord, as evidenced by nymphomania and satyriasis, is often relieved by this drug. Some forms of vomiting (in pregnancy, after inhalation of ether, etc.), spasmodic states of various sphincters, are also to be cured by Kbr. It is in the treatment of the great neurosis epilepsy that this medicine is the most employed, and it is concerning its usefulness in this affection that great discussions have occurred. The use of Kbr. in epilepsy was begun by several physicians about the same time, but Drs. Brown-Séquard and Laycock were the first to call attention to it. The generally received opinion is that Kbr. is the medicine which possesses more power than any other over epilepsy; that in the majority of cases the frequency and severity of the seizures are very much diminished while the medicine is being taken (the symptoms soon reappearing if it be discontinued); and that a case here and there may be cured

by its use. In hospitals with large numbers of epileptic patients the effects of giving and withholding Kbr. are very strikingly in favor of the utility of the drug. For my part I wholly accept this as a correct estimate.

There are a few general rules to be observed in the treatment of epilepsy by Kbr.

In the first place enough Kbr. (and other bromides if you please) should be given to reduce the reflex function and keep it below the normal standard. A test of the sufficient action of the medicine lies in the reaction of the palate and fauces to irritation; a diminution or abolition of the well-known reflex movements of these parts indicating diminution of the reflex excitability. Another general rule is to give more of the medicine at night than in the day-time; a direction of great value, for which we are indebted to Dr. Brown-Séquard. We usually give three-day doses, and a dose in the evening twice or thrice the size of the day dose. A third, and most important rule is to administer the Kbr. in a perfectly continuous way for months and years. Dr. Brown-Séquard has known patients remain without seizures for two years while taking his prescription for mixed bromides, having a return of convulsive seizures in a short time after ceasing the medication. I have seen similar though less striking results.

There are a few epileptics who cannot tolerate the bromides; who become easily "brominized," and whose attacks are made worse by these drugs. These paradoxical patients are very rare, I believe. While recognizing the great value of Brown-Séquard's compound bromide solution (Kbr. + $\text{NH}_4 \text{ br.} + \text{KI}$), I more commonly employ a simple solution of bromide of potassium, giving gr. v three times a day, and gr. xv or $\frac{1}{2}$ j at bed-time, at first in adults. Children require relatively very large doses of the bromides, and, contrary to what is sometimes taught, I see in anæmia no counter-indication to the use of the remedy, nor do I believe that any law can be laid down for the giving or not giving of it, from observations upon the retinal circulation. Such a view is based only upon belief in the more than doubtful physiological theory that cerebral hyperæmia and anæmia are usually prime factors in the pathological state called epileptic.

CLASS C.

Tonics and Restoratives.

By restoratives I understand, with Headland, those remedies which restore to the system an element, diminished by a disease, or whose diminution causes a disease. A few of this class are especially useful in diseases of the nervous system, two chiefly,—phosphorus and fats.

I would not be willing to admit that there is any defined morbid state of the nervous system which can be shown to depend upon a diminution of the phosphorus, which is so important an ingredient of nerve tissue, yet I am the first to recognize that in some nervous diseases much phosphorus is excreted, and that in very many of them much benefit, even to a cure, is obtained by giving phosphorus. In practice the various phosphates, the acid phosphates, the hypophosphites, etc., if they do good, do so very slowly, and are hardly to be used in the treatment of serious cases, except as adjuvants. Phosphorus itself may be administered in the form of the official oil, or in the non-official solutions (Thompson's), and as phosphide of zinc. The dose of phosphorus ranges from $\frac{1}{10}$ to $\frac{1}{2}$ grain; that of zinc phosphide from $\frac{1}{6}$ gr. to $\frac{1}{2}$ gr. In administering this powerful remedy, please bear in mind that some organizations are very susceptible to

its toxic influence. In cerebral mal-nutrition, in neuralgia, in "spinal irritation," in hysteria, and in varieties of paralysis, this drug is of the highest value.

Fatty food and cod-liver oil are indicated in the conditions which demand phosphorus.

Among the tonics the chief are strychnia, arsenic, zinc, iron, quinia, and cold. Cold should, for its tonic effect, be applied only for a short period of time. This may be done by sponging, the shower-bath, cold compresses, the cold sheet, and sea-bathing.

A corresponding reaction follows, which consists in hyperemia and improved nutrition. (*Vide infra*, counter-irritants.)

We are unable exactly to explain why strychnia, or arsenic, or zinc should benefit the general nutrition, but daily experience teaches that these remedies are invaluable in many morbid states of the nervous system.

Strychnia, in cases of irritability, of hysteria, spinal irritation, and in some palsies, may be given in small doses for long periods of time; doses of $\frac{1}{10}$ gr. or $\frac{1}{2}$ gr. The action of arsenic is often marvellous in chorea, and very satisfactory in other nervous diseases. Fowler's solution is the arsenical preparation most commonly employed, and in chorea it should be dealt out with no sparing hand; doses of $\mathfrak{M}\text{iv}$, $\mathfrak{M}\text{vi}$, or even $\mathfrak{M}\text{x}$ being well borne. The oxide and lactate of zinc have been much used in states of exhaustion of the nervous system, after sexual excess, or in chronic alcoholism, and in epilepsy. In the nervous states caused by alcohol the zinc oxide proves almost as satisfactory as arsenic in chorea. I have usually employed it in combination with extract of nux vomica. Since the introduction of Kbr. into general use, the zinc treatment of epilepsy has fallen into (perhaps unmerited) disuse.

Quinia, in moderate doses, would seem to act as a tonic. It is possible that it does so by causing more food to be taken and digested, yet from the immediate improvement in well-being and in cerebral activity, which many experience while taking it, I am inclined to the opinion that this remedy does exert a direct effect (restorative?) upon the nervous centres.

Iron I have not spoken of, because it does not especially affect the nervous system. It improves the condition of the blood, and, by so doing, cures morbid states of the nervous system (neuralgia), which depend upon anemia or chlorosis.

Perhaps it were well that I should here speak of two so-called specific modes of medication, very useful in nervous diseases, and which would otherwise not enter the classification offered you. I refer to the treatment of constitutional syphilis, which often gives rise to morbid states of the nervous system. Nearly all of these morbid states are a part and parcel of the third (tertiary) stage of syphilis, depending upon affections of fibrous tissues of bones, of blood-vessels, and upon the presence of gummata in the nervous centres. I would only speak of one point in connection with this subject, and that is the necessity of using the iodide of potassium in really effectual doses, giving from $\mathfrak{z}\text{i}$. to $\mathfrak{z}\text{vi}$. a day, until improvement takes place. You will be surprised to see how a patient with tertiary syphilis will gain while taking $\mathfrak{z}\text{ss}$. of KI. in the twenty-four hours, after having resisted smaller doses. No unpleasant symptoms attend the taking of large doses, provided that restoratives and good food be also given.

The other specific medication is the treatment of malaria in its original form by quinia. Malarial neuralgia is a well-known and an obstinate affection. It may be cured by quinia in the usual way; but a much more rapid removal of the disease is obtained by using

the quinia in the shape of hypodermic injections over the affected nerve. We then obtain the specific effect of quinia on the nervous centre and counter-irritation on the nerve. Nearly seven years ago* I published the results of my experience with this medication in the New York Hospital, giving full details of the practice. As a general rule, in nervous disorders dependent upon malaria, do not err by giving *too little* quinia.

CLASS D.

Counter-Irritants.

By counter-irritation is understood a localized irritation, which modifies the nutrition or mode of activity of another part than that irritated, either just beneath it, or at a distance from it. Counter-irritants almost always act through the spinal cord, and their mode of action is typified by a morbid process that takes place as a consequence of severe burns. If a limb or part of the body be scalded or charred, the patient is not in danger merely because of the shock of the injury, or of the exhausting discharge accompanying the healing of the burn, or of the pyemia which may take place during the continuance of this suppuration, but he is also likely to suffer from certain visceral complications which occur in parts bearing a definite relation to the burn. Brown-Séquard demonstrated many years ago that by cutting across the spinal cord, above the origin of nerves going to the burnt part, no visceral lesions occurred; thus proving that these lesions were set up by a morbid state of the spinal cord, produced by the burn. The burn corresponds to our counter-irritation, and the altered nutrition of the viscera to the distant effect produced. In the one case a morbid process is induced; in the other a beneficial change, not yet understood by us, is determined.

The alternate application of cold and heat does much to improve the nutrition of paralyzed parts, and is used for many special purposes.

Brown-Séquard has recommended the use of these means to prevent the formation of bed-sores, and to heal those which may be already formed.

The method consists in applying an ice or snow-poultice over the part for five or ten minutes, following this by the immediate application of a hot poultice. This should be done once a day over the parts threatened with the formation of bed-sores.

When the same thing is done twice a day to sores already formed, as a rule, sloughs come away, circulation is improved, and granulations will soon spring up. I have seen huge bed-sores healing under this treatment while the patient was failing.

The actual cautery is a means of the utmost value in the treatment of nervous affections. It is one, however, which has fallen into very great disrepute in consequence of the manner in which it was formerly employed. A burn, sufficient to produce suppuration, is not necessary, surface-irritation being what we seek to produce.

The theoretical view that surface-irritation is most useful, has, like several others brought forward in this lecture, a true physiological basis. It rests upon the well-known law that the terminal nervous twigs, and their special terminal bodies, are more irritable than nerve trunks.

Brown-Séquard has revived the use of the actual cautery; and by means of his form of cautery we are enabled to produce much skin-irritation, with little pain to the patient, and no subsequent annoyance from sore surfaces.

* On the Subcutaneous Use of Sulphate of Quinia in Cases of Malarial Neuralgia. New York Medical Journal, 1877, p. 402.

The cauterizing iron which he employs is tipped with platinum. The platinum never gets rough by ordinary heat, as does iron, and there is, consequently, a smooth surface to come in contact with the skin every time the cautery is used.

The white-heat is necessary in using the actual cautery, because it produces the maximum degree of irritation to the nerve, with a minimum of pain.

The cautery thus heated (in a coal fire) should be rapidly drawn over the part selected, four or more strokes, of from one to six inches in length, being made. This can be done in a very few seconds, and in many cases no real pain is experienced by the patient. The strokes remain as reddish-brown welts, which are quickly surrounded by a zone of hyperæmia, which is sometimes immense. A moderate degree of burning pain is felt for twenty minutes or two hours after the application. Sores never result from the burning, and not once in twenty strokes have I ever seen blisters arise. The epidermis is cast off dry in a few days, leaving a brownish stain which passes off wholly in a short time. The cautery can be used upon the face with perfect safety. I have made use of this most valuable means in women, and children 13 years old, without anesthetics. The disagreeable ideas connected with the words "burning" and "cautery," in the minds of physicians and of patients, are the barrier to the more general use of the platinum cautery.

Setons have so much gone out of fashion that I need hardly stop to enter a protest against their use. It is very doubtful if a suppurating sore produces more irritation than the cautery or blisters, and there are grave objections to using setons.

Blisters are invaluable means of producing counter-irritation. Let me ask you to use them in such a way as not to produce suppuration: repeat the blisters and heal the blebs as soon as possible. Great good is often obtained from a series of small blisters.

Dry cupping is beneficial in many spinal affections. The number of cups applied should be large—from 10 to 20. It is not necessary to use the cups immediately over the seat of the disease. Ten cups may be applied upon the back, and ten in front, with the same benefit as if all were applied behind.

It is a matter of doubt whether wet cups act better than, or in a different manner from, the dry. The degree of skin irritation produced by the process of wet cupping is certainly very much greater than in that of dry cupping; and it cannot be positively denied that the loss of blood is useful. In various inflammatory affections of the cerebral and spinal meninges, and in some functional disorders, wet cups are still used.

Sulphur baths do good by the irritation they produce upon the surface, rather than from any effect of the sulphur upon the system generally. These baths may be employed liquid or in the shape of vapor. For liquid sulphur baths, the sulphuret of potassium is dissolved in water, and the patient soaks himself awhile in the solution. A better application is obtained by vaporizing sulphur in a chamber into which steam is let in, the patient's head being kept out of the bath, of course. A stay of ten or twenty minutes in this atmosphere produces a great deal of cutaneous irritation, which, in time, leads to a decided desquamation. Some of the natural sulphur spring waters are also used for bathing purposes, but are much less effectual. In spinal diseases, particularly posterior spinal sclerosis (locomotor ataxia), series of such baths have done great good. They are also useful in lead poisoning. Many medicated baths likewise act by producing extensive skin irritation.

CLASS E.

Electricity.

We employ all three forms of electricity in medicine, Franklinism or static electricity, Galvanism (or Voltaic electricity), and Faradism or induction electricity.

Any one of these forms may be used in the treatment of diseases of the nervous system in a rational or an empirical way.

The rational applications of electricity are to produce muscular contraction (passive exercises) and to affect the nerves of sensation (irritation, sedation).

What I may call the empirical use of electricity is when we attempt, by means of it, to modify the mode of activity of deeply placed organs, such as the brain, spinal cord, and the ganglia of the sympathetic.

It would be out of place for me to attempt, in a few words, to speak of the special application of electricity. A great deal has been written about this matter in the last few years, and I am glad to say that there are a few small books on the subject which I would urge you to study. I need only say that within certain limits, corresponding with our physiological knowledge, I have the greatest faith in the power of Faradism and Galvanism as remedial agents, and that I use them a good deal.

CLASS F.

Hygienic Means, etc.

The cases of nervous disease which are strictly speaking active, due to hyperæmia, or over-action of the nervous centres, I regard as being exceedingly rare. Consequently, I regard the immense majority of cases as requiring a supporting diet and such hygiene as shall tend to improve nutrition.

There are very many points to be considered in this connection.

In the first place, many paralytics suffer from slow digestion and constipation. The diet of such patients should consist of such articles of food as leave little detritus, as meats, fish, eggs, milk, and fats. Vegetables and starchy or sweet articles should be allowed sparingly.

In the second place, the bladder in many cases (spinal palsies) requires to be emptied by means of the catheter. In such cases you cannot exercise too much gentleness and care in introducing the instrument, for fear of setting up cystitis, or of aggravating one already present.

Thirdly: In many spinal cases there is immensely exaggerated reflex activity of the spinal centres: spinal epilepsy is set up by the contact of the bed-clothes, your hand, etc., with the palsied limbs; and an overloaded bowel brings about attacks which seem spontaneous. By strict orders to the nurse and by the help of mechanical contrivance you can reduce these spasms to a minimum. If one occur, recollect that you can stop it by forcibly flexing one or both great toes, as indicated by Brown-Séquard.

Fourthly: I would ask you always to bear in mind that bed-ridden paralytics are peculiarly liable to fatal attacks of bronchitis, broncho-pneumonia, and pneumonic phthisis. Remembering this, you will give directions to obviate all that which might expose your patients to such chest complications.

Fifthly: Inasmuch as bed-sores are likely to occur among the complications of nervous diseases, a few words may be added to what has already been said concerning their prophylaxis.

It is important to make every piece of clothing beneath the patient smooth. Consequently, a pretty

hard mattress or water-bed is the best for them to lie upon. Special care is to be taken that the under-sheet does not get wrinkled and drawn into folds; its ends may be fastened down by tapes. The shirt worn by the patient should be kept smooth under him, and perfect cleanliness must be enforced. Special attention to these apparently small matters will in most cases be sufficient to prevent the formation of eschars.

In case a bed-sore has formed, the best course to pursue is to clean away all necrosed skin and connective tissue (tow-like shreds) by means of forceps and scissors, and then to use the ice and poultice treatment as above detailed. When healthy granulations spring up, ice poultices are still useful once or twice a day, to be succeeded by ointments, or adhesive plaster strapping.

Sixthly: In the matter of coffee, alcoholic drinks and tobacco. You will hear physicians asking their patients to give up the use of these articles, simply because they have a disease of the nervous system. I am afraid, gentlemen, that this is very illogical. For my own part I do not proscribe these luxuries unless there is evidence that their use has had something to do with the development of the morbid state. Usually I do not at all interfere with the use of coffee, and ask that a less quantity of alcoholic drinks and tobacco should be used. The worry and nervousness consequent upon the giving up of an established habit is worse for the patient, in my opinion, than the moderate use of the above-named articles.

Let me close this rather fragmentary lecture, by calling your attention to something which is not wholly extra-medical. I allude to the care of your patients' spirit—their emotions and fancies, if you will. Never let *alarm* be one of your medicaments. If necessary, in order to bring about the reform of bad habits, lay the picture of consequences before your patient truthfully, but not in the language of exaggeration. Even in hysterical cases you need not be so frank as to hurt your patient's feeling: it will often do if her relatives know precisely what you think of the value of the symptoms. In cases of mental disorder, pray do not forget that even very maniacal or melancholic patients attend to and remember all your words and actions, and will treasure any kind and careful behavior of yours, as well as bitterly recall any unkind or hasty phrases and acts. As a general therapeutic rule, I would have you be as anxious to avoid wounding the sensibilities of your poor or wealthy patients as of injuring their tissues.

NEW METHOD OF SUPPRESSING HEMORRHAGE DURING OPERATIONS WITHIN THE MOUTH.—In doing operations in the mouth, as staphylorraphy and uranoplasty, the surgeon is met by two especial sources of annoyance. First, the impracticability of both anæsthetizer and operator working simultaneously necessitates the loss of much time; and second, the sponging required by the usually abundant hemorrhage in these operations, causes frequent and annoying interruptions. Thus the operator gets but a relatively small portion of time in which to use his instruments. Prof. Andrews, of the Chicago Medical College, recommends, to obviate these disadvantages, that after having etherized the patient in the ordinary manner, the cone be exchanged for the spray apparatus, which is filled with ether. He claims that the use of this does not interfere with the operator's work; that the cold produced by directing the spray upon any particular part represses the tendency to hemorrhage, and, moreover, that the patient's inhalation of the vapor thus supplied adequately sustains the state of general anæsthesia.—*The Medical Examiner*, March 15.

Original Communications.

A SIMPLE METHOD OF REDUCING THE DISLOCATION OF THE FOREARM BACKWARDS.

By ALEX. MURRAY, M.D.,

NEW YORK.

JAMES JOHNSON, aged 36 years, a blacksmith, is a large, healthy, muscular man. On the 8th of March, 1874, while driving a horse and wagon through Tenth street, he was thrown with violence to the ground and sustained a dislocation of the elbow-joint. He stated that when he fell he instinctively extended his arms forwards to save his head and face from injury, and believes he received the force of the fall on the palm of the right hand. His companion, who was riding in the wagon with him, was also thrown out, and fell directly against the injured arm, which was probably more directly the cause of the dislocation than the violence of his own fall. On recovering himself he found the joint nearly immovable, and was unable either to straighten it or bend it to a right angle. Previous to his visit to me, his friends had made several ineffectual attempts to reduce the luxation. I saw the man about four hours after the receipt of the injury, holding with the sound hand the fingers of the dislocated arm, to prevent any motion of the limb.

On examination, I found considerable swelling around the joint, shortening of the forearm, the olecranon projecting nearly two inches backwards and upwards—in short, a complete dislocation of the ulna and radius backwards.

The first case which came under observation for treatment by the method I shall presently describe, was in June, 1854; and was that of a man named Elliott, a mechanist, residing at Eighth street near Avenue C, an employé at the "Novelty Iron Works." He was an athlete, a powerful, muscular individual about thirty years of age. He had been on a drunken frolic for several days, and from the effects of his debauch and a few falls, had lain in a sort of stupor for three days altogether unconscious of the injury to his elbow-joint. On the fifth day after the occurrence of the accident, two physicians were engaged for nearly an hour in endeavoring by the use of pulleys, etc., to reduce a luxation of the forearm backwards. They were about sending the man to Bellevue Hospital for treatment, when my assistance was requested. We could not by any argument induce our patient to submit to etherization. I requested the man to stand up, and asked him if he would not take a little good brandy, and with a strict injunction that he should not drink it until such time as I should give him permission. My object by this little diplomacy was to withdraw his attention directly from the nature of his injury and the result which I was desirous of accomplishing.

I took my position at the outside of the dislocated arm, and placed the palm of my right hand to the palm of his left, dove-tailing my fingers between each of his fingers. In this way I had secured a firm hold to make extension. I then placed my elbow as a fulcrum and for counter-extension on the forearm in front and against the lower end of the humerus, and by a steady pressure downwards and backwards, and at the same time flexing the forearm towards the shoulder, I caused the luxated bones in a few moments to slip into their natural place.

I am not aware that this mode of reducing luxation of the elbow-joint has been adopted by any other physician, nor do I find any reference to it in our works on surgery.

Sir Astley Cooper recommended placing the knee between the arm and forearm (bend of the elbow), and by forcible flexion of the latter reduce the dislocation. This method suggested the one I have already detailed and practically tested in a few cases.

The incomplete or lateral dislocation, with or without fracture of the olecranon, can also be reduced in the same manner. The advantages of the above method are, that we have a ready means at command to make extension, counter-extension, also a fulcrum and leverage power; all of these aids can be brought into harmonious action at the same moment, to overcome the muscular resistance which opposes the reduction of the luxation. From its simplicity and easy execution we can reduce a dislocation of the ulna and radius backwards in two or three minutes, without the assistance of a second person, or of anaesthetics or pulleys. Although the reduction of this form of luxation is not generally attended with much difficulty, yet we do occasionally meet with cases which give considerable trouble.

I have met with six cases of complete dislocation of the forearm simply backwards; two of these were in school-boys, aged twelve and fourteen years respectively, and four in adults. Five were reduced by the method I have already described, and one in the manner recommended by Sir A. Cooper.

If the injured individual should be too weak, or unable to stand erect, he should be seated sideways on a chair, and made to grasp its back firmly with the sound arm, while the surgeon takes his position at the side of the injured limb parallel to the patient.

259 E. 10th STREET.

A CASE OF PUERPERAL CONVULSIONS TREATED BY HYPODERMIC INJECTIONS OF MORPHIA.

By G. O. MORRISON-FISET, M.D.,

LATE HOUSE PHYSICIAN IN CHARITY HOSPITAL AND RESIDENT PHYSICIAN OF THE SMALL-POX AND FEVER HOSPITALS, NEW YORK.

VARIOUS hypotheses have been advanced by different authorities on the probable poison giving rise to the series of symptoms that are witnessed in the course of Bright's disease, and sometimes in the puerperal condition.*

If we accept the views of Frerichs, who says that carbonate of ammonia is the active poison, the result of decomposition of urea (which is retained in the blood) by the action of a ferment, or that urea itself is the agent producing the mischief, we agree to the action of a poison on the system, expending its force upon the two great nerve-centres, the brain and spinal cord. The channels through which that poison is to be eliminated are, the skin, intestines, and kidneys. The production of diaphoresis and catharsis has been recommended, to the exclusion of diuresis, by some of the best authorities upon this important subject. It is argued that the kidneys, being in an inflammatory state, should not be overtaxed, but that the morbid matter present in the blood should be eliminated by the skin and intestines. However, mild diuretics, *e. g.*,

digitalis and the bitartrate of potash, have been administered with good results.

One of the best diaphoretics at our disposal is the active principle of opium—morphia—administered hypodermically. Yet not so many years ago, opium was considered a very dangerous drug to use in the treatment of acute albuminuria. Tanner, in connection with the treatment of uremia, speaks thus: "The practitioner must carefully avoid the use of calomel; for even one or two moderate doses may develop mercurial pyralism in cases of renal disease. So also opium is generally objectionable; although on the principle of selecting the lesser of the two evils, I have not hesitated to resort to it when there has been great irritability and sleeplessness."*

Professor Loomis, of the University of New York, has recently written an article, which was published in THE MEDICAL RECORD, relating a number of cases of uræmic convulsions treated by hypodermic injections of Magendie's solution of the sulphate of morphia and the internal administration of infusion of digitalis. The cases occurred in his own and in the practice of others; the results obtained were favorable in the majority of the cases thus treated. If opium is admissible in the treatment of uræmic convulsions due to organic disease of the kidneys, it is none the less in the treatment of the convulsions of parturition, which are due to an active congestion of the same organs, caused by pressure of the gravid uterus. The nerve-centres are irritated by the same poison in both instances; therefore the same remedies should be applied.

Always bearing in mind that the removal of the predisposing cause (which is the child) is indicated, we should, nevertheless, endeavor to eliminate the urea during our operative procedure, thereby controlling its virulent action upon the nervous system, manifested by a series of spasmodic contractions.

The frequency of the convulsions should be our guide in the administration of the drug.

I venture to predict that, before many years have elapsed, the treatment of uræmic convulsions by this method will be the acknowledged practice; and that when they occur during the act of parturition (provided uræmia is the only complication present), the employment of this valuable drug, as indicated, will be successful, without hastening that process which, under ordinary circumstances, we trust to nature.

This mode of treating puerperal convulsions I have tried in the following case, while in charge of the obstetrical wards of Charity Hospital:

Bridget W., single, æt., 24; admitted to ward 12, May 19, 1873. The patient was a primipara, and menstruated for the last time in the month of September. The pelvis was found to be normal in every respect. She was taken with pains at 10 A.M., August 21. I was called to see her on the next day at 12 o'clock, and found that the os was just beginning to dilate; at four, it was dilated to about half of its extent; the fetal heart could be heard to the left of the umbilicus. At eight o'clock, I was summoned in all haste to the patient, and found her in a convulsion which lasted about five minutes. She having regained her consciousness while I succeeded in introducing a flexible catheter, through which only a few drops of urine flowed, but not in sufficient quantity for me to test. I therefore left the catheter in the urethra, hoping that I should shortly obtain enough urine for that purpose.

The spasms were tonic, and affected the whole body. The pupils were dilated, and frothy mucus issuing from

* Frerichs believes that the so-called uræmic symptoms are the result of cerebral anæmia, due to oedema of the brain. Niemeyer agrees with him to a limited degree.

* Tanner's Practice of Medicine, page 48.

her mouth. Her skin was dry. Dr. W. E. Ford, of the house staff, was called in consultation, and we administered ten minims of Magendie's solution of the sulphate of morphia. The nurse was ordered to keep the patient thoroughly covered with a blanket, to encourage diaphoresis. At a quarter to nine the patient was in a profuse perspiration, which continued for a few hours.

The uterine contractions (inertia uteri) were feeble and not frequent. At one o'clock the next morning (August 23) no urine had yet been obtained. The patient was made to lie on her side (in order to relieve the pressure upon the ureters caused by the uterus) and the catheter was introduced. About one ounce of a dark, smoky-colored urine was drawn off. This was tested by heat and alcohol, and found to contain albumen in large quantity. No convulsions had recurred up to this time. At nine o'clock the membranes ruptured, the os was then fully dilated, the head presenting, and in the left occipito-iliac anterior position—the uterine contractions being feeble and irregular, and the head engaged in the excavation. At four o'clock the labor had made but little progress, though the contractions occurred oftener and were more powerful. I then called a consultation of all the members of the house staff at eight o'clock in the evening. The vagina was hot and dry, the pulse frequent and small. Chloroform was administered, and I applied the forceps; after making traction for about twenty minutes the child's head was delivered. The inertia uteri was now complete, and traction was made with one finger of the right hand in the child's left axilla, and the left hand upon its head; at the end of ten minutes the body was delivered. I could not detect any heart sounds in the child; however, artificial respiration was kept up for a long time after its delivery, during which period no signs of life were manifested. One drachm of the fluid extract of ergot was administered to the mother, and ounce-doses of whiskey given every forty minutes. At ten o'clock the placenta was still firmly attached, and the inertia complete; hemorrhage now occurring, the hand was passed into the uterus, and the placenta was extricated, followed by the removal of all clots of blood. Ergot was given, and ice applied over the abdomen, at the same time kneading the uterus, which now began to contract, and very little blood was lost. Upon examination the placenta and membranes were found to be intact. No return of the convulsions has taken place, the patient having been watched constantly. One hour later no hemorrhage had occurred. The pulse was quick and feeble, I therefore ordered half-ounce doses of whiskey to be given every hour or two, during the remainder of the night; but if the patient was sleeping, to give one ounce every three hours; I then gave another hypodermic (ten minims) injection of Magendie's solution.

The next morning I found that she had slept well during the night; her pulse was now firm, but still rapid. I ordered the whiskey to be continued as before, and her diet to consist of milk and beef-tea, given at intervals in small quantities. I also prescribed eight grains of sulphate of cinchona every three hours. At seven o'clock in the evening, the patient complained of soreness of the abdomen, but no well-defined pain; she had vomited frequently during the day. Lime-water added to her milk was prescribed. The legs were still œdematous, and the patient was uncertain as to the amount of urine passed by her. I consequently prescribed the infusion of digitalis in two-drachm doses every four hours. On the morning of the 25th, I found that the mucous membrane of the lower part of the vagina was in a sloughing condition. Her pulse

was 108 and full; she could now retain her milk, and had had no secondary hemorrhage nor convulsions. A poultice of equal parts of animal charcoal and linseed, saturated with a solution of carbolic acid (3 iij. to Oi.) was ordered to be applied to the vulva three times a day. The sphincter vesicæ was paralyzed from the prolonged and difficult labor, and the urine dribbled away, consequently the catheter had to be used frequently. On the last day of August, I saw the patient for the last time; she was fast improving, and could now pass her urine without the aid of the catheter. Her pulse was regular and full. The slough having separated from the vagina, a healthy granulating ulcer remained, which continued to improve under appropriate treatment.

CASE OF RETENTION OF URINE FROM ENLARGED PROSTATE — ASPIRATOR USED NINETEEN TIMES.

By JAMES A. HALL, M.D.,

ELMIRA, N. Y.

Mr. T., of Schuyler county, aged 78 years, of temperate habits, and an otherwise healthy man, had been suffering for some time from enlarged prostate, and after having, as he thought, "taken a little cold," found on rising, March 21st, that he was unable to evacuate the bladder, and the retention continuing, in the afternoon he sent for his physician, Dr. J. W. Thompson, of Watkins. Dr. T., who had attended the patient during a similar attack a little more than a month previous, and was at that time able to relieve him by the use of the catheter, made persistent and repeated, but unsuccessful, attempts to enter the bladder, using the common silver catheter, the gum elastic, and finally Squire's vertebrated instrument, which had been most readily introduced on the former occasion. Twenty-four hours later I saw the patient, and became associated with the doctor in the care of the case. Attempts were again made to introduce catheters, but with negative results. The gland, by examination per rectum, was found to be very much swollen—in size larger than a hen's egg—and exceedingly sensitive. Under these circumstances I proposed to use the aspirator, and early the following morning (March 23d), 48 ounces of highly colored, strongly ammoniacal urine were drawn by aspiration, and the patient greatly relieved. During the four days following, the patient, not suffering severely from the distended bladder, and being several miles out of town, was visited but once a day, and an average of 46 ounces of urine was drawn by aspiration on each occasion; but on the fourth day, on visiting the patient, the secretion of urine seemed to have increased, the bladder was very much distended—the summit reaching nearly to the umbilicus—the patient was suffering intense pain, and the amount of urine drawn was 59 ounces. During the next three days, in order to prevent the extreme distention of the bladder, and the suffering consequent upon that distention, aspiration was performed once in sixteen hours instead of once in twenty-four hours, when, the urine diminishing in quantity, one aspiration in twenty-four hours was deemed sufficient.

Aspiration was first performed on the 23d of March, and was continued until April 8th, or for a period of 17 days, the number of aspirations being 19. Every three or four days attempts were gently made to intro-

duce the catheters, but were unsuccessful until April 8th, when Dr. Squire's vertebrate catheter was introduced with no difficulty. The urine flowed readily, and from that time till the present writing (May 12th), there has been no difficulty in the introduction of the catheter, and since April 17th that operation has been intrusted to the son of the patient.

In using the aspirator the needle was introduced near the median line, and about 1½ inches above the pubes; and to show how insignificant the wounds were, it is sufficient to say that the entire nineteen punctures occupied a space less than three-fourths of an inch in diameter, without the slightest inconvenience being felt from them.

The character of the water drawn was the same as at first, till March 29th, when 46 ounces were removed, the last eight of which flowed very slowly, settled immediately to the bottom of the receiver, and was a thick, grayish-colored, mucous deposit, with a very offensive smell. The day following, this deposit was much less in quantity, and passed away entirely in about three days, and with it the high color and strong ammoniacal odor; and from that time on the urine was normal. The first drawn by the catheter had all the appearance of healthy urine, and flowed readily, there being no "thick tenacious mucus" to interfere, as troubled Dr. Spier in his case, reported in *THE RECORD*, March 2d.

That trouble can be guarded against by placing the patient, when operating, *upon the side, with the abdomen as dependent as possible.* When lying upon the back, as Dr. Spier says, "the upper portion of the urine is usually drawn off, and there is a constant accumulation or deposit of mucus and salts at the bottom of the bladder." The only way to prevent this deposit is to *empty the bladder completely*, and this is a hard matter to accomplish with the patient lying upon his back. It was not until I recognized this fact, and changed the position of the patient, that the mucus was drawn by the aspirator and the bladder completely emptied in this case. The force of gravity will keep the bladder nearest the spinal column, and as it is being emptied by aspiration of its contents, and contracts, the weight of water remaining still pressing the posterior wall of the bladder towards the sacrum, the anterior wall is drawn backward and away from the abdominal parietes, and eventually it slips off the end of the aspirator needle; the water ceases to flow, and the operator imagines that the bladder is empty. Dr. Spier's trouble may have been caused by a partial emptying only of the bladder; for while the distended organ reached nearly to the umbilicus, he only removed, at the most, 35 ounces of water, while in the present case, the fundus of the bladder not reaching the umbilicus, 59 ounces were drawn at one time, as before mentioned. Now, if the patient be placed upon his side, inclined as far forward, or as much upon his face as possible, the bladder will, by the force of gravity, be held in apposition with the abdominal parietes, and, instead of receding from the point of the needle as it is emptied, it still grasps it, while the water gravitates to the needle's eye; the bladder is completely emptied, no water remaining to undergo decomposition; there is no deposit of mucus and salts, and no necessity for injections and washings.

In this case, by using the aspirator the prostate—not provoked and irritated by constant attempts at catheterization—was allowed a rest, the acute inflammation subsided, and with it the excessive swelling, till at last the catheter could be easily introduced.

I have reported the case as one of general interest, and to call special attention to the importance of *position* when emptying the bladder with the aspirator.

A CASE OF PARASITIC GROWTH IN THE EXTERNAL AUDITORY CANAL.

By W. SHAW BOWEN, M.D.,

OPHTHALMIC AND AURAL SURGEON, TO THE HARTFORD HOSPITAL.

Mr. E., æt. 29, in delicate health. Has had a discharge from both ears for twenty years, the result of scarlatina; has been advised by physicians that "a discharge from the ears is healthy," and that "it is unsafe to tamper with it." First seen January 10th, 1874. Hearing distance, watch, A. D. $\frac{5}{8}$; A. S. $\frac{3}{8}$. Tuning-fork loudest in right ear. Slight tinnitus at times in both. Discharge subject to exacerbations. There have been no mastoid complications, and but little pain until within a few weeks. Has a bad catarrh of the pharynx and nasal passages of the proliferous type. Eustachian tubes pervious and somewhat relaxed. The left meatus and canal normal. Membrana tympani and ossicles gone; the former represented by a narrow thickened annular rim; the peristome of the tympanic cavity inflamed and bathed in pus; a small granular mass sprouting from the promontory. The right canal was narrowed so that only the smallest sized speculum of Gruber could be introduced. At the inner fourth the canal was blocked by a whitish mass, at first supposed to be a plug of cotton, the patient being in the habit of using such to control the discharges. As a thorough syringing failed to detach this, a fragment was removed with Wilder's forceps. A parasitic growth was suspected, and repeated efforts with the forceps finally dislodged the entire mass, leaving the characteristic red and glistening dermoid layer of the canal, exceedingly painful on contact with the blades of the forceps. The denuded surface was swabbed with a solution of calcaria hypochlorosa, gr. iij. ad f ʒj., as advised by Wreden, and the canals were syringed at frequent intervals for several days. There was no return of the growth. Its seat remained sensitive for several days, and at times was irritated by the saturated solution of nitrate of silver used to check this purulent discharge from the drum. The removed mass had the appearance of yellowish-white epidermic scales, of a cataceous consistence, and under the microscope was determined to be a specimen of *Aspergillus Flavescens*. The right membrana tympani and the ossicles were absent, and several fungoid granulations were attached to the posterior wall of the cavity. The discharge was checked in about ten days. Hearing distance the same as when first seen. There has been no return of the discharge, or of any inflammatory symptoms.

HARTFORD, CONN., 15th March, 1874.

INTERMITTING LAMENESS.—A very curious fact has been described by Dr. Sabourin, viz., that lameness may ensue from obliteration of arteries. Horse lameness is so obscure that any light on the subject is desirable. It is not, however, confined to the horse, but extends also to man. The cause observed by him is owing to obliteration of the aorta and iliac arteries. Commonly, after previous good health, the subject begins to limp in one or two limbs; to tremble, and finally to fall. Rest is commonly productive of relief. MM. Bouley and Goubaux long ago pointed out the nature of the affection in horses, while M. Charcot first called attention to its existence, comparatively rare, in man. Arteritis has been supposed to be the occasion of its existence in horses, owing to the violent efforts they have to make, and embolism in man.

Reports of Hospitals.

BROOKLYN CITY HOSPITAL.

Reports of Practice and Peculiarities in Treatment.

INHALATION OF CHLOROFORM IN A CASE OF STRYCHNINE POISONING.

PATIENT took five (5) grains of strychnine with suicidal intent.

Before admission to the hospital he was given twenty grains of sulphate of zinc with effect. He had had repeated convulsions, and, while being taken from the ambulance, was seized with one of tetanic form, which plainly showed strychnine poisoning. Every muscle was rigid, and tetanus complete. Opisthotonus, irregularity of pulse, varying from 120 to 140 in the minute, with all the accompanying symptoms, were noticeable.

He was immediately placed under the influence of chloroform. The convulsions ceased from the commencement of the anæsthesia, under which the patient was fully kept for three (3) hours. The chloroform was then removed, but the patient did not awake until six (6) hours afterwards—a case of recovery.

CHRONIC DIARRHŒA.

In those cases where the epithelium is stripped from the tongue, and the patient presents the cachexia of the disease, good results have been obtained by the administration of pulv. ipecac, in twelve-grain doses, three (3) times daily, given mid-time between meals to prevent emesis.

This is continued until the stools are of a perfectly serous nature, when the ipecac is discontinued, and

Zinci oxide.....gr. iv.

Ext. quassia.....gr. vj.
in capsule given three times daily.

Guarana in powder has been used in similar cases with apparently very good cures; but as it is impossible to keep trace of the patient, the permanency of the cure is not established.

PNEUMONIA.

The method of treatment is that generally employed, viz., quinine and stimulants; but as a marked feature in a fair proportion of the cases is the entire absence of expectoration, or, if present, the rusty color is not observable.

An interesting point in the history of a fatal case was the finding at post-mortem examination of innumerable hepatic abscesses and cicatrices of old ones. Prior to this attack of double pneumonia he could not account for a day's sickness.

PECULIAR INJURY OF FINGER.

A somewhat peculiar case was brought to our notice of a machinist, who, while at work, had the end of his index-finger caught in the machinery.

The ungual phalanx was torn off, and attached to it was thirteen inches of the flexor tendon, and muscular connection. No inflammation of arm ensued.

ERYSIPELAS.

As a local application in erysipelas, the following has proved as efficacious and cheaper than the lead and opium wash:—

Plumbi acetat.,
Magn. carb.,
Gum camphor..... āā ℥i.
Aque.....Oj.

NIGHT SWEATS.

For night sweats of phthisis the combination of extract of belladonnæ with oxide of zinc:—

Belladonnæ ext.....gr. $\frac{1}{4}$

Zinci oxide.....gr. iv.

is found acceptable.

EXCISION OF PORTION OF STERNUM.

This is a case where the greater portion of the manubrium was excised, by Dr. Spier, for necrosis.

The result of the operation was very satisfactory.

RUPTURE OF LUNG.

Patient, seventeen years of age, was suddenly caught, and crushed between two cars, resulting in fracture of neck of humerus, and death from emphysema.

Autopsy revealed rupture of left lung through apex, four and a half inches in depth. No fractured rib to cause it; but the lungs being filled, and in the sudden pressure the air was not able to escape by the natural passage, a rupture was the consequence.

COMPOUND DISLOCATION OF ANKLE-JOINT.

Injury was received by patient stepping from car—dislocation outwards.

There was considerable laceration of tissues, malleolus of tibia projecting.

Reduction was immediately performed, edges of wound brought together, and sealed with styptic cotton and collodion. A somewhat severe inflammation ensued, but patient is now progressing favorably.

BELLEVUE HOSPITAL.

A CURIOUS CASE OF HEMIPLEGIA.

THE chief feature of interest in a case of hemiplegia under observation related to the cause of the trouble. The history of the case was as follows:

Mrs. L—, at 50, domestic, was admitted to the Hospital, December 10, 1873. Being unable to speak, the history was obtained from her friends; she had been a healthy woman, and there was no previous history of rheumatism. During the forenoon of the day upon which she was admitted, she attended to her work, but about 12 o'clock it was thought, judging from her actions, that she was not feeling usually well. It was noticed that she had difficulty in grasping the bail of a kettle she wished to remove. She was advised to sit down and rest for a while, which she did. Half an hour afterwards she fell upon the floor speechless, and it was at once discovered that she was partially paralyzed. She was immediately conveyed to the hospital. Sensation and motion were partially paralyzed over the entire right side. Temperature of the right side of the body was somewhat lowered. Pupils equally dilated. Orbicularis muscles normal in the performance of their function. Angle of mouth dropped. She was unable to protrude the tongue to its full extent, and, when protruded, it turned to the right. At no time had there been loss of consciousness. Upon admission all the muscles of the body seemed rigid, but those of the paralyzed side soon became relaxed, and remained in that condition. Muscular contractility intact. Old cardiac murmur, aortic obstructive, present.

Dec. 12.—There was slight motion upon the affected side. Unable to articulate. Understands perfectly. Paralysis of motion slightly increased. Subsequent to admission, her pulse, respiration, and temperature were as follows: Dec. 10, P. 80. R. 18, T. 100 $\frac{1}{2}$ °; Dec. 12, P. 84, R. 21, T. 101 $\frac{1}{4}$ °; Dec. 13, P. 88, R. 20, T. 100 $\frac{3}{4}$ °;

Dec. 14, P. 78, R. 26, T. 99 -, evening, T. 98 +; Dec. 15, P. 80, R. 14, T. 99½; evening, T. 99½; Dec. 16, P. 68, T. 98½; evening, P. 61, T. 98½ +; Dec. 17, P. 76, T. 98; evening, T. 100½; Dec. 18, T. 99 +.

This completes the history of the case; the remaining organs were found to be in a healthy condition.

The question was, what was the cause of the hemiplegia in this case? In the first place, it was altogether probable that the morbid condition, which stood in the relation of cause for the paralysis, was within the cranial cavity. The previous good health of the patient, and the suddenness of the attack, reasonably permit narrowing the grounds of disputation down to three causes, namely, thrombosis, embolism, and cerebral hemorrhage. These three causes were carefully studied by both the house staff and the visiting physicians. The doctors disagreed.

In favor of thrombosis of an artery was the fact that there was certainly an interval of half an hour between the development of the first symptoms and the time when the patient fell upon the floor. The time, however, was regarded as being a little too short for the development of thrombosis.

In favor of embolism was the fact that the muscles were relaxed almost from the outset; that the lesion was upon the left side of the brain; that there was no loss of consciousness; and that there was cardiac disease. The extensive loss of power was against embolism. The slow development of the paralysis was not necessarily against embolism, for a small embolus may have been caught in the artery and coagulation occurred around it, which would require a little time for its formation; and one of the visiting physicians expressed the opinion that he believed that it would require more than half an hour to complete such a coagulation.

Progress of Medical Science.

AN OVERLOOKED SOURCE OF BLOOD-SUPPLY, FOR TRANSFUSION IN POST-PARTUM HEMORRHAGE.—Dr. William Highmore, writing to *The Lancet*, calls attention to the use, for purposes of transfusion, of the blood which has escaped from the open uterine vessels. By collecting and defibrinating this blood, and warming it to the requisite temperature, it may again be returned to the circulation of the patient, and enable the attendant to save a life in cases where an equally good source from which to obtain a supply of blood does not exist.

EXPERIMENTS UPON THE HUMAN BRAIN.—In *The American Journal of the Medical Sciences* for April Prof. Bartholow reports some "experimental observations of the functions of the human brain." The experiments were made upon a girl who had lost a portion of the cranium over a small space near the vertex, in consequence of an epithelioma of the scalp. For about two inches the dura mater was exposed and the pulsations of the brain visible. It was desired to ascertain the effect of irritation of the dura mater and cerebral substance through local faradization, galvanism, etc. Five needles, guarded to near their points, used as electrodes, were thrust into the dura mater and brain-substance of either hemisphere. When the needles were passed into the dura mater no evidence of sensibility appeared. Faradization of the dura mater of one side caused muscular contractions of the opposite side, especially of the extensors of the extremities. The faradic reactions of the posterior lobes

was tested by thrusting one needle into the brain while the other was placed in its vicinity in contact with the dura mater. A weak electric current caused painful tingling in the opposite extremities, dilatation of the pupils, and muscular contractions of the opposite side. The strength of the current being increased, convulsive action upon the opposite side ensued, followed by frothing at the mouth, stertorous breathing and coma. The attack lasted twenty minutes.

The galvanic reaction of the posterior lobes was to have been tested, but rapid extension of the disease to the left hemisphere, with grave cerebral symptoms, precluded continuance of the experiments. The case soon resulted fatally. At the *post-mortem* no especial injury to the brain matter appeared to have been directly due to the needle-punctures. Their course was marked by lines of diffident cerebral matter, but the surrounding tissue did not seem to have been affected by the lesion.

DR. LEVINS' CASE OF ANEURISM TREATED BY THE INTRODUCTION OF HORSE-HAIRS.—At a meeting of the Pathological Society of Philadelphia, Dr. Longstreth reported the results of the autopsic examination of the above case. The aneurism was of the right subclavian artery. Dr. Levis had operated by introducing horse-hairs through a fine canula into the aneurismal sac. Twenty-four feet and nine inches of hair were thus introduced without difficulty, and without causing any local irritation. The patient died with symptoms of engorgement and pressure on the upper lobe of the right lung. At the *post-mortem* examination the artery was found dilated both upwards and downwards. The upper dilatation was about one inch and a half in diameter, and was filled with a firm, white, fibrinous clot. The lower dilatation had an oval orifice of about one inch in its longest diameter, and was also partially filled with a fibrinous clot. The lung was found compressed inwards and forwards, consolidated above and collapsed below, and behind it was a large mass of dark clotted blood which extended beyond the line of the rib as far down as the sixth rib, and could be felt as a fluctuating mass underneath the pectoral muscles. The first two ribs had disappeared. From the third, fourth and fifth ribs, pleura and periosteum had been stripped, which latter, together with intercostal muscles, were crowded before the clotted blood into the axillary space. The intercostal arteries were lacerated. At the upper part of this soft thoracic clot a dense white clot was found attached around the lower aneurismal opening. In the outer portion of this clot the hair was found embedded. The walls of the artery could not be traced beyond an inch from the arterial orifice, the aneurismal wall in this situation having been alone supplied by the condensed lung tissue, together with the muscles at the apex of the thoracic cavity. It was therefore a diffuse aneurism. It was ascertained, however, that the soft clot in the thorax did not communicate with the aneurismal cavity above. It appeared that after the operation the position of the clots formed in the sac directed the full force of the blood-current upon the proximal portion of the lower dilatation, but its force being here opposed only by the yielding tissue of the lung and thoracic muscles, the walls of the cavity gradually receded, stripping the ribs and lacerating the intercostal arteries. To hemorrhage from these latter is ascribed the origin of the soft clot within the thorax.

Dr. L. is of the opinion that had the aneurismal sac been supported by the walls of the vessel, the formation of a firm laminated clot might have been expected, and consequent cure of the aneurism.—*Phila. Med. Times*, No. 126.

TREATMENT OF PARAPHIMOSIS.—M. Bardinot suggests the following simple mode of reducing a paraphimosis:—He passes between the prepuce and corona a blunt lever—the blunt end of an ordinary hair-pin answers well—one being placed in the upper, another at some nearly corresponding place beneath. The fingers are then used in drawing forward the prepuce by a sort of screwing movement, the hair-pins or other blunt instrument, such as the handle of an ordinary teaspoon, acting as a lever to slide the prepuce over.

PRESERVATION FROM HYDROPHOBIA.—At the meeting of the French Academy of Sciences on April 13th, M. Bouley laid before it a memoir by M. Bourrell, a veterinary surgeon of Paris, entitled "A Complete Treatise on Rabies in the Dog and Cat, with a Method of Preserving one's self against It." The means of preserving from rabies recommended by the author, consists in taking off the edge of the teeth of the animal with the aid of nippers or a file. (?) M. Bourrell had the daring to perform this operation of filing down the teeth of three dogs when they were in a condition of raging madness. Six dogs kept for experiment were then turned loose among the rabid animals, who attacked and bit them furiously, but without breaking the skin in any one of them. The dogs experimented on were watched during six months, and madness did not show itself in any one of the number. M. Bourrell, convinced that the blunted tooth of the dog could not penetrate through clothing, gave his hand, covered with a glove, to one of the mad dogs. "When," he says, "the dog released the glove was intact, and the bite had only produced a deep impression." The same experiment repeated on dogs which were not rabid proved that the blunted tooth, however violent the effort of the muscles of the jaw, would not penetrate the skin of animals, and affected the human epidermis in very exceptional cases only.

EXTERNAL TREATMENT OF VARICOSE VEINS.—Dr. Livier says, in the *Tribune Médicale*, that he has for years treated such cases with success by swathing the leg in a flannel compress wet with a solution of chloride of iron in water, forty-five grains to the ounce, and then applying a roller bandage of flannel over it firmly for twenty-four hours. This is to be repeated daily for a week or two weeks, when the patient is or ought to be well.—*Med. Press & Cir.*

A CAUSE OF DEATH IN WHOOPING-COUGH.—M. du Castel says that death often supervenes in this disease from spasm of the glottis. He refers to Jaccoud's *Traité de Pathologie Interne*, where are described spasmodic accidents of greater or less gravity in whooping-cough, as the result of excitation more or less severe of the laryngeal nerve. According to M. du Castel, there is found on autopsy a cerebral lesion as the result of the asphyxia.—*Ibid.*

LEMON-JUICE AS A LOCAL APPLICATION IN DIPHTHERIA.—In a clinical lecture by M. Bucquoy, delivered at the Hôpital Cochin, he expressed his preference for lemon-juice as a local application to diphtheria, to acids, chlorate of potash, nitrate of silver, perchloride of iron, alum, or lime-water. He uses it by dipping a little plug of cotton-wool, twisted around a wire in the juice, and pressing it against the diseased surface four or five times daily.—*Jour. de Médecine.*

THE STRUCTURAL CHANGES IN GONORRHOEAL EPIDIDYMITIS.—Schepelern has had an opportunity of studying two cases of this form of disease in the acute stage. The patients died suddenly of other diseases,

In one there had been an epididymitis of the left side, which had lasted eight days, and had followed urethritis. The urethra was found injected at its superior portion only. The left vas deferens was one-half thicker on the left side than on the right; its vessels were injected, in part dilated and tortuous; the lower extremity of the epididymis was swollen and infiltrated and fibrous, and in the anterior portion there was a collection of matter larger than a pea. The testicle itself was healthy. In the lower part of the tunica there was a small quantity of serous fluid, corresponding to the infiltrated inferior extremity of epididymis, and commencing adhesive inflammation with false membranes. Microscopical examination showed that there was catarrh of the vas deferens. In the second case the pathological changes were a collection of pus the size of a pea in the lower extremity of the epididymis and false membranes, and serous fluid in the cavity of the tunica. The purulent collections were regarded as abscesses of the connective tissue.—*Med. Chir. Rundschau*, April, 1874.

ALBUMINURIA A SYMPTOM OF AN EPILEPTIC ATTACK.—According to Huppert, albuminuria is a constant concomitant of epileptic seizures. The urine which is passed three to four hours afterwards always contains a little albumen. Simple epileptic giddiness passes off without any albuminuria that is recognizable, while mild forms have a moderate amount. When attacks succeed each other rapidly, or the nervous affection lasts a long time, the renal trouble is proportionately well marked. Casts are usually not found after a light attack, but in advanced cases they are numerous. Red blood-corpuscles are seldom found, but seminal elements are relatively frequent. In the epileptiform apoplexies of paralytics the urine is albuminous, and often contains red corpuscles. This latter symptom is regarded by the author as indicating an essential difference in the pathological processes.—*Virchow's Archiv*, LIX, 3 and 4.

THE DANGER OF MIXING CHROMIC ACID WITH GLYCERINE.—In preparing mixtures of this kind, which have been so highly recommended for diseases of the mouth and throat, care should be taken not to add these reagents together too quickly, for it is said that the fluid may take fire and explode. There is no danger if the glycerine be added drop by drop, for then a little warmth only will be generated.—*N. Racogol. Med., Memorabilien*, 2, 1874.

THE STATE MEDICAL SOCIETY OF NEW JERSEY held its 108th anniversary at the Mansion House, Long Branch, on Tuesday and Wednesday, May 26th and 27th. Dr. Thomason, of Monmouth, as President, delivered the opening address. His subject was Medical Truthfulness. He discussed the temptations to which the physician is subjected, either to play a part for impression on others or for concealment from the patient himself. Avarice, credulity, selfishness, vanity, and idleness often prompt to pretence. He claimed that it was due to science, to our profession, and to our patients to deal with them in integrity. The father of medicine in his aphorisms shows himself a teacher of morals not additionally but because he was a true physician, and the Hippocratic oath has in it the high tone which belongs to truthful science. The address was worthy of the occasion, and was listened to with much interest. Two sets of delegates appeared from the Hudson Co. Medical Society. The difficulty in that society, which has existed for three or four years, was, however, disposed of by a clear, full report from the Committee on Ethics, and the delegates from the Legal Society admitted. The session of Wednesday was chiefly occupied with the report of the Standing Committee. This consists of a résumé of the reports from each county society. Dr. Wickes, of Orange, the permanent chairman of the committee, collates and arranges so admirably, and by previous inquiries so well draws out facts, that this document is of very great value as presenting the prevalent experience of practice in the State. Three special inquiries were made the last year.

What is your experience in the use of chloral-hydrate?

What is your experience as to the value of hypodermic medication?

Have medical men by their habits of prescription aided and abetted the excessive use of alcohol?

Nearly all the county societies answer favorably as to the use of chloral, especially as a hypnotic, the dose generally being large. In the asylum it is greatly valued as a quietener. As a sedative to control inflammatory action it does not at all take the place of opiates.

Most of the counties reply in favor of the use of the hypodermic syringe, especially for morphia medication. No evil results are reported, while very many attest its value. We should like to have heard the question discussed as to whether it is to be preferred to stomaehic prescription in cases where the stomach retains well.

As to alcohol, it was strongly affirmed that the evils arising through medical prescriptions are greatly overstated, both because there is a convenient excuse for inebriates and a favorite assumption with intemperate zealots in reform.

Dr. Schenck, of Canada, read a paper on the forceps, and Dr. Kipp, of Newark, treated ably "The Diseases of the Eye arising from Variola."

The meeting was an exceedingly pleasant one socially, and profitable professionally. Dr. Newman ably represented New York, and Dr. O. Leary, Rhode Island. The New Jersey Society is quite a model in the precision with which it despatches business, and its meetings are always satisfactory.

It had a larger number of counties represented this year than ever before, and the district societies are mostly in good working order. This speaks well for the *esprit de corps* of the profession in the State.

CROWDED COLUMNS.—In consequence of the space occupied by the Reports of Sections, a number of items are crowded out of our present issue.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, July 1, 1874.

THE SECTIONS OF THE AMERICAN MEDICAL ASSOCIATION.

THE meetings of the Sections of the American Medical Association were very well attended, and, as will be seen by the reports in this number, the subjects presented were in the main of practical interest. The arrangements for the meetings of these bodies were as near perfection as a well-organized system could make them, and, judging from what we saw, we believe ourselves safe in saying that nearly every member attended some of those sessions. Those of Surgery and Practical Medicine were the best patronized, for the obvious reason that the subjects naturally discussed in such meetings were calculated to interest a larger number of general practitioners. No more important topic than that of fractures, for instance, could be brought up before the Section on Surgery. It is, in fact, a subject in which every general practitioner is forced to become interested; but especially those who practise in the rural districts, and who for the most part are compelled to rely on self-help, or individual brains and practical common sense. The discussion on the paper of Dr. Sayre showed how much attention has been given to the matter by the active practitioners all over the country, and how ready they were to dispute the views of the author on the one hand, and confirm them on the other. The very independence of opinion in these respects would prove even to the casual observer the capabilities and intelligence of that class of medical men whom metropolitans are apt to speak of only as country practitioners. The same may be said for those gentlemen who were attracted to the meetings of the Section on Practical Medicine, although, with one or two exceptions, the papers presented were not of a character to bring out much discussion.

The professed obstetricians and gynecologists very naturally looked to their particular section for edification, and we presume that they were not disappointed.

The papers brought forward were of such a nature that it required a specialist to discuss them. The sphere of general usefulness was narrowed down to the requirements of such as confined themselves to the practice of high art. Still, there were enough members present to give a great deal of interest to the meetings and maintain it until the end.

The Section on Hygiene did a great deal of work, thanks to its capable and energetic chairman. The papers were in abundance, and the subjects were of great practical interest. Those discussions on the benefits of drainage were particularly valuable and suggestive, and should teach every medical man the importance of the necessary reforms advocated. It is in the direction of systematizing some plan to secure effective drainage of low lands, swamps, and other unhealthy districts that the department of State medicine and hygiene must achieve its greatest triumphs and rest its most urgent claims for the aid of scientific medical men. There is not a practitioner anywhere to be found who cannot testify, from personal observation, that a great majority of the preventable diseases are due to a lack of attention to matters of drainage. Each should do his part by contributing his mite of observation to the common stock, that it may be utilized, and in this way form the foundation for intelligent legislation. The matter has been brought up before our County Society, also by the society of our State, and much good has already been accomplished in the required direction. Every County Society, and every State Society has something to say on this point, some suggestion to offer, and some good influence to exert. The work is a stupendous one, but is not beyond the possibility of a brilliant success.

If we educate the authorities to appreciate the direct bearings of effective drainage upon the health of communities, the requisite initiation for the systematic sewerage of villages, towns, and cities will soon become an accomplished fact. Nor only should a systematized plan be agreed upon to remedy existing defects, but every effort should be made to prevent such a necessity.

The recommendation for a National Sanitary Bureau was a good one, but is a little premature. The efforts should be directed in the first place towards the formation of Health Boards in the different States, similar to the Board already existing in Massachusetts. When this is accomplished the formation of a National Bureau will be an easy task.

The discussion upon the effects of liquor was well enough in its way, and was only excusable because nothing very radical was aimed at. Medical men, as a class, take the right view in regard to the action of alcoholic liquors; but these views have no particular bearing upon the so-called moral aspect of the question.

The community, on the other hand, are pretty well settled upon the strictly social bearing of the evil, and

no particular recommendations of a body of physicians can sensibly affect it one way or the other. In fact, the duty of setting ourselves right before the community is a merely fanciful one, and we only waste our time upon the discussion of a question upon which every conservative thinker can have but one opinion.

The reports of the sections were taken by special reporters provided by the Committee of Arrangements; but these official reports were not published during the session of the Association, as was expected. This could hardly have been done, as there was not time enough allowed to get lengthy reports ready. In the place of such reports, however, we had the account in the daily papers of Detroit—notably the *Free Press* and *Tribune*—and which were singularly accurate, and remarkably full. But after all, perhaps, this plan of enlisting an interest in the proceedings by the local press will be the only practical manner of solving the difficulty of having the proceedings for the prompt use of the members.

The press, not only in Detroit but everywhere else, as far as we are aware, have treated the Association well, but the best of all was, that there was no occasion for any disparaging remarks on behalf even of such as would strain a point to crack a joke at the expense of scientific medicine. We hope it may always be so with the Association.

Reports of Societies.

THE SECTIONS OF THE AMERICAN MEDICAL ASSOCIATION.

PRACTICE OF MEDICINE. MATERIA MEDICA AND PHYSIOLOGY.

DR. N. S. DAVIS, of Chicago, Chairman.

Tuesday, June 2.

This section met at the Detroit Theatre, at 2.30 p.m., June 2, 1874, and was called to order by the chairman, Dr. N. S. Davis, of Chicago.

ON ECZEMA.

DR. L. D. BULKLEY, of New York, first read a paper on "The Management of Eczema," in brief as follows:

Eczema, the most frequent of skin diseases, attacks all classes and conditions of persons, and must, therefore, demand a very varied treatment, different in each case, which to be successful must depend upon its pathology. It must be regarded as a dermatitis, but differing from all other inflammations of the skin in its catarrhal feature, which is more manifest in its acute states. In chronic eczema we have rather to do with the products of inflammation—the infiltrated cells which are found by the microscope in the rete mucosum, derma, and even between the fatty elements of the adipose tissue, and which are discovered clinically by the increased thickness of a fold of diseased skin. While this thickening remains the disease will return.

Every dermatitis is not an eczema. Simple dermatitis may be produced by irritants, chemical or traumatic, which will tend to recover spontaneously on the removal of the cause; while true eczema may result, in

some cases, where the special cause exists, in a dyscrasia, which although incapable of demonstration is as sure as that resulting in gout or rheumatism.

Although eczema has been divided into acute and chronic, there is no definite line to be drawn between the varieties, as they merge gradually into each other, and are often coexistent; hence the difficulty in managing the disease. The main indications are to soothe the irritable and stimulate in chronically inflamed eczema, and this Hebra had been one of the first to clearly define. Where there is much hyperæmia such applications as washes containing gently astringent powders are called for, as calamine, oxide of zinc, bismuth, etc.; but the first indication is always to remove irritants. Thus in scabies we destroy the itch mite, and the artificial dermatitis ceases, and in eczema of the head, caused by lice, we cure the eruption by destroying the cause. But it is very necessary to remember that air and water are very irritating to an eczematous skin, as also scratching in any way, and these elements must be removed, however difficult the task, and this is accomplished by powders, washes, ointments, and collodion. Powders in very acute states, composed of starch or lycopodium dust, with zinc or bismuth, and camphor or morphine to allay itching; these must all be very finely pulverized or they will surely irritate. Ointments are called for when exudation has more or less ceased, and these act quite as much mechanically as by virtue of any medicaments they contain. Cod-liver oil, or mutton suet, with hard, suffice very well.

It is very essential that all greasy applications be perfectly fresh, as the least rancidity acts most injuriously. Much harm is done by the crude and irritating preparations dispensed with culpable carelessness by druggists. Oxide of zinc ointment is widely known and very efficient; but others are likewise very serviceable, as white precipitate and red oxide of mercury well diluted, or tannin or bismuth. Hebra's diachylon ointment is valuable, but has not seemed to answer as well here as in Vienna. Flexible collodion may be painted over small patches of subacute eczema, with healing effect; but if the surface is at all raw, it is painful, and if there is any exudation it is quickly forced off.

Chronic eczema is quite a different affair in its local treatment, as here we have the products of disease to remove and the morbid cell action to overcome. Hebra stimulates violently with strong potash solutions or green soap; but American skins do not stand this harsh treatment well, and few will submit to it; and, finally, the same ends may be accomplished often by other means. The compound tincture of soap of Hebra, composed of equal parts of the green soap, oil of cade, or tar and alcohol, is valuable in many instances, but is unpleasant of application and removal, precipitates on dilution with water, and, moreover, the alcohol is not always well borne. For these reasons the "*Liquor picis alkalinus*" is brought to public notice, where the tar is made to combine with water, by means of caustic potash, after the formula:

R. Picis liquidæ.....	5 ij.
Potass. causticæ.....	5 i.
Aqua fontan.....	5 v.

M. ft. "*Liquor picis alkalinus*." Sig. used diluted.

This we presented to the profession at a meeting of the New York Dermatological Society, and published in the Archives of Scientific and Practical Medicine, in February, 1873, and have used daily since with increased confidence. This relieves itching greatly, and may be employed in various ways. Diluted 1 part to 12, 16, or more of water, in acute cases, followed

by an ointment, or 1 part in 5 to 10 for the more subacute form, and with equal parts of water or full strength in very chronic cases. It may also be advantageously employed in ointments, adding $\frac{3i}{j}$ to the ounce.

More severe measures are sometimes necessary, as cantharidal collodion, or acetum cantharides, or very strong solutions of caustic potash, or nitrate of silver, or the strong mercurial ointments.

Between these extremes of treatment many varieties and forms of eczema demand corresponding alterations and combinations, care being taken to soothe when required, and to restrain stimulating applications from doing harm.

Local measures have been described first—not because of greatest importance, but for the opposite reason—to impress the fact that their effects are but local and temporary, rendered necessary by each recurrent attack; whereas true eczema is a constitutional affair, demanding constitutional management; while a knowledge of topical means is necessary to insure present relief, to assist internal medication in breaking up a local dyscrasia, and to prevent patient and friends from applying what will be actually injurious. But arsenic is not the only remedy for eczema. Its constitutional management is embraced under three heads—1. Dietetic; 2. Hygienic; 3. Medicinal—all very important. Infantile eczema is often caused and kept up by some error in diet, a correction of which may cure the disease. The same is true of adults; a hearty meat diet increases an acute general eczema, and alcoholic stimulants but add fuel to the flame, while dyspepsia renders many cases incurable. 2. Hygienic measures are essential: fresh air, bathing, exercise, recreation, etc. 3. Medicines are called for, because true eczema cannot fix and maintain itself in a perfectly healthy organism; its presence is an evidence of debility.

Internal medication comes under many heads—cathartics, diuretics, alkalies, tonics, sedatives. *Cathartics* are serviceable on entering treatment, but their continuance and abuse increases cutaneous irritation. *Diuretics* are demanded in a goodly proportion of cases, as also *alkalies*, because imperfect oxidation and acidity lie at the bottom of much cutaneous pathology. The various ways of removing this acidity must be employed as required. Acetate, bitartrate, and citrate of potassa, sulphate and carbonate of magnesia, carbonate and solution of the acetate of ammonia, sweet spirits of nitre and liquor potassae, also soda with rhubarb, are precious remedies to those who have tried well their effects. The "*Liquor picis alkalinus*" may also be given in quarter to half teaspoonful doses, largely diluted, between meals, thus giving an alkali combined with tar internally, which latter has long been of some repute in eczema. *Tonics* are exceedingly valuable, and the list in daily use is not large. Quinine, strychnine, iron—of which the ammonia, citrate, sulphate, pyrophosphate, tincture of the chloride, syrup of the iodide, and sweet wine of iron, are the most common—arsenic, the mineral acids, vegetable bitters, as cinchona, gentian, columbo, and quassia, with colchicum for the gouty. Arsenic occupies but a single place here; its use has been greatly overrated in skin affections, although it is one of the purest nerve-tonics we possess. Cod-liver oil comes nearer to being a specific for eczema, and is of inestimable value, not only in strumous cases, but in many apparently in excellent health. *Sedatives* become necessary at times; they are opium and morphine, bromide of potassium, and ammonium and hydrate of chloral. This latter, chloral, gives quiet sleep, and may be used in the daytime, or half an hour before undressing.

All this constitutional management, one may say, is only that which might be called for were no eczema present; and that is exactly what is desired to be impressed by the paper, that attention to all these points is necessary to really cure the disease. Skin diseases, to be well treated, must be managed on sound pathological principles, diagnoses correctly made, and causes removed as far as possible. The local management presents some difficulty at times, as all must confess; but remembering the acutely irritable nature of most skins with eczematous inflammation, and the necessity of cooling derivative measures used conjointly, we will be less liable to do violence to nature, and to hinder the attempts she is making toward cure.

The subject is by no means exhausted, but what has been said may be embraced in the following propositions:—

1. True eczema is a catarrh of the skin, properly acute, but very commonly subacute and chronic, and is entirely analogous to catarrh of the mucous membranes, which are indeed but involution portions of the cutaneous envelope. The absence of moisture in many cases does not disprove this, for if these dry parts be kept covered with any impermeable dressing, we soon find that the material which forms scales is the same as in other cases, catarrhal, and stiffening linen.

2. This catarrh tends to run a certain course, accompanied by definite pathological changes; and the disease which we meet with more commonly is largely made up of the relics left in the skin—that is, thickening caused by a deposit of adventitious cells, mostly in the rete mucosum, but also capable of extending into the papillary layer, derma, or even deep into the adipose tissue.

3. Much that is called eczema is properly only a dermatitis, or ordinary inflammation of the skin, tending to spontaneous recovery when the cause is removed and irritating agents kept away.

4. Eczema, in its true sense, is not a local affair, but one intimately associated with blood changes, represented in the main by a sub-oxidation or hyper-acidity, as found in the stomach and kidney; and this state, moreover, is closely allied to gout, rheumatism, and serofula.

5. Debility, pure and simple, does not cause eczema, but may, by its existence, prevent either the recuperative action of nature or the beneficial effect of remedies.

6. Eczema being an acute disease, running a definite course, our treatment must consist principally in avoiding irritating elements, correcting systematic errors, debility, acidity, etc., favoring the action of the emunctories, and locally making such applications as soothe and restore tone to an irritated and inflamed integument.

7. The products of eczema, the thickening and consequent scaling and itching, are removed by stimulating applications, and such pure tonics as act directly on the nerves, causing absorption through the capillaries, as quinine, iron, arsenic, strychnine, and the like.

8. Arsenic and zinc ointment, while serviceable in many instances, are so far from being specifics for eczema, that their use is injurious in many cases, while almost always other remedies either will suffice alone or greatly assist their action.

This paper was referred to the Committee on Publication.

Some discussion followed, after which Dr. D. J. FARNSWORTH, of Iowa, read a paper on "The Therapeutics of Ammonia," which was referred back to the author, with a request to publish in some medical journal.

Wednesday, June 3.

WEST VIRGINIA HERBOLGY.

A paper was presented from Dr. E. A. Hildredth, of West Virginia, on the medical botany of that State, giving a catalogue of indigenous plants, with their therapeutic effects, etc. Without being read the paper was referred to the President, with authority to have the same published in the Proceedings if he deemed it suitable.

THE CINCHONA TREE.

The President presented the report on the cinchona tree in the United States, which was submitted to the general session on Tuesday, and by it referred to this section. The committee reported favorable progress, and asked to be continued. On motion, the section concurred in the recommendation, and the committee was continued.

CEPHALIC CIRCULATION.

An elaborate paper on "Mechanism of the Cephalic Circulation," prepared by Dr. R. A. Vance, of New York, was read by the Secretary. His conclusions as to the peculiarities of cerebral circulation are condensed as follows:

1. Atmospheric pressure operates in such manner as to keep the fluid contents of the skull at all times the same.
2. The heart can, under certain circumstances, exert a compressing influence upon the encephalic structure; and
3. The relative qualities of arterial and venous blood and extra-vascular serum vary with cardiac contractions, respiratory movements, sleep and wakefulness, and mental excitement and repose.

Some criticisms were ventured upon the paper, the chief of which were that there was nothing original in the views advanced; that they can be found in the modern standard works on physiology. One speaker took exception to the statement that atmospheric pressure has anything whatever to do with cephalic circulation. On motion, the paper was referred back to the author, with permission to publish the same in any medical journal at his own expense.

MISCELLANEOUS MATTERS.

On motion, the annual address of the chairman of the section, read in the open session in the morning, was made the special order of the section for Thursday, at 2.30 o'clock.

Dr. F. R. BURCHAM, of Flint, Mich., read a paper on "Uræmia." After a somewhat extended discussion the paper was referred to the Committee on Publication.

Thursday, June 4.

Dr. L. D. BULKLEY, of New York, read a paper presenting a "New Remedy for Pruritis."

DR. DAVIS' ADDRESS.

The address of Dr. Davis, president of the section, delivered before the Association and referred to this section, was taken up.

Dr. GRAY moved that it be referred to the Committee on Publication, with a request to publish.

Dr. McLAUGHLIN wanted a little light on points which were not clear to him in the address. If it condemned old-fashioned blood-letting, he had some remarks to make, and if it did not, there was room for remarks.

Dr. DAVIS said the paper made no assertion touching the doses. It did condemn the extremes run into in old times in the matter of bleeding and purgatives. The aim of the paper was to counsel against following fashions without investigation.

VENESECTION.

Dr. McLAUGHLIN rose to the defence of the old-fashioned blood-letting. Forty years ago he had bled freely, and believed he did right. He did bleed now, and thought he was right now as well as then. Men had changed, and were not sick now in the same way they used to be. He also believed that the same medicine would produce directly opposite effects, according to the dose.

Dr. QUIMBY liked the address because of the happy medium it struck, which was just the thing the profession needed. The tone of the paper on the use of alcohol suited him; it was the most abused of drugs, and the profession are largely responsible for intemperance.

Dr. CUTBROOK, of Elmira, N. Y., ROUSE, of Detroit, and BUCKHAM, of Flint, discussed the paper.

Dr. DAVIS said the point which he wished to have considered was the suggestion as to the practicability of instituting here lines of investigation. Golden opportunities for investigation were lost because men were not at their posts. Take up a subject and pursue it, even if they do not get enough in a year to make three printed lines. He suggested the appointment of a committee to take observations throughout the country, simultaneously, of the atmospheric conditions at different points, and thus catch any epidemic that is going. Then let the working practitioners trace the diseases to their incipient causes, and that these committees send their reports to the president before the meeting of the Association, and have all things brought together.

Dr. GOMER thought no physician should be allowed to collect a fee until he had spread a record of the symptoms on his register, showing a true case of disease.

Dr. BULKLEY moved an amendment to the motion, to the effect that the suggestions of the president for investigating committees be adopted; Dr. Davis to be chairman of the Committee on Disease, and Dr. Toner, of the Meteorological Committee, with power to appoint the members of their respective committees. The amendment was agreed to, and the motion as amended passed.

HYDROPHOBIA.

Dr. GARRISH, of New York, read a paper on hydrophobia. Referred to some medical journal.

Dr. E. W. GRAY, of Bloomington, Ill., presented a very interesting paper on "Physiology and its Relation to the Practice of Medicine." Dr. Edgar Weeks moved that it be referred to the Committee on Publication, as, if not highly original, it was a paper highly suggestive. It was so referred.

Dr. SEGUN gave an exhibition of the workings of his system of "Mathematical Thermometry." The thanks of the Association were tendered to the doctor, and an outline of his system was ordered to be incorporated in the minutes.

A paper on "Electricity as a Restorative Agent in Narcosis and Asphyxia," sent to the Association by Dr. J. J. Caldwell, of Baltimore, was referred to a committee, consisting of Drs. Bulkley, Edgar, and Frothingham, for such action as they may deem proper. The section then adjourned.

SURGERY AND ANATOMY.

Dr. S. D. GROSS, of Philadelphia, Chairman.

Tuesday, June 2.

TUMOR OF STERNUM.

Dr. DUNLAP, of Springfield, Ohio, addressed the meeting, and read a paper relative to an operation performed by him in removing a very large tumor from near the sternum. The patient was H. S., of Greenville, Ohio, and the doctor was first consulted on the case in September, 1870. He advised that nothing be done then, there being a probability that it might subside. It continued to grow, however, and in April last Dr. Dunlap, assisted by several physicians, undertook the operation of removing the tumor, which was successfully performed. The patient survived the operation some six weeks. The tumor removed was a very large one, weighing three pounds, and another weighing five pounds was removed after death. The paper was referred to the Committee on Publication, to be published.

EPIPHYSEAL FRACTURE OF HEAD OF HUMERUS.

Dr. E. M. MOORE, of Rochester, read a paper on epiphyseal fracture of the superior extremity of the humerus, of which the following is an abstract:

Professor R. W. Smith has stated that separation of the humerus at the line of junction of upper epiphysis and shaft to be not uncommon in early life. The head of the bone can be distinctly felt in the glenoid cavity; a slight depression is felt beneath it, the head remaining motionless when the shaft is rotated. A striking and abrupt projection is observed beneath the coracoid process, caused by the upper extremity of the shaft being drawn inward by muscular action. The shaft seldom clears the head, and hence the small amount of shortening. This projection is smooth and slightly convex, in contrast to the irregular margin of ordinary fracture. The elbow projects but little from the side, and can be readily brought in contact with it. Pressing the upper end outward, while holding the elbow to the side, and making extension and counter-extension, the deformity disappears, to recur as soon as left to unopposed muscular action.

Diagnostic points are, first, the projection beneath the coracoid; and second, the immediate recurrence of the deformity when the means for reduction cease retaining the shaft in place, there being no fracture of superior end of the humerus in which retention is so difficult. In general, the true nature of the injury is unrecognized, although the symptoms have been clearly stated by Sir A. Cooper and Professors R. W. Smith and Frank H. Hamilton. This arises from no accurate conception of the change of position having been put forth, and no method securing precise retention having been proposed, in so far as he (Dr. Moore) was aware.

The symptoms of this fracture are striking and uniform. The shaft of the humerus is so inclined as to carry the elbow a little backward and outward, while the superior end of the shaft is brought forward so as to make a prominence less rounded than the head, and lower down. It is usually found an inch and a half (at the age of twelve or fourteen) below the acromion and near the coracoid process. The curved line from the acromion down to the projection has a long sweep, instead of the small sphere of the natural head. This appearance is pathognomonic, and may be safely trusted in diagnosis without insisting upon crepitus. As in other epiphyseal fractures this is not clear and sharp, as when the fracture is of bone, but is muffled. When

the arm is moved gently, and without grasping the head, the peculiar lock of the surface is sufficient to cause the head to rotate, and thus the timid practitioner fails in getting his pathognomonic sign; but if the head be firmly grasped it cannot only be felt in the glenoid cavity, but held sufficiently firm to get this muffled crepitus by rotating the humerus or by carrying the elbow inward, and thus rubbing the two surfaces on each other. In addition to these striking symptoms we may add a shortening of half an inch or a little more. When the two shoulders are inspected from behind, the impression given is that of luxation, for there is a slight flattening of the shoulder produced by drawing the fibres of the deltoid a little forward. The breadth of the shoulder is also increased when seen in profile. The motions of the arm are somewhat circumscribed, the ability to carry it upward and forward, as well as upward and outward, is impossible much beyond a right angle with the body, but affects the rolling of the scapula so that the hand can be placed on the head.

Reduction is effected by carrying the arm forward and upward to the perpendicular line. Retention is effected by moderate extension while bringing the arm down by the side, maintaining this slight extension until dressings for the purpose of continuing it are applied. Swinburne's method fulfils the indications easily and perfectly.

Even if not restored the arm soon becomes useful, and nature gradually rounds off the prominence of the diaphysis and elongates the capsule at the lower border, allowing the motion upward to improve.

Dr. HUGHES, of Pennsylvania, said the danger is likely to be that a fracture of the anatomical or surgical neck of the humerus will be mistaken for the fracture which Prof. Moore speaks of, and that his method of treatment for one would be injurious to the other.

Dr. KELLER stated that the cases to which Prof. Moore referred occurred only in childhood or adolescence, before ossification of the epiphysis takes place. He had never known of a case occurring in a person over fifteen years of age, and Prof. Moore gives a case in which the oldest was nineteen years. This was the oldest person in which a case of this kind occurs.

Several other gentlemen spoke on this subject, all agreeing to the practicability of Dr. Moore's method, and he himself explaining some minor details relative thereto.

Dr. GROSS, the chairman, was called upon by one of the members, and was asked his opinion on the matter presented by Prof. Moore. He stated that he concurred entirely with the views of Prof. Moore, and had no doubt that the method of reducing this fracture, which has been found so difficult, was a correct one.

THE TREATMENT OF FRACTURES.

Dr. SAYRE, of New York, stated that he had a long paper prepared, but did not propose to read a word of it. He would only explain some of the points. Within the past few weeks there had come to his knowledge three cases of compound fracture treated in the almost obsolete rule of waiting for nine days for the swelling to subside. He held that a fracture should be reduced as soon as it occurs, or as soon as it is practicable, and that the bone should be perfectly adjusted at once. He thought it was wrong to wait until the swelling subsided before any effort is made to reduce the fracture. If a fracture is perfectly adjusted, as it can be in every case by proper care, there will be no shortening of the limb or bone. Of the several ways of treating a compound fracture, he preferred the use of plaster-of-

Paris, by which means he has secured the best results. The patient should be allowed to get around and use his limb as soon as practicable. Of 115 cases treated in Bellevue Hospital last year 111 showed that there was less shortening of the limb than any like number of cases on record. Dr. Sayre explained his points by a mechanical appliance, showing the action of the muscles when a fracture of the bone occurs, and explaining the means of adjusting the fracture.

Dr. GREGORY, of St. Louis, Mo., was astonished that a gentleman of the medical profession from New York should come here and state that a compound fracture could occur and be reduced without a shortening of the limb. He had never seen a case of this except in young people. The inflammatory process necessary to the adhering of the fractured bones, rendered it necessary that it should be shorter. He claimed that it was a practicable impossibility for a fracture to be adjusted without any shortening of the bone. He uses plaster-of-Paris in the reduction of fractured bones, but he did not think it was superior to the extension and, coextension method used by other physicians of his place.

Wednesday, June 3.

This section resumed the discussion of the paper read by Dr. Sayre, on the previous day, upon the management of fractures.

Dr. PIERCE, of Illinois, suggested that the discrepancy of opinion, in regard to shortening, might be due to the fact that deductions were drawn from the result of measurements which had been made in different cases at different stages of the reparative process; that contraction of the cicatricial tissue binding together the broken fragments might and would go on increasing for several months, and then the surgeon who in a given case might dismiss his patient with little or no appreciable shortening, would find on subsequent measurement undoubted shortening.

Prof. SAYRE said that in the cases which he cited the measurements were made by Prof. Frank Hamilton as well as himself, and that, too, with a preconceived prejudice and expectation of finding more or less shortening, but that no shortening was appreciable, and he therefore knows that shortening is not necessary, and at his request Dr. King, who was present, presented himself as an example where fracture of the femur had united without any appreciable shortening. The success in this, as in other cases, was attributed to the very close watching and adaptation of the broken fragments by extension, increased or diminished as appeared necessary, even several times a day.

Dr. Sayre said he was afraid that his statements, in regard to the treatment, were not correctly understood. The direction which he intended was to make extension and counter-extension until the broken fragments are in coaptation, and then simply retention. The muscles and soft parts are in their normal position, and shortening is not natural if properly treated. There is no need of keeping up extension after it is in its proper position; simply retention is required.

The many patent appliances for dressing fractures the practical man will not rely upon, but will improvise whatever is needed for the occasion. Do not wait two or three weeks, as is frequently done, but dress the fracture at once, and keep the parts in apposition if you expect a good result.

After some further discussion respecting the best appliances and methods of dressing fractures, Dr. King moved that Dr. Sayre's paper be referred to the Committee on Publication, with the recommendation that it

be published. The motion was carried, after which the section adjourned.

Thursday, June 4.

Dr. W. T. BRIGGS, of Nashville, was called to preside.

Dr. BEARD, of New York, delivered an address on the uses of electricity. He first spoke of a case of goitre, the patient measuring sixteen inches around the neck, which he treated with electricity with great success, the cure being almost complete. The last quarter was more difficult to reduce, and required more time than the first three-quarters. Benign tumors, he said, can be treated successfully by electricity. If a tumor is not a malignant one, it can be cured by this means, but malignant tumors cannot thus be treated. In operating on tumors he plants the needle beneath it, and works up the base by electrolysis. He has also been treating by electricity diseases of the skin and nervous diseases. He spoke of a case of eczema in the limbs, which he treated successfully by galvanism. He applied electricity through the nerve-centre at the brain, and the diseased part was not touched with electricity. The patient was quite cured in a few weeks. This looked as though the nervous system had much to do with this disease of the skin, and that it can be treated through the nerve-centre. He hoped that others would try this method. What electricity did, it did by improving nutrition. He thought that eczema and prurigo could be treated successfully by electricity. His conclusions are as follow:

First. That certain benign tumors, as goitres, enlarged glands, and cystic, can be made to diminish or disappear under electrolysis.

Second. That fatty tumors and enlarged lymphatic glands are usually very difficult to diminish by electrolysis, and sometimes they will not diminish at all.

Third. That malignant tumors will not usually diminish, and rarely, if ever, entirely disappear under the electrolysis; but the pains connected with them can be treated most successfully by electrolysis.

Fourth. That malignant tumors, when sufficiently accessible and not too far advanced, may be treated by electrolyzing the bases, or "working up the base," as he terms it, and this method promises more permanent results than have been obtained by the usual treatment.

Fifth. That certain diseases of the skin—herpes, eczema, and prurigo—may be treated by different methods of using electricity, with the highest success.

Sixth. That diseases of the skin may be treated by local and central methods of using electricity, but some of the most brilliant results in the treatment of chronic eczema have been obtained by galvanizing the nerve-centres, in the method of central galvanization, without making any application to the diseased parts. The results of this method of treatment seem to show pretty conclusively that chronic eczema is, to a considerable extent, dependent on the central nervous system.

FRACTURES AGAIN.

Dr. HUGHES, in view of the discussion and action taken on Wednesday, on treatment of fractures, offered the following:

Whereas, The members of the surgical section of the American Medical Association have listened with interest to the report of Prof. Sayre, of New York, on the subject of fractures; and

Whereas, Statistics accompanying said report evince

in the institution represented (Bellevue Hospital) unusual results: therefore,

Resolved. That this section, after free discussion of the report, and its reference to the Publishing Committee, would express their opinion, based upon experience, that the results in relation to shortening following fractures is better than can be looked for in general practice.

The resolution was adopted.

DR. PIERCE, of Illinois, offered a resolution that Dr. Sayre be requested to make a second examination, as far as possible, of all the cases reported by him, one year after they have been discharged from the hospital as cured of fractures, and report the result to this Association next year.

DR. KELLER, of Louisville, Ky., moved to lay the resolution on the table. Lost, and the resolution was adopted.

The section then took up the paper read by Dr. Gross in the meeting of the general Association on Wednesday, on syphilis, and it was discussed by Dr. Sayre, of New York; Dr. Gunn, of Chicago; Dr. Keller, of Louisville; and Dr. E. M. Moore, of Rochester, and was ordered printed.

DR. KELLER moved that in furtherance of the views expressed in the valuable address on syphilis, delivered by Dr. Gross, a committee of three be appointed to report the most feasible plan of State legislation to interrupt and control the rapid spread of syphilis.

The resolution was laid on the table.

DR. SAYRE said he wanted to present a case of a boy who had his leg broken, an oblique fracture, and it was treated by Dr. Farrand, of this city, and so successfully has it been treated that he wanted those who did not believe that a fracture could be reduced without shortening to tell from an examination which leg was broken. The boy was taken into the jury room and there examined by a number of physicians, who subsequently made reports on the matter, some of them finding no shortening, others reporting about one-sixteenth of an inch, and one physician not being able to say which leg was broken.

Dr. Sayre exhibited an apparatus which he had made for disease of the hip-joint, and explained its method of operation. He had applied it to a child eleven years old, who had broken her hip-joint when twenty-three months old, had suffered great torture for nine years, and one of whose limbs was four inches shorter than the other, and was obliged to go on crutches. He applied the apparatus, and extended the limb, and in six months the child was able to run about very well.

The section then adjourned *sine die*.

OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.

DR. T. PARVIN, of Indiana, Chairman.

Tuesday, June 2.

THE THEORY OF GENERATION.

DR. JOSEPH R. PECK, of Fort Wayne, Ind., read a paper on the "Theory of Generation," founded upon observations made on a case of prolapsed uteri. The patient was a blonde, aged 32, of amorous disposition, and was suffering from a prolapse of the uterus in the second stage (the os uteri being just inside the vulva). In the course of the manipulation to replace the organ, the patient had an orgasm, which revealed to the observer what he believes to be the function of the uterus during coitus. The os externum opens by successive gasps, and when the crisis arrives it is drawn powerfully into the cervix, thus giving the cervix a sucking motion for the semen.

The paper was discussed by Drs. Sims, of N. Y.; White, of Buffalo; Pallen, of St. Louis, and others; the prevailing sentiment being that the case was not a fair one for illustration, as the nervous irritability of the female would of itself induce abnormal nervous phenomena, and that it was quite likely that this peculiar action of the os uteri came under such a category.

Wednesday, June 3.

INVERSION OF THE UTERUS.

DR. BONTÉCEU, of Troy, N. Y., read a paper on the "Inverted Uterus," in which he detailed a modification of Dr. White's repositior.

The paper was discussed by Prof. Sims, of New York, and Prof. Byford, of Chicago, after which it was referred to the Committee on Publication.

DR. LUCAS presented, on behalf of Dr. Scott, of Woodstock, Canada, a new species of the pessary, and Dr. Scott explained somewhat minutely the method of using it. Its merits were discussed by Drs. L. F. Warner, of Boston; Julius Miner, of Buffalo; M. A. Pallen, of St. Louis; Prof. White, of Buffalo; Prof. Byford, of Chicago; Dr. Ditherby, of Syracuse; Dr. Stockwell, of Port Huron, and Dr. John Morris, of Baltimore.

A vote of thanks of the section was tendered to Dr. Scott for presenting the instrument.

Thursday, June 4.

The meeting was devoted to the general discussion of "Transfusion in Ovariectomy."

DR. PARVIN presented for the inspection of the Society some instruments used in transfusion, whose merits were discussed by Drs. White, of Buffalo, Forbes, of Ohio, and Bussey, of Washington.

The treatment of the pedicle in ovariectomy was discussed by Drs. Sims, of New York, and Dunlap, of Springfield, Ohio.

SECTION ON PUBLIC HEALTH AND HYGIENE.

DR. A. N. BELL, of Brooklyn, President.

Tuesday, June 2.

A NATIONAL SANITARY BUREAU.

The report of DR. BOWDITCH, of Massachusetts, was read. It recommended the establishment of State Boards of Health, and gave a history of the establishment of the Massachusetts Board, which was organized on June 21st, 1869, though the idea was suggested twenty years before. It consisted of seven members, with seven years' term of office, one retiring each year, appointed by the governor and council. Its members were three of them physicians, and four laymen. The same proportion has since been maintained. The writer thought the admission of the laity was wise, and worked admirably. The board has power to close up any manufactory or branch of trade obnoxious to health, and have frequently been called on to do so. The courts have sustained them, and granted injunctions at their request. One of the greatest triumphs of the board was the erection of the Brighton *abattoir*, in place of the many stinking slaughter-houses, which is kept clean by the rules of the board. Dr. Bowditch was not in favor of the establishment of a National Sanitary Bureau at present, but recommended members to urge the organization of State and local boards of health.

The resolutions referred to the section for consideration and action this year were read. They (first) de-

clare in favor of the establishment of a National Sanitary Bureau, similar to those of agriculture and education; and (second) request the United States Educational Bureau to extend its scope of inquiry so as to include vital disease and mortality statistics in relation to local and other influences, and to disseminate the information thus obtained.

Dr. R. C. KEDZIE favored the first and opposed the second resolution.

Portions of a paper by the secretary of the section, Dr. A. B. STUART, were read, favoring a National Sanitary Bureau in the future, but recommending that for the present the Surgeon-General's office be the repository for vital statistics.

Dr. BELL read a portion of his report on the subject, holding that at present the establishment of a national bureau is not advisable, and urging that work be now directed to the organization of State boards of health. There are now only six States which have established boards of health, Maryland being the last State to organize such a board.

Dr. BROWN, of Waco, Texas, said that a State medical board had been organized by the State Association of Texas, and progress was being made toward the establishment of a State board of health. He also suggested the establishment of State medical journals.

Dr. COCHRANE, of Mobile, Ala., spoke at some length. He opposed the present establishment of a national board of health, criticised the details of the organization of the Massachusetts Board of Health, and spoke of the history of sanitary legislation in Alabama.

Dr. KEDZIE moved the following resolution:

Resolved, That it is expedient at this time to petition Congress for the establishment of a National Sanitary Bureau.

The resolution was discussed at length, Drs. Kedzie, of Michigan, Brown, of Texas, Westmoreland, of Georgia, Pratt, of Michigan, Johnson, of Illinois, Cochrane, of Alabama, Van Dusen, of Tennessee, Waterhouse, of Wisconsin, Jones, of Ohio, Baker, of Michigan, and Hitchcock, of Kalamazoo, Michigan, favoring it, and Drs. Thoms, of New York, Howard, of Maryland, Graham, of Illinois, and the president, Dr. Bell, of New York, opposing it, on the ground that it might interfere with the work of establishing State boards of health. It was finally adopted.

After some further discussion and suggestions, the following resolution was adopted, to be reported in connection with the one above:

That, with a view to the establishment of a national sanitary bureau, it is expedient, at the present time, to press, through State societies and physicians, in all the States, upon the Legislatures of our several States, the importance of establishing State boards of health.

The section then adjourned.

Wednesday, June 4.

PUBLIC DRAINAGE.

Dr. R. C. KEDZIE, of the Agricultural College of Michigan, read his paper on "The Influence of Drainage on the Public Health."

After referring to the topographical features of Michigan, and the influence of drainage upon the health of the State, he stated that he had prepared a circular letter, which he mailed to physicians all over the State, requesting categorical answers to the following questions:

1. Does the field of your medical practice embrace any considerable amount of swampy or wet lands with imperfect natural drainage?

2. Has any considerable amount of such lands been drained by ditches within ten years past?

3. Has drainage of such swamps removed, diminished, or modified malarial diseases in their neighborhood?

4. How large a percentage of diseases in your practice is of malarial origin?

5. Does the drainage of swamps have an *immediate* influence of any kind on the classes or the type of disease?

6. Has the type of diseases, as a whole, changed in your field of practice within ten years past? If so, what are the changes?

7. Please state any views you may have of the influence of drainage on public health, as witnessed in your practice or coming under your observation?

He had received numerous replies to these questions, which he embodied in his paper, and which proved in quite a satisfactory manner the good effects of drainage.

The paper concluded as follows:

The fall of 1856 was very dry in this State; the marshes became so thoroughly dried out that autumnal fires, which often prevail here, spread to the marshes, and hundreds of thousands of acres of peaty matter were burned up. The air became filled with a white smoke, having the same appearance and creosotic smell as the smoke from a charcoal pit. So dense was this smoke in the central parts of the State, that for a week business was almost suspended. Farmers were lost in their own fields, and in travelling on the roads it was almost as difficult to avoid collisions as on a dark night. Many persons were killed by the stifling smoke, and great numbers of cattle were destroyed by inflammation of the lungs caused by the smoke. The fish were killed in most of the streams, and it was feared that a pestilence would be caused by their putrefaction.

The trees in these marshes were burned out by the roots, but without consuming their trunks or branches. The marshes thus became filled with a vast amount of fallen timber.

The years 1857-8 were characterized by a large amount of rain-fall, so that the marshes, filled with fallen trees, again became filled with water. The decomposition of this amount of vegetable matter caused an amount of malarial fevers in 1859-60 such as had never been known in this region. The effluvia which arose from these marshes was horrible.

It might seem that the large destruction of slowly decomposing vegetable matter by the fires of 1856 would diminish the amount of malaria; and such would very possibly have been the result if a large amount of vegetable matter had not been added in the bark and branches of the fallen timber, which, undergoing much more rapid decomposition, gave rise to a vast increase of malaria.

DRAINAGE IN VIRGINIA.

The Chairman announced that, without any conference between the gentlemen, Dr. J. L. Cabell, of the University of Virginia, had prepared a report on the effects of drainage on the public health of Virginia, and had taken precisely the same method as Dr. Kedzie, *i.e.*, inviting replies from physicians. A number of extracts were read from Dr. Cabell's report, the conclusions reached being that one-half of all the mortality, and sometimes three-fourths, was caused by defective drainage.

Limited time prevented the reading of the entire report of Prof. Cabell, which Dr. Bell characterized as being in all respects a most valuable one.

DEFECTIVE DRAINAGE IN NEW YORK.

DR. BELL, as representing New York in the section, read a paper on defective drainage as a cause of disease in the State of New York. His paper began with a review of the topographical and hydrographical survey of the State, which was begun in 1830 by the Medical Society of the State of New York. With regard to the city of New York—after enlarging upon the beauty and glory of the city, its general salubrity and commercial importance as the metropolis of America—Dr. Bell showed that the sewerage of the city was inefficient to carry off all the water, and conforming as it did to the rectangular plan of the city, the sewerage was incompatible with the thorough drainage, and a cause of epidemics. Within the last two years, however, a law had been enacted and measures taken to secure deep drainage in that city.

The report of Dr. Bell was not read entire, but will be published in the Transactions of the Association.

The Chairman then read the report of Dr. Robert D. Murray, Surgeon U.S.M.H. service, on climatic influences of Key West.

DR. BELL, of Brooklyn, gave his views on the malarial influences arising from the non-absorption of surface-water in heavy clay soils, after which

DR. KEDZIE, of Lansing, explained the peculiarities of the clay soils of Michigan and their modes of drainage, either natural or artificial.

DR. FOSTER PRATT, of Kalamazoo, gave facts regarding under-drainage, as discovered by the digging of wells in and about his locality. From such observations the deduction was made that a considerable percentage of disease was due to the percolation into the wells of surface-water, and the natural accumulations of a large town.

DR. E. W. GRAY, of Bloomington, Illinois, inquired of Dr. Pratt the prevailing types of diseases in Kalamazoo.

DR. PRATT answered that fifty per cent. of them were malarial or typhoid.

DRAINAGE IN CHICAGO.

DR. H. A. JOHNSON, of Chicago, recited the physical and topographical features of that city, which rested, he said, upon a bed of alluvial clay descending toward the lake, and covered with sand of gradually diminishing depths from the shores of the lake westward. When he first went there the diseases were of the distinctive malarial type, which the Doctor remembered in his boyhood days as being common about Lapeer and Macomb Counties in Michigan. Something like twenty-five years ago all the surroundings of Chicago were regarded as swampy, and the watershed was so low that boatmen passed from the head of the Chicago River to the head of the Desplaines with a portage of but twenty-five miles. Since that time a good system of sewers had been inaugurated, and with such remarkable hygienic effects that a case of fever and ague was now very rare.

There was probably no city in the world of a like population which covered so large a territory as Chicago, and as refreshing breezes were constantly blowing either from the lake or the prairies, and an abundance of excellent fresh water obtained by a tunnel into the lake; the health of the place had greatly improved, and some of the more distinctively malarial diseases had disappeared entirely, a fact greatly due to the drainage of the surrounding country. Cerebro-spinal meningitis and congestive chills were rare and exceptional diseases. The conclusions reached were that not one-tenth of the cases now were of the malarial

type common twenty-four years ago. Deaths by consumption were about in the same proportion to the whole number of deaths, and there had been an increase in zymotic and typhoidal diseases.

At the request of Dr. Pratt, Dr. Johnson detailed the mode of sewerage in Chicago.

After the discussion of business of minor importance the section meeting adjourned.

Thursday, June 4.

VENTILATION OF PUBLIC BUILDINGS.

DR. R. C. KEDZIE, of the Michigan Agricultural College, moved the appointment by the chair of a committee of three who should consider the subject of the ventilation of dwelling, school houses, and other public buildings, and report to the section at the next annual meeting of the Association. The motion was agreed to, and the following gentlemen appointed as the committee: Drs. R. C. Kedzie, Michigan; A. B. Stuart, Minnesota; R. J. O'Sullivan, New York.

A NATIONAL COUNCIL.

DR. H. B. BAKER, of Lansing, Michigan, offered a resolution, the purport of which was that the chairman of the section should appoint a committee of three to prepare a bill for the establishment of a National Council of Health at Washington, and to otherwise forward that proposed measure, and report at the next session of the American Medical Association.

The resolution was adopted, and the following gentlemen appointed, viz.: Dr. H. B. Baker, Lansing, Michigan; H. A. Johnson, Chicago, Illinois; and J. M. Toner, Washington, D. C.

LEGISLATIVE RESTRICTION.

DR. FOSTER PRATT, of Kalamazoo, Michigan, offered a resolution to the effect that the chairman of the section appoint a committee of three to report at the next meeting of the Association, who should inquire what, if any, legislative action can be taken to secure the appointment of State Boards with authority to examine and license all who propose to enter upon the practice of medicine.

After some discussion the resolution was adopted.

The Chairman appointed as the committee called for, Drs. Foster Pratt, of Michigan; S. G. Armour, of New York; and D. W. Yandell, of Kentucky.

THE PROFESSION AND ALCOHOL.

The Chairman then read the resolutions of Dr. Frederick Horner, of Virginia, offered two years ago, and referred to this section at the last annual meeting of the American Medical Association. The resolutions are as follow, viz.:

Resolved, That in view of the alarming prevalence and ill-effects of intemperance, with which none are so familiar as members of the medical profession, and which have called forth from eminent English physicians the voice of warning to the people of Great Britain concerning the use of alcoholic beverages, we, as members of the medical profession of the United States, unite in the declaration that we believe that alcohol should be classed with other powerful drugs; that when prescribed medicinally it should be done with conscientious caution and a sense of great responsibility.

Resolved, That we are of the opinion that the use of alcoholic liquors as a beverage is productive of a large amount of physical and mental disease; that it entails diseased appetites and enfeebled constitutions upon offspring, and that it is the cause of a large percentage

of the crime and pauperism of our large cities and country.

Resolved, That we would welcome any change in public sentiment that would confine the use of intoxicating liquors to the uses of science, art, and medicine.

Dr. BELL called upon Dr. Homer O. Hitchcock to open the topic, which he did by expressing his conviction that the resolutions were expressive of what should be the action of the medical faculty of America, and concluded by asking Dr. Kedzie to read portions of his pamphlet on the entailments of alcohol, recently published and circulated by the Michigan State Board of Health.

Dr. KEDZIE accordingly did so, selecting the more important passages.

Dr. JOHN MORRIS, of Baltimore, Maryland, thought there was no necessity for this section to decide this matter. It was a most important subject, and when the medical profession of America spoke upon it, their voice should not give forth an uncertain sound. There were but few in attendance, and necessarily any action had upon the resolutions must represent mere individual opinions and not the calm judgment of the great body of the profession. For himself he was the director of an inebriate hospital, and had published a pamphlet taking a view somewhat similar to that of Dr. Hitchcock, although he had treated of the physical only, not the moral degeneration arising from the unlimited use of liquor.

He was satisfied that its use as a dietetic was beneficial if not desirable, and that the consumption by an adult daily of a pint and a half of ale containing five per cent. of alcohol, or a pint of claret containing ten per cent. of alcohol, was strengthening to the system, conserving and building it up. Every drop beyond this was destructive of the life forces, and if taken in excess continuously it would most certainly lead to degradation and to death.

Dr. Morris urged with much force that it was not necessary, or desirable even, for the medical profession to ally itself upon the subject with any set of men in religion or in politics. It would only tend to lessen their professional influence.

Theories written and spoken were well enough in their way, but facts and practice are better. You can't make teetotallers of men at once; the most you can do is to make them temperate. About all that can be expected of the medical profession is to tell men how much they may take with benefit to themselves, and to warn them that, if they go beyond that, ruin, inevitable ruin, must ensue.

In conclusion, Dr. Morris again urged deliberation. The matter should be decided by well-ascertained facts in regard to the medical and physical uses of alcohol, and the demand for it in well-understood cases.

Dr. COCHRANE, of Mobile, Alabama, also deprecated anything that looked like hasty action in this important matter. He asserted that recent discoveries in chemistry showed that alcohol was digestible and absorbed into the juices of the body, and not simply excreted, as had heretofore been held. Other substances were found in the urine which gave the same chemical reaction as alcohol, when it was quite certain that no alcohol whatever had been taken into the system. While agreeing with many things which Dr. Hitchcock had set down in his pamphlet, he was not prepared to endorse them all. For himself he believed alcohol to be a genuine food required in the system in very many cases, and one whose place could not be supplied.

Dr. B. H. CATLIN, of West Meriden, Connecticut,

said that if in passing the resolutions any censure should seem to be applied to the medical faculty, it would, perhaps, be well to modify them in some manner.

Dr. KEDZIE, of Michigan, said the subject was one that the profession were quite familiar with, and understood in all its bearings, and therefore there could be no censure implied in passing them.

Dr. MORRIS, of Baltimore, again took the floor, and dilating upon the importance of the question to the profession at large, offered a resolution that "this section recommends to the Association to appoint a committee composed of — members, who shall examine into the subject and report to the section at its next annual meeting." The motion was seconded by Dr. COCHRANE.

Dr. BELL, the Chairman, said that it was a question whether the section was authorized to refer the matter back from the section to the Association after it had previously been charged with it. For the sake of obviating this difficulty he requested Dr. Morris to reduce his resolution to writing.

HORNER'S RESOLUTIONS.

Dr. KEDZIE read slowly and deliberately the resolutions of Dr. Horner, above given, and said they had been brought before the Association two years ago; that last year they had been referred to the section; that they were plain and to the point, and he again moved their adoption.

The resolutions were finally passed after a long and spirited discussion.

MEDICAL JURISPRUDENCE.

Tuesday, June 2.

Dr. TALLEY, of South Carolina, Chairman.

EMOTIONAL INSANITY.

Dr. E. LLOYD HOWARD, of Baltimore, Md., read an elaborate and interesting paper on the above subject, in which he took the ground that it was impossible to define insanity by any "test" symptoms, and that each case should be examined on its own merits. In regard to the subject of punishment, he remarked:

"We cannot refrain from hazarding the opinion that the ends of justice would be better subserved, the security of society more certain, and the rights of individuals more secure, if the laws exempting insane offenders from punishment were repealed, leaving the jury to determine the guilt or innocence of the prisoner, not on the grounds of insanity alone, but from all the facts; considering, in each case where insanity is alleged, its value, if proven, as an element in forming an opinion as to punishment. No doubt it will seem cruel to many to advocate the doctrine that insane persons should ever be made to suffer criminal punishment. But we must remember the law is not to take cognizance of the sufferings of the individual so much as to the safety of the community. This is its prime object, to be secured at all cost, and mercy can only be considered as subordinate to this first requirement.

"All modern criminal law is based solely upon the principle of protection to society. It recognizes in its administration nothing of the spirit of vengeance or retaliation upon the criminal. It imprisons, or it kills, not because the culprit deserves imprisonment or death. Its penalties are never imposed with a view to cause suffering simply because it is thought merited, and as an atonement for the crime. But, always, its only and

sole object is to protect the community—either by depriving the criminal of further opportunity to commit crime, or, through the example it offers, to deter others from the perpetration of similar misdeeds. Laws are passed to protect each individual in the enjoyment of life, property, and his other rights and privileges, and with primitive provisions that warn others not to interfere with those rights; and when crime is committed—that is, when the rights of another are invaded—punishment is enforced to impress the fact that transgression is not only forbidden, but will be inevitably followed by disastrous consequences to the transgressor. There is no natural inherent right in any government or power to deprive any man of liberty or life. The power is assumed by common consent for the common safety, and is only justified by the law of self-protection, and it becomes a brutality and a tyranny when used beyond these strict requirements. But the great natural law of self-protection is supreme. It has no limits in its proper application. If any member of the community is, either through his own voluntary act or some combination of unfortunate circumstances, detrimental to the community, the community must protect itself from him. If it be through his own voluntary act, as a wilful murder, then a punishment is inflicted to prevent a repetition of the act by the same person or by others. If it be through no fault of his, but a misfortune, as when a homicide is committed in an attack of mania, then the community protects itself by putting the offender in confinement; but no punishment of such is inflicted, because it could have no good effect, as other maniacs would not be thereby deterred from homicide, having no proper conception of the relation of the punishment to the crime. But is it true that punishment, or the prospect of punishment, would have no good effect as applied to insane persons? Is it not a notorious fact that constantly, both in and outside of asylums, insane patients are governed by fear and restrained through dread of punishment? Having seen that it is not at all uncommon for cases of emotional insanity—men clearly and undoubtedly insane—to be possessed of the ability to discriminate right and wrong, and to have sufficiently clear intellectual perceptions of the nature and penalties of crime, could not some provision be made for controlling them through fear of punishment, while at the same time recognizing the fact of their insanity? Both as a matter of protection to the community and benefit to themselves, would it not be wise to apply to many cases of 'moral' and 'impulsive' insanity the same restraining influences we find efficacious for sane criminally disposed persons?

"We find, then, that there are certain cases in which the fear of punishment acts upon the minds of persons unquestionably insane, with a wholesome and restraining influence, and it seems right and proper that the community should receive the protection which can be given it by the enforcement of the laws in this regard. If it be made certain that punishment will always follow swiftly upon the steps of those who do injury to the persons or property of others, many having the insane temperament will be controlled and have their powers of resistance to insane promptings strengthened, who might, with a less certain prospect of punishment before them, give way to their evil impulses."

The paper was referred to the Committee on Publication.

Dr. TALLEY also read a brief paper on the "Relation of Psychology to Medicine."

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Monday Evening, May 25, 1874.

DR. ELLSWORTH ELIOT, PRESIDENT, in the Chair.

THE PAPER OF THE EVENING.

DR. CHARLES P. RUSSEL read to the Society an elaborate paper on Hydrophobia; giving an account of most that had been written on the subject from the earliest times, and comprising an estimate of the total number of cases that had been reported, and the periods of their occurrence.

He furthermore reviewed the symptoms and morbid appearances of the disease in its different stages in the dog, and exhibited a drawing which represented a rabid animal in the advanced stage of rabies.

Considerable space was devoted to the disease as it affects other classes of animals, by which it was shown that it is by no means peculiar to the dog, but that all of the domestic and many wild animals, and even birds, have at one time or another been affected with it.

The latter portion of the paper was devoted to a consideration of the means for preventing the spread of the disease. The method at present in operation in New York, viz., requiring dogs to be muzzled, Dr. Russel considered to be the least effective, since, as the statistics showed, it is enforced at a time of the year when dogs are least liable to the disease, and moreover does not practically amount to protection even of the owner of the animal, since the muzzle is only worn in the street, while at home it is removed. After speaking of a number of plans, the one which was advocated in the most decided manner was that of requiring the owners of dogs to procure a license which should be renewed annually for dogs above a certain age; of requiring that all dogs should wear a collar carrying the name and address of the owner and the number of the license; of instructing each dog-owner in the symptoms of rabies, and requiring that every sick dog should be submitted for the inspection of an expert who should be a municipal officer.

DR. GARRISH emphasized especially the points that the affection was common among, or entirely confined to pet animals; and that the period of latency of the disease in the human subject had been known to extend to twenty years.

PROF. JOHN C. DALTON was requested by the President to favor the Society with his extensive experience in the matter, and remarked that although he would gladly speak, it was a mistake to suppose that he had any practical knowledge of hydrophobia. He was sorry to say that he had never seen a dog which he knew to have hydrophobia, although, in a very intimate acquaintance with the animal, he had seen him and experimented on him under a great variety of circumstances, and had seen a number which had been *said* to be mad, but which, on careful examination, were proved to be sick of some other disorder—such, for example, as epilepsy.

He then gave a very graphic description of a case of this sort which he had seen the day before, in which a whole neighborhood had been excited by the strange behavior of a terrier dog which was lying quietly in the gutter, suffering apparently from some disturbance of the nervous system. Two policemen were summoned, and after the dog had been treated to a douche bath with a bucket of water—for what reason the doctor did not know—he was killed by a blow on the head with a policeman's club.

The amount of fear exhibited by the spectators on this occasion was characteristic of this affection, and the doctor confessed to having shared it in some degree at the time; and although perfectly aware that the dog was not rabid, he would have objected most decidedly to handling him. It is, no doubt, a fact that the great interest which attaches to the consideration of this disease is to be attributed not only to the dreadful character of the symptoms, but also to the uncertainty regarding the time of their accession.

He agreed with Dr. Russel regarding the importance of precautionary measures and the necessity for more accurate general knowledge of what should be done in the way of therapeutics when persons had been bitten; since it was frequently some time before a surgeon could be obtained, and, as often occurred, the animal which had inflicted the bite may have escaped, it became a matter of impossibility to say whether the dog was really rabid or not. The three to nine months of uncertainty which must follow in these cases was of itself one of the most dreadful features of the malady.

He was much interested in the doctor's suggestion that instead of requiring dogs to be muzzled, the owners of them should be required to pay a tax and keep a collar marked with the license number and owner's name attached to the dog's neck. If then all dogs found without such evidence of ownership should be systematically destroyed, we would possess a guarantee that the dogs which existed would be under the observation of an owner. If then information with regard to the symptoms of hydrophobia was made general, and owners should be required to take their animals to some place where they could be examined by an expert, we would have a better means of preventing the disease and its consequences than we have heretofore possessed, or more likely to have, through an ordinance requiring the use of a muzzle.

The public have an idea of three cardinal points in the question of a dog having hydrophobia or not, and he need hardly say that all three of them were wrong. 1st. They think that dogs have the disease only in hot weather. 2d. *Hydrophobia* they consider an invariable symptom; and 3d. They have an idea that a rabid dog is always savage and aggressive.

The opinion on this matter was so general and decided that he had frequently seen something like this occur in the streets:—A dog would be seen trotting along the street having something strange about his gait or general appearance, and the passers-by would turn and watch him anxiously until seeing him stop to drink out of some pool in the road, and noticing that the weather was cool and that the dog did not attack anybody, they would turn with a sigh of relief and go on, having settled in their minds that it being cool weather, that the dog lapped water, and that he was not aggressive, therefore he could not be rabid.

Owing to the faulty nature of the public information on this subject, he had no doubt that many wounds had been contracted from animals who had not been noticed to be diseased, and he therefore hoped that Dr. Russel's paper might be condensed into such a form that it might be published by the Board of Health for circulation about the city—especially in police stations and like public places.

With regard to the shyness which had been spoken of as characteristic of the early stages of rabies, Professor Dalton's experience had been that *all* sick dogs are shy. When a dog has an inflammatory disorder or even derangement of the digestive system, his instinct leads him to go to some hiding-place and stay there. The rabid dog has this symptom in the earliest stage; but the difference in the case of rabies is, that

the rabid dog is restless and remains for only a short time in one place.

Another point in the diagnosis of rabies is, that the appetite is not lost, but is depraved, and the diseased animal will eat his own dung, bits of wool, mortar, and pieces of charcoal. He gnaws furniture, and tears up and swallows bits of clothing, carpeting, etc. The speaker was aware that small pets would frequently tear and destroy furniture and clothing, but they would not swallow the pieces. This symptom is so diagnostic that Youatt says that when he finds masses of wool or pieces of charcoal in the stomach of a dog, he does not hesitate to affirm that the animal has had hydrophobia.

These symptoms of restlessness and depraved appetite Prof. Dalton thought would be of most practical value to the public, and there should be an ordinance obliging persons owning sick dogs to carry them to some place where they could be kept under intelligent observation.

One point which had been alluded to by Dr. Garrison would be ludicrous if it were not connected with so serious a matter; that was, the disposition on the part of the public to kill at once any dog which had bitten a person, or which had been suspected to have rabies, without waiting to see whether the dog was really rabid. The dog once dead, nobody knows or can know the truth of the matter, and the bitten person is condemned to months of torturing uncertainty.

This disposition to kill the dog at once had evidently some foundation in a superstition that in case the beast should ever in future become rabid, the person bitten would be attacked with hydrophobia. The absurdity of this belief renders comment unnecessary.

Prof. Dalton expressed it as his opinion that nineteen out of every twenty dogs reported to have hydrophobia are only epileptic, and that the killing puts it out of our reach to establish the fact, and tends to increase the popular prejudice in the matter. In fact, he believed that the greater part of the terror which exists regarding hydrophobia is based upon popular prejudice, and has no warrant in facts.

DR. GARRISON cited several cases, in one of which a hydrophobic patient never refused water and had no difficulty in drinking. The spasms of the muscles of the throat and chest were relieved by bleeding; twenty-four hours before the death of the patient the voice of the patient imitated the voice and bark of a dog, and symptoms of meningitis supervened.

DR. CALKINS believed that cases had been cured. M. Bouisson had the disease, but under the influence of a vapor-bath at a temperature of 93° the severity of the symptoms declined and ultimately passed off. Another cure had been reported by Dr. Rosseau in which a faradic battery of thirty-five plates [?] had been employed, and the patient recovered. Dr. Calkins thought he would employ both remedies if he should have a case. The great thing, however, is prophylaxis, and he cordially endorsed what had been said by Dr. Russel and the previous speakers with regard to the desirability of measures for the prevention of the spread of the affection.

As regards the immediate treatment of the wound, nothing could be better than actual canter. With an iron at a white heat, the pain was trifling. A favorite mode with Larrey of producing canter, was with boiling oil. Dr. Calkins also discussed briefly the question whether the disease could ever be of spontaneous origin, and whether its spread could depend upon the liability of other animals than the dog to its attacks.

DR. CARO gave his opinion that a very common cause of the disease in the dog is bad quality of food. The Society then adjourned.

Original Lectures.

CLINICAL LECTURE ON CLUB-FOOT.

By LEWIS A. SAYRE, M.D.,

PROF. OF ORTHOPÆDIC SURGERY IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

(Phonographically reported for THE MEDICAL RECORD.)

GENTLEMEN:—The cases which I shall bring before you to-day will give occasion for some remarks relative to the very common deformity known as club-foot.

The first case, which you here see, is one of double congenital talipes varus. The child is now five months old, and the deformity has never been under treatment.

Here, at the very outset, we come in contact with the violation of an extremely important principle, which should influence the management of this class of deformities. The principle is, that the treatment of congenital club-foot should begin at the birth of the child. This principle has already been mentioned in my book upon club-foot; but I have found that it has not been announced with force sufficient to attract the attention which it deserves. As proof of this I have this day received a letter making inquiry with regard to the proper time for the commencement of treatment.

Treatment of these cases should be commenced the instant the child is born. The busy practitioner may, perhaps, be excusable if he shall first see that the placenta is properly delivered, the third stage of labor completed, and the necessary duties of the lying-in chamber discharged; but, as soon as these duties are discharged, the feet of the child should receive attention, and the proper treatment instituted before the medical attendant leaves the house.

In cases of acquired talipes the same rule is equally important, and treatment should be commenced *immediately upon the receipt of the injury.*

The importance of this rule of management can at once be seen, if for a moment we refer to the most serious obstacles which stand in the way of successful treatment of talipes. In brief, these are structural changes which the muscles are liable to undergo from neglect in the performance of their normal action, and the effects attending an inflammatory process set up in the various soft parts in consequence of the irritation produced by walking with the foot or feet in an abnormal position. In a large majority of instances, if proper attention is paid to the correction of the deformity, from the birth of the child onward, the foot can be made to maintain the normal position without the aid of tenotomy.

How is this to be accomplished?

Take the deformed foot in your hand, as you see me do in this case, and, by gentle manipulation and careful tension gradually increased, accompanied, perhaps, with light frictions to the foot and leg, bring it into its normal position. This manipulation should be repeated at intervals of a few minutes, until the foot can be *easily* placed in the normal position. When this can be done the foot is to be secured in that position by means of adhesive plaster applied in the following manner: In the first place, the most serviceable adhesive plaster to be used in these cases, and in all cases where it is desirable to sustain long-continued traction, is Maw's moleskin plaster, manufactured in London. Plaster spread upon cotton flannel may be

used, but it is not nearly as good as the "moleskin plaster."

Now, cut a strip of adhesive plaster two or three inches wide, and of sufficient length to go nearly around the foot and reach some inches above the upper extremity of the tibia. The plaster is to be applied by commencing upon the dorsum of the foot, with one extremity placed at an oblique angle, so that it may be wound around the foot smoothly in the direction in which the foot is to be drawn. When the plaster has been wound nearly around the foot, care being taken not to completely encircle it, then place the foot as nearly as possible in the normal position, and carry the plaster up the leg to the head of the tibia, and secure it by means of a well-adjusted roller bandage. When the bandage has reached the head of the tibia, the strip of plaster which extends some inches above must be removed, passing down the leg, and then the bandage is to be removed and made to follow it, securing the plaster in such a manner as to prevent all slipping. It is also advisable to nick the edges of the plaster over the ankle, lest free circulation should be interfered with.

If this plan of treatment is faithfully carried into execution, and continued in the same manner as necessitated in the proper carrying out of all other plans, if you would make them successful, it will in a large number of cases effect a complete cure.

There are, however, certain cases which will require a little more energetic and independent method of treatment than that which we have just described. There are cases in which the muscular rigidity is so well developed that it will not readily yield to the manipulation which can ordinarily be applied and *continued*.

Under such circumstances no more efficient apparatus can be employed for overcoming the deformity than that suggested by Mr. Barwell, of London.

The main principle involved in the apparatus is the application of constant tractive, elastic force for the purpose of overcoming muscular rigidity. The application of the constant elastic force is made by means of what have been designated as artificial muscles, which may be constructed and applied in the following manner:

Cut a fan-shaped piece of adhesive plaster, and attach to its narrow extremity a wire loop with a ring in the top.

Slit the plaster into strips at its wide extremity, and adjust it to the foot in such a manner that the wire ring shall be placed at the exact point at which you wish to make the *insertion* of the artificial muscle. Secure the plaster thus adjusted, by means of other strips of adhesive plaster and a smoothly applied roller bandage. The artificial *origin* of the muscle is made by taking a plate of tin or zinc, about two-thirds the length of the tibia and one-fourth the circumference of the limit in width, and carefully shaping it until it shall fit the curved surface of the limb. At the upper extremity of the tin or zinc plate is fastened an eye, made of wire, which is subsequently to receive one of the hooks attached to the artificial muscle.

To prepare the plate so that it can be securely attached to the limb, cut two strips of plaster, long enough to go around the limb, and in the middle of each strip cut two slits equal in length with the width of the plate. When the plate is introduced into these slits, and applied to the limb, and the strip of plaster carried around the limb, all lateral motion will be prevented. Then cut a piece of plaster somewhat wider than the plate and about double its length. Apply this smoothly to the side of the leg upon which the traction

is to be made, beginning as high up as the tuberosity of the tibia.

Now apply the tin plate, placing its upper extremity nearly upon a level with the upper extremity of the plaster, and then secure it by encircling the limb with the strips of adhesive plaster before described. Now, turning the piece of plaster first applied to the limb over the plate, cutting it off just underneath the eye at the top, secure the whole with a roller bandage. When the top of the plate has been reached with the bandage, reverse it, and carry it down the limb until the whole is properly secured. A short piece of small chain is then attached to the eye in the plate or to the ring of the other part of the apparatus. The artificial muscle is made by fastening hooks into the extremities of small pieces of India-rubber tubing, one-fourth of an inch or more in diameter, and from two to six inches in length.

The hook at one extremity of the artificial muscle is now attached to the *insertion* of the muscle, and the hook at the other extremity is attached to the short piece of chain. By placing the hook in different links of the chain, the amount of tractile force may be varied according to the requirements of each case.

(A more complete description and illustration of this apparatus can be seen in the second edition of the author's book upon club-foot.) A great advantage of this plan of treatment is, that it encourages movements in imitation of the natural movements of the parts. At the same time it permits the natural movements of the joints and muscles to go on unrestrained. The joints and muscles of the human body were designed by the Creator of all things for active motion, and as far as is possible these natural movements should be retained, stimulated, and strengthened.

It is for this reason that I always condemn any apparatus devised for the cure of these deformities which places the foot in a fixed position.

The deformity is essentially a paralytic one, and the treatment of cases of paralytic deformity by retention in a fixed apparatus is all wrong. Such apparatus, therefore, as plaster-of-Paris, gutta-percha, or shoes made with a certain set of iron fastenings and screws, by means of which the foot is held in a certain fixed position, is all wrong.

What will be the result of such a fixed apparatus if worn for any considerable length of time? The inevitable result will be that these muscles which are kept quiet will undergo structural changes, which will place them beyond all hope of ever again being able to perform their normal function.

This is a very important principle, and one which should influence your management not only of this class of cases but very many other cases when it becomes necessary to apply measures for overcoming muscular contraction, or to retaining the muscles in a state of rest for a certain length of time, as in the treatment of fractures. The total rest which must necessarily occur in a muscle, when secured in some fixed apparatus, will certainly induce fatty degeneration of the muscular structure if long continued, and thereby destroy all possibility of ever overcoming the deformity by the restoration of normal muscular power. One great idea, therefore, in the plan of treatment which we recommend, is the permission of motion at the ankle-joint and among the muscles. In addition, these muscles should be stimulated to action by means which are hereafter to be mentioned, as much as can be done within the bounds of discretion, and without producing over-fatigue. There are certain objections which can be urged against the apparatus just described, such as, the liability of producing irritation of the skin,

a serious objection, especially among small children: the liability of the plaster slipping about, becoming worn out, requiring frequent adjustments, especially in warm weather, etc., etc.

For the purpose of overcoming these objections, and at the same time making use of the same principle as far as possible, I have devised a shoe, which is constructed upon the general plan of "Scarpa's shoe." The essential difference between the two instruments is, I make use of rubber tubing or elastic bands for the motive power, instead of the ordinary springs used for that purpose. I have also made the additional modification of substituting a ball-and-socket joint opposite the medio-tarsal articulation, for the old hinge-joint which permitted of motion only in a lateral direction. The ball-and-socket joint will permit of motion in every direction. The sole is also constructed very much like that of an ordinary shoe, and has a low heel.

A complete description of this instrument and its modifications will be found in the second edition of my manual upon club-foot, and I will therefore not consume more of your time in its description at this place.

The next important question to be decided is, How are we to determine whether, in any given case, we shall be compelled to cut or not?

The law is, if while the patient is anesthetized, a part contracted so as to produce a deformity—whether it be muscle, fascia, or tendon—can be overcome by manual tension gradually applied, and brought to its normal position and retained there, and then, if an additional point of pressure, made with the point of the finger or thumb upon the parts rendered tense, *produces reflex contractions*, that fascia, muscle, or tendon must be cut.

If, on the contrary, you can bring the parts into their normal position by manual tension gradually applied, and the additional point of pressure does *not* produce reflex contractions, the deformity can be permanently overcome by constant elastic tension, and the more cutting the more damage there is done.

This is an important law, which you will do well to remember; for its application is universal in deciding the question of cutting contracted tissues.

Suppose it is decided that the operation must be performed, how is it to be done?

In the first place, a properly made tenotome instrument should be employed, if you would avoid the risk of wounding important structures. The instrument should be somewhat rounded at the point, and have a double bevel like a wedge, so that when introduced it splits rather than punctures the tissue through which it passes.

The cut is to be made subcutaneously, introducing the tenotome flatwise, splitting the theca and carrying it beneath the tendon or fascia, turning its edge upwards, and then pressing the tissue to be cut down upon the edge of the instrument, while at the same time a teetering or slightly sawing motion is given to the blade until the tendon or fascia is felt to give way. When the cut has been made, the instrument is turned flatwise and withdrawn. The thumb with which pressure has been made is passed over the wound, which is then immediately covered with a piece of adhesive plaster. A little pad of cotton is then placed over the wound, and the foot firmly bandaged. Next, immediately restore the foot to its normal position, and retain it there. Do not wait a few days for inflammatory action to take place and subside, but restore it at once, and apply an apparatus for retention, which shall be constructed as follows:

First, apply a *guy* or a strip of adhesive plaster in the

same manner as already described in the first treatment the congenital talipes should receive.

Next, cut a piece of board a little longer than the foot, square at the toe, shaped by the sole of the foot, and about two or three-eighths of an inch thick. (Cigar-box answers a good purpose.)

Cover the board with a piece of adhesive plaster equal with it in width, and sufficiently long to pass entirely around it, and reach from the toes to some inches above the knee.

Apply the adhesive side next to the band, commencing at the anterior extremity, upper surface, returning from the posterior extremity along the under surface, thus leaving the remaining portion of the plaster in the proper position to be subsequently attached to the anterior surface of the leg. The apparatus is now ready. Now, bring the foot into its normal position as nearly as possible by careful manual manipulation and traction, and then set it upon the board, securing the heel by a strip of plaster which passes around the ankle and heel part of the board, and then secure the whole by a well-adjusted roller, which is to be carried over the foot and above the ankle. Again, bringing the foot as near as possible into the normal position, the long strip of adhesive plaster is to be firmly drawn up and attached to the anterior surface of the leg, and then secured by a continuation of the roller bandage, which has already reached above the ankle. When the head of the tibia has been reached, the plaster is to be reversed, carried downwards upon the leg, and followed by the roller, which will secure the entire dressing more firmly in its position. If there is a tendency, after the dressing is applied, to either valgus or varus, an additional *guy* can be applied in a manner to overcome such tendency, and secured with another roller.

This apparatus is simple, cheap, and more efficient than any which I have ever employed.

Now, gentlemen, we come to the important part of the management of these cases, namely, the after-treatment.

The mere cutting operation is the most insignificant part of the treatment, so far as cure is concerned. The cutting may be necessary, but the deformity must be treated afterwards in the proper manner, if you would have any benefit follow, save the treatment from falling into disrepute and yourself from being regarded as a man of questioned ability.

After three or four days the external wounds will be healed, and as soon as that is the case the foot is ready to receive a variety of passive movements, which are to cure the deformity. Handling the foot, gentlemen, is the great secret of curing it. Here is a little boy who has had his foot cut five or six times, and yet he comes to-day with his deformity as bad as ever, and why? Simply because the treatment which he has heretofore received after the operation has been by means of fixed apparatus, which was regarded as sufficient. The parts have been permitted to remain in a quiescent condition, and adhesions have occurred which renders the case as bad as it was before the operation.

Without manipulation the result will be exactly what you see here. Everything has been cut, but no proper after-treatment following, only a few months elapse before everything is as bad as it was previous to the operation, in consequence of the adhesions which have been formed. The more frequently the child's foot is manipulated, the greater will be the benefit derived from the operation, providing the manipulation is performed thoroughly but gently, and never carried to over-fatigue. Friction with the hand is also very serviceable among the means to be employed for restoring motion to the paralyzed muscles. Electricity is

another means; but I have a few directions to give you relative to the employment of this agent, which I regard as being of the utmost importance. When employing electricity for the restoration of paralyzed muscles, be careful that you do not apply it too long. Three or five minutes every day, or every other day, is sufficient.

Be careful that you do not apply it too strong. A strong current is very liable to cause over-fatigue of the muscles, and this is especially the case if too long continued in the treatment of paralyzed muscles; and the over-fatigue induced will be positively injurious. *Over-fatigue* of the muscles must be assiduously avoided. Another exceedingly important point with regard to the application of electricity for the purpose of restoring muscular action is always to restore the muscle to its normal position by some artificial means, approximating its origin and insertion before applying the battery.

The principle is, the paralyzed muscle should be placed in such a position that, when stimulated to contract by the application of the electric current, it can do so *without carrying any weight*. If the muscles are compelled to act without exercising these precautions, permanent damage may be done to them, rather than permanent benefit. You will always recollect, therefore, to approximate the origin and insertion of all paralyzed muscles, bringing them as near as possible into the normal position, before applying the electric current for the purpose of restoring lost muscular power.

The administration of $\frac{1}{60}$ gr. doses of strychnine three times a day, and the subcutaneous injection of $\frac{1}{60}$ of a grain into the muscle once in eight or ten days will also be of much service.

The deformity, depending as it does upon a paralyzed condition of certain muscles, renders it necessary that the treatment shall be continued until the muscles have become so restored that they can act in obedience to the will of the patient. Until that time arrives the deformity is not cured. This, as you readily see, will require time for its accomplishment. It will be necessary, therefore, to give some artificial support to the muscles, until recovery has been so far established that the patient can voluntarily place the deformed foot in its normal position. Barwell's apparatus, or the shoe already described, should therefore be employed to assist the movements of the muscles until they have become thoroughly accustomed to the performance of their normal functions.

UNUNITED FRACTURE OF THE THIGH TREATED BY THE INJECTION OF AMMONIA.—Bourguet has reported a case in which he has employed this treatment with success. A fracture of the diaphysis of the femur had not united after a period of five months. At this time 10 drops of a solution of ammonia, in the proportion of 1 to 3, were injected into the thigh, immediately about the extremity of the upper fragment. Four weeks later, 20 drops were injected about the lower fragment. Three days later a third was made between the fragments, and a week later a fourth of 20 drops, containing equal parts of ammonia and water. Within the next five weeks four injections were made with a solution of iodine and iodide of potash. The leg lay in a water-glass splint. The phosphate of lime was given internally. Six months after the first injection the consolidation was complete and the callus very extensive. This is the second case that Bourguet has treated successfully in this way.—*Alg. Med. Central Ztg.*, 39, 1874.

ELECTRO-THERAPEUTICS OF THE MALE GENITAL ORGANS.

By A. D. ROCKWELL, M.D.,

ELECTRO-THERAPIST TO THE NEW YORK STATE WOMAN'S HOSPITAL.

IN the consideration of disease the intelligent practitioner is first required, so far as possible, to clearly apprehend the indications, and then as nearly as may be to meet them by his remedies. In certain disorders—and these constitute not a small proportion—the indications are often uncertain, and therefore unsatisfactory, and necessarily lead to empiricism. In other diseases the indications are most clearly defined, and the only difficulty is to find some remedy or method that will adapt itself to them and thus hasten recovery. In anesthesia, the cry of the sensory portion of the nervous system is for a direct and peculiar form of stimulation to the nerve-centres, along the course of the nerves, or to their peripheral expansion.

To meet the first indication (where the nerve-centres are involved), central galvanization is not unfrequently of essential service; localized galvanization or faradization is called for in the second condition; and where the peripheries alone are in fault, faradization with the wire brush is usually beneficial. In paralysis of a motor nerve we desire in the same way to stimulate either the nerve-centres or the nerve itself, and substantially the same method of procedure may prove of service. Most admirably do some pathological conditions of certain of the nerves of special sense serve as illustrations of this principle. In anosmia, or loss of the sense of smell, similar indications are afforded as above; so also in impairment of the sense of taste, and in many cases they are as successfully met by the same method of treatment.

A nerve is in a condition of heightened irritability; there are disturbances of circulation dependent primarily on a perverted or weakened influence of the great sympathetic, and secondarily on disturbance of the vaso-motor nerves.

Muscular atrophy is making rapid progress through lack of nerve nutrition, and certain secretory and excretory organs fail to properly perform their functions for want of a sufficiently stimulating influence. In all these conditions the indications are positive and sufficiently well defined, but with perhaps the exception of the last, in which the symptoms are sometimes met by internal medication, the treatment by the old and accepted methods affords but an uncertain and unsatisfactory prognosis. Electricity, however, in one or another of its manifestations, or by some one of its varied methods of application, excellently meets all these requirements, and accomplishes what with our present knowledge and methods would be impossible without it.

All this applies equally to the diseases which this paper proposes briefly to consider.

In spermatorrhœa, seminal emissions, and impotence the indications are often sufficiently clear and well defined; but the one great difficulty has been to find a remedy that can reach and successfully fulfil them. The remedy that I offer is, again, electricity, and it is offered not only on the ground that it has practically equalled the expectations that it held out, but that, theoretically, it ought to be of service. In the first place it must be remarked that of these three conditions, viz.: spermatorrhœa, seminal emissions, and im-

potence, the latter, taking the cases as we find them, yields the most uniformly and readily to the treatment that we are considering. These three conditions are, however, very frequently associated, and the symptoms suggestive of each may be so intermingled as to render it difficult to decide which presents the most prominent features for treatment.

There can be no question that true spermatorrhœa is much less frequent than is generally believed.

It consists in an involuntary discharge of semen, without erection, and as there are several secretory glands besides the testicles, the secretion from which lubricates the urethral canal, and may appear externally even in a healthy condition of the parts, the activity of charlatans has had a fair field in which to excite alarm among the credulous.

In regard to the treatment of spermatorrhœa, it is hardly necessary to say that no one method of electrization will answer in all cases.

The applications may be localized externally or internally, and in addition we frequently use with advantage general faradization, sometimes central galvanization even. There is one method of procedure, however, concerning which I have positive convictions. I refer to galvanization of the ejaculatory ducts, or the parts in their immediate vicinity, by means of the insulated catheter electrode. It is true that if employed with great caution and with a current of very slight tension no harm may result. Currents of considerable electrolytic power even may frequently be borne without any after ill effects; but it is equally true that these same applications, whether weak or strong, have in numbers of instances been followed by profound and lasting irritation, and in my hands I am not satisfied that it ever accomplished good in true spermatorrhœa. Deaths have been known to result from the effects of the *porte-caustique*, and doubtless most of us have knowledge of cases in which it has produced inflammation or chronic irritation. From the history of one case at least, it seemed sufficiently clear to me that this treatment had laid the foundation of an obstinate stricture; and in another case, of complete destruction of the virile power, which I saw with Dr. Jerome Smith, it was evident that the symptoms were in a measure due to a most severe and ill-advised cauterization of the ejaculatory ducts. Electrolytic action is of course more completely under control, and although its physiological influence is different from that of the caustic, it is yet occasionally followed by substantially the same effects, and I hesitate to make use of it internally in the irritable condition that we are considering.

In lieu of this procedure, however, and in addition to the external methods of treatment, I am highly in favor of the direct application of the faradic current to the urethra, and on the same principles and to meet the same indications that the occasional introduction of the ordinary catheter is attempted.

Mechanical pressure alone tends to unload the congested capillaries, and to very decidedly lessen the sensibility of the urethral nerves, and, when combined with the vibratory action of the faradic current, I am convinced that its good effects are markedly increased.

Seminal emissions consist in an involuntary discharge of seminal fluid, with erection, and demands treatment only when it becomes excessive, and is associated with, dependent on, or is the cause of constitutional disturbance. Unlike spermatorrhœa, impotence in its various grades of impairment of the sexual power is of very frequent occurrence; indeed is present far more universally than is generally supposed. So far as my experience goes, it would seem that the mildest

and most frequent form of impotence manifests itself by a premature ejaculation of semen, with no special diminution of sexual desire, but with some impairment of the power of erection. A somewhat more persistent condition is shown by an appreciable diminution or capriciousness of the sexual appetite, with a marked decrease of the power of erection; and thirdly, there is not unfrequently an entire absence of sexual desire and power of erection. I shall not attempt to enter into any consideration of the causation of these symptoms further than to say that the vast majority of cases of this character depend on the same general cause—over-taxation. Not only in its incipient, but in its more advanced stages, impotence not unfrequently is the result of organic disease of the nerve-centres, and its treatment by electricity is of importance only so far as it serves as an illustration of the extraordinary stimulating or tonic influence of the remedy. I have had patients suffering from incurable chronic hemiplegia, progressive muscular atrophy, locomotor ataxia, etc., where there has been, under local and general electrization, a most extraordinary increase in the desire and capacity for sexual intercourse. As a rule this increase has been of a temporary character only, but occasionally the effects have been lasting. In one case of Addison's disease of the supra-renal capsules, where the desire and power had been completely lost for eighteen months, both were approximately restored by treatment. Now, in the consideration of the various degrees of impaired sexual power, the question at once arises, What are the indications; and again, how are these indications to be fulfilled? In the milder forms of impotence, where there is simply premature ejaculation of semen, with some diminution of the power of erection, as well as in the more advanced stages, where the desire is capricious and the power of erection pretty well destroyed, it is evident that there must be a degree of paralysis at the root of the disorder dependent on structural changes in the nerve-centres, or else this impaired power or tone in the muscles and erectile tissue may be of a purely local character. In the latter case the indications are clearly the same as in other forms of local paralysis, and by faradization of the ischio-cavernosus, bulbo-cavernosus muscles, etc., much may be accomplished.

In recent cases of impotence, where there is considerable power remaining, as well as in its more advanced stages, where the power is approximately lost, we not unfrequently find that the seminal secretion is markedly reduced not only in quantity but quality, and reasoning from analogy it would seem that in such cases there were undoubted indications for the use of electricity.

The galvanic current especially has the power of exciting to increased activity the secretory function of various glands, and not unfrequently accelerates physiological mucous discharges. The salivary and lachrymal glands, as well as the liver, are susceptible to stimulation by electrization, and it is undoubtedly true that the lacteal secretion has been augmented by passing the current through the breasts of nursing women.

It is highly probable, then, that a deficiency in the secretion of semen, when it is dependent on paralysis or exhaustion of the nerves controlling this function, and not on pathological changes of a structural character, may be successfully remedied by galvanizing the spermatic nerves and the testicles. We must not, however, in all cases depend on local treatment alone.

Not only may impotence be associated with, but it may result wholly from, disorders of a general character.

The excessive use of sedative narcotic remedies, sedentary habits, and general mal-nutrition from any cause lead to the condition under consideration, and demand the constitutional tonic influence of general faradization.

It is a fact worthy of note that some cases of sexual incapacity are associated with diminished electro-cutaneous sensibility of one lateral half of the penis. Occasionally the anesthesia is quite profound, and as a rule the sexual weakness is in proportion to the degree of anesthesia. The numbness in these cases is more than an accidental association; it would indeed appear as if it was a range, and to a certain extent a cause, for by the application of the ordinary electric brush to the parts, in the same way that we treat any case of local anesthesia, the numbness is often removed and the integrity of the sexual function restored. Impotence, as before remarked, may manifest itself by many symptoms and in various degrees, but there is one phase of it that is, I believe, not very common.

It consists in an inability to ejaculate semen, while the power of erection remains vigorous, and to this condition the term aspermatisms was first proposed by Ronbaud, in 1855. Dr. Wm. H. Van Buren, in an article published in the *N. Y. Medical Journal* for November, 1868, suggested that the difficulty in ejaculating the semen was caused by an exaggerated spasmodic contraction of the muscular fibres of the walls of the ejaculatory ducts, leading to their occlusion under extreme excitement. On this theory it would seem that the indications called for galvanization of the ejaculatory ducts; but in two cases that have come under my observation, and that might fairly be placed under the head of this affection, the treatment failed to afford relief. Cases illustrative of the possibilities, as well as of the limitations of the electrical treatment of impotence might be abundantly given, but it is not my purpose to weary my readers with the dry details of a clinical report.

In order, however, to give to those who are interested in this subject an approximate idea of the measure of benefit that may be derived in the treatment of the various phases of this disease, it may not be amiss to state briefly the general results of my efforts. During the last three years, and in private practice exclusively, I have been enabled to thoroughly follow out the treatment of twenty-eight cases of impotence, in its various degrees, by some one or several methods of electrization.

Of these twenty-eight cases, eight failed to receive appreciable benefit; while twenty either recovered completely, or approximately, or were very greatly improved. Of the eight cases, most of them were from one to several years' standing, generally representing individuals approaching or beyond middle life, and, as a rule, the result of long-continued sexual excesses or repeated attacks of syphilis or gonorrhoea.

When the sexual power has once become very decidedly impaired through excesses, it is not to be expected that in general the old vigor will return in full strength, and therefore it can only be said of the twenty cases that were benefited, that the majority recovered approximately, but permanently; and it is only fair to add, that quite a number of them were of several years' standing, occurred in persons of middle age, and were the result of unusual excesses.

The symptoms that I have briefly considered are of real importance. More probably than any other manifestations of physical debility do they lead to deeply deplorable results.

In their wake follows that dreaded mental condition—hypocondriasis, which, when once it firmly

possesses a man, unfits him for every duty. As it has been doubted whether the resources of electro-therapeutics are capable of affording any decided and lasting benefit in these diseases, I here record not only as the result of my own experience, but from a knowledge of the experience of others, that no case in which there have been reasonable grounds for hope can be said to have been fairly treated until the proper applications of electricity have been attempted. The records, I am firmly persuaded, justify the assertion that of cases of impotence not dependent on incurable organic disease, the majority will not fail to be more or less improved by electricity in some of its forms or methods of application, even after the failure of the internal administration of medicine.

A CASE OF

TRAUMATIC PARALYSIS OF THE SUPERIOR RECTUS AND INFERIOR OBLIQUE MUSCLES OF THE EYEBALL,

WITH APPARENT ATROPHY OF BOTH OPTIC NERVES, TERMINATING IN COMPLETE RECOVERY.

By CHARLES S. BULL, A.M., M.D.,

ASSISTANT-SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY, MICROSCOPIST TO THE MANHATTAN EYE AND EAR HOSPITAL.

THE following case of injury to the head and spine, causing complete paralysis of the superior rectus and inferior oblique muscles of the eye, is one of peculiar interest, as there was associated with the paralysis of the muscles an affection of both optic nerves so perfectly resembling a progressive atrophy as seemed to demand an unfavorable prognosis, and yet resulted in a complete recovery of vision. The patient was a young man, 28 years of age, of a sallow, unhealthy complexion, a book-keeper by occupation, who was seen by the writer at the New York Eye Infirmary in November, 1872. Six weeks before I saw him he had fallen down a long flight of steps, and struck upon his back and vertex. He was taken up in an insensible condition and carried to a drug-store, where it was discovered that his right arm was fractured about half-way between the shoulder and the elbow. He remained unconscious for about an hour, and was then able to walk three blocks to a car, and rode home. He complained of feeling numb along the spine and lower extremities, but had no difficulty in walking, except from a feeling of vertigo. He also said that he could not see well, and complained of diplopia. During the six weeks that he was confined to the house with his fractured arm he suffered from no unpleasant symptoms consequent upon the fall, with the exception of the dimness of vision and the diplopia. When I first saw him there was nothing abnormal to be seen about his eyes, on a cursory examination, except a localized subconjunctival redness in the region of the inferior rectus muscle of the left eye. This, he told me, had been much more extensive, and had made its appearance soon after the accident. On testing the vision of each eye separately, I found that with the right eye he could read $\frac{20}{20}$ of Snellen's types with some little difficulty, but with the left eye he could only read $\frac{20}{100}$. There was no improvement in either eye by any glass, spherical or cylindrical. The diplopia was still very annoying, so that he habitually kept the left eye closed. On examining him very

carefully, it was found that he had paralysis of the superior rectus and inferior oblique muscles, so that with binocular vision there was not only vertical and lateral diplopia, but the image corresponding to the affected eye also stood inclined to that of the other eye.

The ophthalmoscopic examination showed a most interesting state of affairs. Both optic nerves were of a brilliant white color, as markedly discolored as we see them in cases of advanced atrophy. Their outlines were sharply defined against the red background, and the retinal arteries were reduced in calibre to mere threads: they were barely recognizable. The veins were, perhaps, a trifle engorged. There was no atrophic excavation of the optic papillae, as we usually see it in advanced atrophy of the optic nerves; and its absence I explained by the short time that had elapsed since the accident. But there were two points in the case that I could not explain, viz.: First, the apparent rapidity of the course of the atrophic degeneration of the nerves, as evinced by their color, and the condition of the retinal arteries, without a single sign of any inflammatory process either in the nerve or eye; and, second, the remarkable fact that, with an apparently markedly atrophic nerve in the right eye, his vision was yet almost normal. The only explanation that occurred to me, to account for the rapid progress of the nerve degeneration, was that a hemorrhage had occurred from the central artery of the retina in the course of the optic nerve, which by compression had cut off the nutritive supply of blood to the nerve tissue, and it had consequently atrophied. There were probably also one or more hemorrhages at the base of the brain at the time of the accident, which had compressed the two filaments of the third nerve, which supply the superior rectus and inferior oblique muscles, and had caused paralysis of these muscles. Yet it would seem rather a curious coincidence that a hemorrhage should have occurred into both optic nerves; and the subsequent course that the affection ran went far towards rendering this explanation unsatisfactory. The result might have been traced to a fracture at the base of the skull, involving both optic nerves in front of the chiasm, or both optic tracts behind it. But if this were the case the main trunks of both third nerves would have ruptured, and we should have had paralysis of all the ocular muscles supplied by these nerves, and probably also paralysis of the superior oblique and external rectus, owing to the fourth and sixth nerves being involved. Moreover, the patient did not have a single symptom of a fracture at the base of the skull. His hearing has never been affected, and since he recovered his consciousness after the accident he has felt perfectly well. I resolved to watch the case; and, by way of experiment, he was ordered to take the iodide of potassium in ten-grain doses three times a day, and carry it up to toleration. At the expiration of a month he went south, and while there the eyesight improved somewhat; but while there he fractured the same arm again, and during the necessary confinement the vision grew worse. While south he was bled several times from the left temple, but without any improvement to the vision or the diplopia. In April, 1873, six months after the accident, he came again to the Infirmary, and an examination showed the eyes to be in the same condition. He was then advised to go into the country and try some manual, out-of-door work, which he did, and remained there till the following year. In April of this year he presented himself at the Infirmary, with the remark that he was entirely well, but that his eyes became very soon fatigued when he used them for reading or

writing. On examining him, his vision in *both* eyes was normal, reading Snellen xx at 20 feet. His range of accommodation was normal, and the diplopia had entirely disappeared. An ophthalmoscopic examination showed a perfectly *healthy* pair of optic nerves, normal in color and outline, and the retinal arteries had *regained* their natural size and appearance. I dilated his pupils and paralyzed his accommodation, but could find no error of refraction to account for his asthenopia. There was no insufficiency of muscular power in any of the muscles, and I was entirely at fault to account for the asthenopia. He was ordered a pair of convex glasses, of 36 inches focal distance, to use for reading and writing, and, after a two-weeks' trial, has expressed himself satisfied with them.

The interest of the case centres in the obscurity of origin and very doubtful causation of the trouble, and in the complete restoration of the functions of the optic nerves, which at first were apparently undergoing rapid atrophic degeneration.

214 WEST 41TH STREET.

WOUND OF THE TENDO-ACHILLIS.

By T. H. KEARNEY, M.D.,

PROFESSOR OF PRINCIPLES OF SURGERY IN THE MIAMI MEDICAL COLLEGE, CINCINNATI, OHIO.

IN THE RECORD of May 15th a case of incised wound of the tendo-achillis is reported by Dr. Geo. H. Mitchell. The notes of that case are so brief that, on some points at least, I find it difficult to comprehend it. The case is one of so much interest, and differing in its results so widely from such cases in general, that it is to be hoped Dr. M. will give it, at some future time, more in detail.

The following case has recently been under my own observation; and, it will be noticed, resembles Dr. Mitchell's only in the manner of its causation, but contrasts strongly with his in the progress of the reparative process. The coincidence of the two accidents happening in precisely the same manner strikes me as being very remarkable; for the occurrence of such an injury, happening in that particular way, would be strange even in a solitary instance.

Mr. B., about forty-five years of age, and in rather delicate health, being the subject of hæmoptysis, etc., was attempting to wash his feet at a stationary wash-stand. While standing on one foot, the other, which had been resting on the edge of the marble, suddenly slipped, and his heel struck the bottom of the porcelain basin with such force as to break through it and to divide the tendo-achillis against the edge of the broken ware. The basin, it may be stated, was previously cracked, a circumstance that contributed to the result. This happened on the 20th of November last, and I saw Mr. B. in a very short time after the occurrence. On examination there was found a transverse wound, about an inch and a half in length, and situated just above the point where the tendon becomes free from attachment to the bone. There had been moderate bleeding. The tendon was completely and smoothly divided, and its upper cut extremity was retracted to the extent of about one inch. The cut surface of the lower extremity presented itself in the wound. Relaxation of the gastrocnemius by flexion at the knee, and full extension of the foot, allowed of the close approximation of the divided ends. The limb was therefore secured in this position by an anterior splint, and the wound closed by a few inter-

rupted sutures and strips of plaster. Nothing more seemed necessary, and therefore the question of using sutures in the tendon itself was not considered. A simple evaporating lotion was ordered as soon as inflammatory heat began to be manifested. The splint was replaced by strips of plaster attached to the sole and instep, and connected by tapes with a collar of plaster encircling the limb just above the knee. A very moderate degree of inflammatory action took place, the tenderness extending upwards, probably, throughout the whole extent of the sheath of the tendon. The amount of suppuration was very limited, and the healing of the wound proceeded quite satisfactorily, though slowly. The maintenance of the relaxation of the muscle, by the means already mentioned, and the accurate coaptation of the ends of the divided tendon, by compress and plaster, constituted the main objects of the treatment. Slowly but steadily the injury was repaired, and on Feb. 12th I made my last visit and inspection of the part. Then the wound was entirely healed, and Mr. B. was moving around with the aid of crutches and a high heel to his shoe. A few days since I met him on the street, walking without the aid of a cane even; and only complaining of some remaining slight limitation in the movements of the joints. This result I should regard as highly satisfactory if I had not read the account of Dr. Mitchell's case. Professor Gross says of such injuries that reunion of them "will certainly seldom take place under any circumstances, however propitious." Had I reported my case a few weeks sooner, I might have been led into the use of a somewhat boastful tone. But in view of the history of a similar case, which sets forth the facts that on the fifth day "the patient rises on a cane," and "attends to business and other duties" on the seventh, I am bound to record my patient's weeks of tedious recovery with becoming modesty. What, it may be fairly asked, was the condition of the parts in Dr. Mitchell's patient at these early periods? Could there, possibly, have been any organization of the reparative material sufficient for the restoration of the function of the injured part in any degree? For these are points which cannot be determined from a reading of the brief account given. Paget and others have demonstrated the prompt repair of divided tendons in rabbits, when the section was made subcutaneously and carefully. But results fully equal to those are hardly to be expected in man; and particularly do the results following carefully performed subcutaneous section differ from those that attend open wounds, more particularly when these latter injuries partake somewhat of the nature of lacerated wounds. It will be noticed that Dr. M.'s case was attended with "copious arterial hemorrhage," such as required a resort to "torsion and styptics" for its control. Now, such treatment of a wound, of course, forbids all possibility of any form of prompt or speedy union. The case appears to have been reported on "the thirteenth day after the injury;" and perhaps I may be permitted to suggest that the actual result could hardly have been determined so soon; and on the other hand, a very interesting postscript might be written.

The author of the report asks the questions, "Is this result exceptional? And what would be the effect of bringing the cut ends together by silver sutures?" If I may presume to reply, I will say in answer to the first, that, in the light of recorded experience it is, most assuredly, "exceptional;" and as to the second interrogation, would it not be like painting the lily to attempt any further improvement on such a result as he has obtained.

C. CINCINNATI, June 9, 1874.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

First Surgical Division.

DR. BROOKS, HOUSE-SURGEON.

The first bed we visited contained a patient, female, *et.* 40 years, who had received an extensive lacerated wound of the leg produced by the wheel of a street-car. The limb was lying in a fracture-box; sloughing was abundant, and every effort possible was being made to get her general condition up to the amputating point. Her stomach, inclined to be irritable, was left at rest as much as possible from the perturbing influence of remedies. Quinine was administered hypodermically in the form of Lente's solution. This form of solution is employed for the purpose of preventing the formation of abscesses, having never been known to produce an abscess in this hospital.

The following is the formula for its preparation which varies, but not essentially, from the formula published by Dr. Lente:

R. Quinine Sulph. grs. i.
Aqueae. i.
M.

To this add sulphuric acid drop by drop until the solution clears up, and then add π iv. of alcohol and grs. iv. of carbolic acid. In preparing the solution, first heat the water until it vaporizes; then add the quinine, clear the solution with the acid, and then add the alcohol and carbolic acid. Thirty minims is equal to between two or three grains of quinine, and was administered to this patient two or three times a day. The remark was made that the effect of such a dose, administered hypodermically, was sometimes equal to that produced by ten grains of pure quinine.

PENETRATING WOUND OF THE ABDOMEN.

A man had received a wound in the abdomen produced by a ball from a pistol. The ball had struck the abdominal walls about half an inch above the umbilicus, and nearly in the median line; passed obliquely through the muscles, and entered the abdominal cavity. Well-marked peritonitis was developed within three hours from the reception of the wound. Twenty-four hours after the reception of the wound the peritonitis was very violent indeed. Opium had no controlling effect, although administered in heroic doses. Post-mortem revealed perforation of the pyloric extremity of the stomach.

NECROSIS OF FIBULA.

A very large portion of the fibula had been removed. The operation had been performed after blanching the limb by the application of Esnarch's bandages, and was done with as much ease as it could be performed upon the cadaver.

COLLES'S FRACTURE.

A case of this description was noticed, which was dressed by the application of splints about four inches in length and secured by adhesive plaster. This is a method of dressing this form of fracture not infrequently adopted in the Division, and the results obtained are equal to those obtained by any other form of dressing. Pistol-shaped splints are not used at all, or any special attention paid to placing the hand in that peculiar position.

CUT THROAT.

This patient had made the ordinary incision from ear to ear, hoping thereby to do himself and his country a favor, but, as is usually the case, his efforts were not crowned with success, and he was brought in for treatment. These cases are treated by first bringing the edges of the wound together and securing them with sutures, if the trachea has not been opened. When the trachea has been opened the wound is left to take care of itself, for experience has taught that the cases do much better than when those wounds are closed with sutures. They are permitted to heal by granulation. Closure of the wound is unsafe, because of the liability of pus producing fatal results. It may be that, after the lapse of several months, a small fistulous opening will remain, that may require closing. These are the principles which govern the treatment of this class of cases in this Surgical Division.

REFRACTURED THIGH.

The patient had been in bed five weeks, and had extension maintained by means of Buck's extension apparatus. The fragments were held in apposition and supported by light lateral splints. The special point of interest was the amount of weight that had been applied and the length of time it had been continued without producing apparent deleterious results.

Thirty-two pounds had been applied and continued for more than a week.

The shortening, which was nearly two inches before the bone was refractured, had been reduced to less than one inch.

SYNOVITIS.

A good result was noticed in a case of this character, which had been treated by means of compressed sponges. Apply dry sponges over the joint and bind them down by means of a roller bandage. Then wet the sponges, and an equable support and pressure is maintained around the joint, which promotes absorption of the fluid, and in very many cases contributes to a rapid recovery.

PISTOL-BALL THROUGH THE BRAIN.

This case was remarkable from the fact that aphasia did not occur until 48 hours after the wound had been received. After aphasia was developed, intelligence remained and continued for some hours.

When post-mortem was made, it was found that both anterior lobes had been destroyed. The third anterior convolution upon right side was entirely destroyed, and upon the left side softened and broken down.

HIP-JOINT DISEASE AND WAXY DEGENERATION OF INTERNAL ORGANS.

Several months ago this lad, who had long suffered from hip-joint disease, begged of the visiting surgeon to operate upon his hip so that he might have a little ease from his sufferings before he died. The appeal was too strong for resistance, and the operation of excision was performed. At the time of the operation there were evidences of waxy kidney, the liver was enormously enlarged, and, in all probability, waxy, and altogether he was in a most precarious situation. Improvement in his general condition began at once after the operation. The wound in the hip is nearly healed. His liver has diminished in size very much, and the waxy changes in the kidneys are apparently arrested. He is in and out of the hospital daily, and is constantly improving. The practical lesson to be learned from this case is, that operations for the removal of dead bone or accumulation of pus are not

contra-indicated by the presence of waxy degeneration of the internal organs.

Medical Division.

HYDRO-PERITONEUM.

During our visit to the hospital to-day, we noticed, first, the patient who had had paracentesis abdominis performed upon him nearly two months ago. The accumulation, when the operation was performed, had been of only about six weeks' standing. Since the operation there has been only a moderate accumulation of fluid, and the man is feeling remarkably well. He is regarded as a standing evidence of the propriety of performing the operation early.

Another case of the same kind was noticed, that possessed features of interest. There was no evidence of specific disease, waxy liver, or cirrhosis. There was probably renal disease, although no casts had yet been found in the urine. The visiting physician expressed the opinion that the renal disease did not account for the predominant amount of hydro-peritoneum. There was a small amount of hydro-thorax. The operation of tapping had already been performed fourteen times within about eight weeks. An effort was being made to remove the fluid by means of acetate of potash and infusion of digitalis; but it was believed that it would soon become necessary to repeat the operation. The doctors were unable to determine the cause of the hydro-peritoneum.

NEURALGIA AND QUININE.

Three cases of neuralgia affecting the sciatic and anterior crural nerves were seen. The three cases were being treated with large doses of quinine. The question of malaria was not mentioned. Each man received twenty grains a day. One had almost entirely recovered. No cinchonism had been produced in either case. The other cases had not been benefited by the treatment, and were to receive thirty grains a day, and so on, until cinchonism was produced, if the disease did not yield before that point was reached. Thirty grains a day cured the other cases.

CABINET OF MORBID PHENOMENA.

This man had cardiac disease; venous pulsation in the jugular was associated with it; probable renal disease; and enlarged spleen. The new feature in his case was the occurrence of jaundice. The jaundice was regarded as being produced and protracted by chronic gastro-duodenitis. His visiting physician had ordered the application of a blister over the epigastrium, and its action had been attended with good results. The additional remark was made that the application of a blister over the epigastrium in this class of cases (jaundice dependent upon chronic gastro-duodenitis) was a favorite, and the most beneficial item in the treatment. Another point with regard to the treatment which was insisted upon was, to particularly avoid all active measures, such as mercurials, purgatives, emetics, etc. The kidneys, however, may be stimulated to assist in carrying off the accumulation of bile. The passage of only a limited amount of bile may persist for a long time, and in this way a chronic gastro-duodenitis may prolong a jaundice perhaps for two years.

KNEE-JOINT.

The case was interesting chiefly with reference to one point. One knee-joint was red, swollen, and painful, and the question was, is the affection synovitis or articular rheumatism. The patient was aged eighteen.

Family history negative. Never had had rheumatism or intermittent. After exposure to cold and wet, he felt pain in head and back; urine became scanty and high-colored, and the bowels were constipated. When admitted to the hospital, Jan. 18, his pulse was 120 and temperature 102°; Jan. 19, T. 102½; Jan. 21, T. 101½; Jan. 22, T. 100½. The febrile movement was regarded as specially significant of rheumatism. Rheumatism affecting a single joint is rare, but such cases do occur, says the visiting physician, and cardiac complication may occur with rheumatism affecting a single joint, as well as when several joints are affected. Correct diagnosis is important, as having a bearing upon the treatment; for the treatment is to have reference to forestalling the cardiac complication. Indeed, in another ward a case of monarthritic rheumatism was seen, in which evidence of endocardial complication had been developed since her admission into the hospital.

Progress of Medical Science.

POISONING BY COLCHICUM IN BEER.—It is well known that within the last ten years the production of various kinds of beer has increased five hundred per cent., while the supply of hops has increased but slightly. It has been surmised that some substitute for the bitter principle of hops is in use among the beer manufacturers. It is notable that the demand for colchicum autumnale has increased very much within the last few years, and it has been supposed by many that the alkaloid colchicine may be the substitute employed.

Dr. Boetern, of Faaberg, in Denmark, writing to the *Hospitals Tidende*, tells the following incident, which proves that this substance is actually used:

He and three companions dined at the house of a friend, and during dinner drank some English ale. About a quarter of an hour afterwards they began to have symptoms of poisoning. In all the cases there was cardiac depression and frontal headache. Three of them had vomiting, and the Dr., in addition, had a profuse watery diarrhoea. A domestic who had also taken some of the ale was similarly affected. There was cardiac oppression until vomiting took place, when there was a feeling of relief; but the oppression soon returned only to be relieved by the vomiting. The following day they all complained of burning heat in the head, thirst, and a sensation of chilliness, and one of them had severe rheumatic pains in the back and limbs. The next day the Dr. had a severe outbreak of lichen over the whole body, but it gradually disappeared after five days' use of warm baths and mineral acids. All the cases finally recovered.

The ale had been imported in a barrel from England, and that drank on the day in question happened to be some of the last in the barrel. Chemical analysis showed the presence of colchicine in considerable quantity.—*Hospitals Tidende*, Nov. 11, 1873.

MICROSCOPIC EXAMINATION OF ATMOSPHERIC DUST.—In order to acquire a knowledge of the bodies diffused through the air, Douglas Cunningham instituted a series of examinations of the atmosphere in the business quarter of Calcutta. The instrument used for this purpose was the aeroscope of Panchet. The results of the examinations may be summed up as follows:

1. Bacteria were never found in the dust of dry air, but were common in the particles deposited from moist air.
2. By mixing the dust of dry air, exposed to tropical heat, with putrefying fluids, fungi and bacteria were

rapidly developed, although previously not a trace of them was to be discovered.

3. Spores and other vegetable cells are constantly present in atmospheric dust, and usually in large numbers. The majority of them are living, as well as capable of growth and further development.

4. There exists no connection between the number of organisms in the atmosphere, or any specific character of the organisms, and the prevalence of an epidemic.

5. The amount of inorganic and amorphous particles suspended in the air is dependent on the degree of moisture of the atmosphere and the violence of the wind, while these circumstances have no influence whatever on the number of organized atoms.—*The Lond. Med. Rec.—Alg. Med. Cent. Ztg.*, xliii. 34.

TAR CANCER.—At a recent session of the German Surgical Society in Berlin, a paper was read by R. Volkman on "*Tar and Soot Cancer.*" The writer had observed some peculiar affections of the skin in persons engaged in paraffine works. These affections were apparently caused by irritation from some of the tarry products of the coal, and occasionally culminated in a disease that resembled in every particular the chimney-sweep's cancer described by the English. The first stages of the affection manifested themselves in a violent itching which among the workmen goes by the name of "tar-itch." Following this the epidermal layer becomes thickened, and the functions of the sweat-glands and sebaceous follicles are stimulated. The epidermis is shining and the cutis becomes leathery and wrinkled, showing little elevations, in a short time, the size of pin-heads, sometimes smooth and sometimes horny as in *ichthyosis hystrix*. Psoriatic patches are very common, together with "acniform papules and hard, occasionally confluent tubercles." These appearances occur in various situations of the body, and in the milder cases are liable to be mistaken for syphilodermata, or in the severer ones for *erythema nodosum*. At this stage of the disease, if the occupation be abandoned, the affection is curable. If suffered to take its course, however, the hyperplasia progresses with inflammatory action and ulceration, and the tar-cancer is developed. The back part of the scrotum and perineum are attacked by preference, and extensive destruction of tissue may occur in this situation. In comparison with other forms of cancer, the course of this disease is decidedly benign. The treatment consisted in maintaining perfect cleanliness, and in cultivating a new integument by transplantation or grafting.—*Berl. Klin. Woch.*, 18, 1874.

STATISTICS OF CROUPOUS PNEUMONIA.—During the years 1857-73 inclusive, 10,303 patients were treated at the Polyclinic in Heidelberg. Of these, 261 were cases of croupous pneumonia which Dr. Jurasz has tabulated in various ways with the view of determining certain interesting facts with regard to the disease. 102 of the cases occurred in children under 10 years of age, and the largest number (16 per cent.) in the third year. After the 1st decennium, the frequency of the disease appears to diminish until the period of middle age is passed. The number of cases in the second, third, fourth and fifth decennium were comparatively small. The least number of cases occurred from 20 to 30; the largest number (46 per cent.) from 70 to 80. These statistics, therefore, do not sustain the commonly accepted rule that pneumonia is essentially a disease of strong manhood.

One hundred and twenty-one of the 261 cases were in males, 140 in females. The implication of this, however, as to the influence of sex, must be modified by referring to the statistics regarding the whole number of pati-

ents, which show a large excess in the number of females over that of the males. Taking this into account it was found that 27 per cent. of the cases were males, and 2.4 per cent. females. Calculating in a similar manner with regard to the 102 cases that occurred in children under 10 years of age, the result shows that 3 per cent. were boys and 27 per cent. girls.

In reference to the situation of the disease in the lungs the statistics indicate that the right lung was oftener attacked as a whole than the left, but that where single lobes were affected the left lower lobe was more frequently attacked than the right lower. Next in frequency after these came the right upper lobe, then the left upper, and finally both lungs together. In pneumonia duplex the inflammation always began in the two lower lobes simultaneously.

A chill ushered in the disease in every instance excepting in small children. Under 3 years of age, the chill was never observed. The duration of the disease was accurately determined in only 146 cases. Of these 60 ran their course in just seven days, and 115 of them in from five to nine days. Phthisis, induration, abscess and caseous pneumonia, which are often mentioned in the text-books as sequelæ of croupous pneumonia, were not observed in a single instance.

But 30 of the 261 cases terminated fatally, or 11.5 per cent. The ratio of mortality was least between the ages of 10 and 30, and next, under 10. After 50 the mortality increased rapidly with the age. Judging from the statistics the writer concludes that the mortality of the disease depends upon the patient's power of resistance, the complications and the extent of the inflammation. The location of the inflammatory process appeared to have no influence in this connection.—*Berl. Klin. Woch.*, 18, 1874.

NEW VIEWS ON AMMONÆMIA.—The term *febris urinosa*, or *fièvre urinaire* of the French, has been used to describe a peculiar complex of symptoms in certain urinary affections that are exceedingly fatal. These symptoms consist of more or less violent fever, with irregular chills, marked gastric disturbance, as shown by a dry tongue, frequent vomiting, disinclination to food and slight diarrhœa; at the same time there is mental disturbance, the patients at first are apathetic, gradually become somnolent, answering briefly to inquiries, later become mildly delirious, and finally die in a comatose condition. In other cases the symptoms are only febrile and gastric. General convulsions or irritation of the motor-nerve system are exceedingly rare. As to the amount of urine passed, it is somewhat less than normal, though not much. It is, however, passed more frequently than usual, generally with some distress, is always alkaline from the presence of the carbonate of ammonia, and contains pus and blood in varying quantity. There is often incontinence, and the urine which escapes in this way gives off a strong ammoniacal odor that can be perceived at some distance. Ammonia cannot be detected in the breath with any certainty. The fact is, that ammonia plays such an important part in the disease that the name ammonæmia was selected for it by Jaksch and Treitz, who supposed that it expressed the *materies morbi*. Rosenstein, of Leyden, dissents from this opinion most decidedly. Experiments on animals that have been injected with carbonate of ammonia show that intense motor as well as cerebral disturbances are peculiar to ammonia poisoning.

To reach the cause of the trouble, Rosenstein says that we must go a step further back and inquire into what produces the ammonia found in the urine. It is doubtless true that it arises from the decomposition

of urea with the addition of water, and it has been supposed that mucus, acting as a ferment, causes the decomposition. This, however, is an error in the majority of cases. Even when blood and pus originate in the bladder the urine is always acid, unless it be retained a long time, as by a stricture, or by hypertrophy of the prostate. Mucus acting upon the urine, even outside the bladder, is slow in making it alkaline. It is important to recognize these points, for it will explode the old notion that pus in the bladder produces an alkaline urine, and pus in the kidney an acid one. Traube was the first to show that alkalinity often follows the introduction of the catheter, and that the urine which was previously free from bacteria, is now loaded with them. In nearly every case of alkaline urine, bacteria can be found; in the remainder it may be due to the injection of certain substances that produce an alkaline urine, or possibly to mucus.

Rosenstein thinks it probable that the symptoms so often ascribed to ammoniemia, are not due to it, for the reasons above named, but are probably due to putrid infection from the absorption of bacteria into the blood. If this theory be true, then the treatment by benzoic acid, as recommended by Frerichs, Robin, and others, is not applicable, and it would be better to prevent the decomposition of the urea by employing anti-fermentatives, such as carbolic acid and quinine.—*Deutsche Zeitschr. f. pract. Med.*, 20, 1874.

THE STRUCTURE OF THE THYROID GLAND.—The views of Boéchat have lately been published, and contain some points which are new. He differs from previous investigators in asserting that the alveoli of the gland freely communicate with one another, are not round cavities, but have an irregular form. The vesicular walls consist of a simple layer of epithelium which separates them from the numerous lymphatics. The epithelium cells are broader than they are long, and are consequently not columnar, as Verson has stated. During early life the vesicles contain a tenacious fluid in which is a variable number of nuclei. In later life, they are filled with colloid material. The lymphatic vessels form large cavernous networks, which are distributed throughout the connective-tissue stroma of the gland.—*Allg. Med. Central-Ztg.*, 43, 1874.

PARASITIC GROWTHS IN THE RUBBER NIPPLES OF NURSING-BOTTLES.—Mettenheimer of Schwerin, who has devoted a good deal of attention to the development of parasitic fungi on the rubber attachments of nursing-bottles and breast-pumps, has lately had further experience in this direction. He has satisfied himself that the action of warmth and moisture, combined with the act of sucking, produce changes in the structure of the rubber which may be a source of disease. He had found by previous examination that the fungi were apt to form on the surface of the rubber, if the strictest attention were not paid to cleansing it. He now finds that the interior may become the seat of various sorts of foreign material even where the surface is kept clean. This is partly parasitic and partly not. The rubber so affected swells up, loses its glossy bright appearance, becomes rough, and has a yellowish color which is due to the fungous growths that are firmly fixed in the tissue. It now tears easily and has lost its elasticity. Within, it contains cavities, which are filled by fat drops, branching fungous filaments and spores scattered about or grouped in spaces or clefts. This condition is most apt to occur when the infant has teeth, and especially if the rubber be torn.

It is inferred that the same change may take place in drainage-tubes, pessaries, etc., if they are allowed to

remain for a length of time in situ. For this reason it is probable that the red rubber which is recommended for these purposes possesses some important advantages. The entire substance of the tissue is impregnated with powdered hematite, the peroxide of iron, which fills up the interstices between the fibres, and prevents the ingress of foreign matters.—*Memorabilien*, 3, 1874.

DRAINAGE-TUBES AND INTRA-PERITONEAL INJECTIONS IN OVARIOTOMY.—The successful results which Spencer Wells, Peaslee, and Sims have gained by the introduction of the drainage-tube, have induced Nussbaum, of Munich, to resort to it in his recent cases. He agrees with Sims that it should be employed in every case, for he believes that the shock of the operation will not be much increased by this additional step, while it serves as a safeguard against one of its greatest dangers. If, however, it be found necessary to do it subsequently, the shock to the patient will be materially increased. He relates a case in which he tried this new method with success. He feels assured that without it the termination would have been fatal. After removing the tumor, which was of large size, and had a short pedicle, he succeeded in allaying the hemorrhage, by several applications of the actual cautery, but he was unable to prevent the oozing from the deeper portions of the abdominal cavity. Fearing that the blood and serum would collect, and might give rise to septicæmia, he determined to establish an opening through Douglass's cul-de-sac. This he did without much difficulty, as the tissues were found to be thin at that point. He then introduced a drainage-tube through the incision, and brought it out through the abdominal opening, and fastened both ends together. The edges of the abdominal wound were then brought together, leaving a space for the drainage-tube. Through this he injected weak solutions of carbolic acid until the fluid which escaped by the vagina was quite clear. During the subsequent three hours, however, a very large amount of bloody serum passed out through the tube. Had this fluid remained it would, doubtless, have been absorbed by the system and the patient would probably have died in a few days of septicæmia. Nussbaum states that in seventy-eight cases in which he has done this operation, he has lost twenty-eight from septicæmia, and he feels confident that the majority of these would have been saved by the drainage-tube. In five recent cases he has adopted the new method, and though he does not feel warranted in basing conclusions on such insufficient statistics as they will furnish, still he feels that the use of the tube, combined with frequent injections through it, have been of the greatest value. He even goes so far as to say that a continuous stream of some mild antiseptic fluid may prove a necessity in certain cases, and he has no fear for the influence of air or water upon the bowels or peritoneum. He adds that the aim of all these operations should be to secure the cleanest cuts with as little wounding of the tissues as possible, and to arrange the parts in such a way that an avenue of escape may be offered at the most dependent portions of the wounds for any secretions that collect.—*Ärztliche Intell. Blatt, Memorabilien*, 3, 1874.

PLACENTAL SYPHILIS.—The chief difficulty which has lain in the way of deciding whether certain placental diseases were syphilitic or not, is due to the fact that the embryo had been macerated by the fluids so that it was impossible to distinguish any reliable sign of the disease. Since Wegner, in his work on bone-syphilis, has shown that osteo-chondritis of the foetus is a constant phenomenon in hereditary infection, we have been furnished with a diagnostic mark in these

cases. Frankel, of Breslau, has undertaken to trace the disease a step farther back, viz., to the placenta; and having a large number of specimens at his disposal, he has examined them with the view of discovering the pathological changes produced by the disease. He has found that affections of the villi are characteristic, and must be regarded as the most frequent form of placental syphilis. This change he believes to be a peculiar growth of granulation cells in the placental villi, such as have been described by Ercolani. The gross changes in the placenta are increase in volume, weight, and consistence; the villi are plump and thick, which is due to the existence of numerous granulation cells, of medium size, that appear to come from the vessels, and proliferation of the epithelial covering of the villi.

If this change has extended throughout the whole placenta, the fetus will die in utero; if, however, it is circumscribed, life may be preserved. There may also be hyperemia, extravasations of blood, more or less formation of connective tissue, but they are not characteristic of syphilis. In one case, where the mother was known to be syphilitic before conception, the maternal placenta was the seat of gummy growths. In another, where infection occurred in the later stages of pregnancy, the fetus and placenta appeared to be unaffected.—*Habilitationsschrift*—*Berl. Klin. Woch.*, 21, 1874.

FREQUENT CAUSE OF MISCARRIAGE.—Dr. J. F. Bird, of Philadelphia, writes: "It not unfrequently happens that miscarriage occurs in the same individual about the fourth month consecutively for several pregnancies. The cause is often to be found in the fact that as soon as pregnancy occurs the uterus settles down and retroverts. In this abnormal position miscarriage must necessarily occur as soon as the farther development of the fetus becomes impossible. The uterus cannot rise into the cavity of the abdomen, and cannot become enlarged much beyond the fourth month, because of its position within the pelvic cavity. It must therefore disgorge itself. The appropriate remedy is the use of a proper pessary in the early months of utero-gestation. This should be removed as soon as the uterus is so far developed as to render it impossible either to prolapse or retrovert."

A Mrs. B. became a patient of mine in her sixth or seventh miscarriage. I had not seen her in any of her former miscarriages. She was exceedingly anxious to have a living child. In her next succeeding pregnancy I introduced a double lever hard-rubber pessary, and directed her to wear it until after the fourth month. She removed to Boston, soon after. At the request of her husband I went to Boston, and removed the instrument on the 12th of June, 1872. Whilst there I introduced the parties to Dr. Wheeler, of Chelsea, who took charge of the case. On the 1st day of December following, she was delivered of a fine healthy male child, and a few months ago presented the boy to me in my office. This case illustrates my position, and could be supported by a number of others of the same character.

TAMPONS OF COAL-TAR IN VAGINITIS.—Dr. Siredey derives great success in treating vaginitis with tampons of tow well soaked in "coal-tar saponine." This appears to be an excellent modifier of inflamed surfaces; being, moreover, an excellent disinfectant. It is best to remove the tampon after twenty-four hours; to use injections the second day, and to renew the application on the third day.—*Jour. de Méd. et de Chirurgie Pratique*.

ARMY STAFF RANK.

THE question of army staff rank, in which the profession has been so much interested for many months past, has at last been settled. It is well, after the struggle is over, after the passage of the army bill by Congress, to see what has really been accomplished. In order to do this intelligently we shall quote that part of the bill referring to the provisions for the medical department. Section 7 of said bill provides:

"That the Medical Department of the Army shall hereafter consist of one surgeon-general, with the rank, pay, and emoluments of a brigadier-general; one assistant surgeon-general, and one chief medical purveyor, each with the rank, pay, and emoluments of a colonel; and two assistant medical purveyors, with the rank, pay, and emoluments of lieutenant-colonels, who shall give the same bonds which are or may be required of assistant paymasters-general of like grade, and shall, when not acting as purveyors, be assignable to duty as surgeons by the President; fifty surgeons, with the rank, pay, and emoluments of majors; one hundred and fifty assistant surgeons, with the rank, pay, and emoluments of lieutenants of cavalry for the first five years' service, and with the rank, pay, and emoluments of captains of cavalry after five years' service; and four medical store-keepers, with the same compensation as is now provided by law; and all the original vacancies in the grade of assistant surgeon shall be filled by selection by competitive examination, and the Secretary of War is hereby authorized to appoint from the enlisted men of the army, or cause to be enlisted, as many hospital stewards as the service may require, to be permanently attached to the Medical Department, under such regulations as the Secretary of War may prescribe. And the number of contract surgeons shall be limited to seventy-five on or before the 1st day of January, in the year 1875; and

thereafter no more than that number shall be employed."

To those who have not given particular attention to the subject, it might appear that justice was done to the medical corps; that, in fact, the profession had received all that it asked for. The contrary is so far the case, that instead of gaining anything in the way of rank—instead of elevating the status of the medical officer—instead of giving encouragement for the right men to stay in the service, offering inducements for the competent young medical man to enter the service, our legislators have taken a step or two backward.

By the provisions of the act in question, two lieutenant-colonels and ten surgeons are cut off. This certainly does not look like an intention on the part of our members of Congress to concede to the wishes of the profession of the United States. If we are mistaken in our interpretation of the spirit of such a legislated measure, we should like to have our error pointed out to us.

In regard to the matter of promotion, the following clause of the same bill will throw some light, and may prove significantly suggestive, to the coming medical man:—

"SEC. 7. That as vacancies shall occur in any of the grades of the Ordnance and Medical Departments, no appointments shall be made to fill the same until the numbers in such grade shall be reduced to the numbers which are fixed for permanent appointments by the provisions of this act; and thereafter the number of permanent officers in said grades shall continue to conform to said reduced numbers; and all other grades in said Ordnance and Medical Departments than those authorized by the provisions of this act shall cease to exist as soon as the same shall become vacant by death, resignation, or otherwise, and no appointment or promotion shall hereafter be made to fill any vacancy which may occur therein."

It will be perceived by those who know what the department was, and what it is now made to be, that all chances for promotion, for at least two or three years, are entirely gone—a pleasing and encouraging circumstance for the army surgeon, and a high compliment to the earnest entreaties of the profession in his behalf!

In spite of all this, we have no doubt that the various Congressmen returning to their homes will have the patronizing effrontery to say to their medical constituents that the army staff rank has been settled in a very satisfactory manner. We wish to say, in the name of the profession, that the question is still very far from being settled. The sooner we can open our eyes to the fact, the better prepared can each and every one of us be to make our respective representatives know that we do not endorse this measure; that we are, in fact, astonished at its provisions, and thoroughly disgusted at the fact of its final passage.

The fight, however, for the principle which we have advocated is not yet over. If we are defeated, we must not be discouraged. Far from letting the matter rest where it is, we must make renewed efforts to obtain what was originally asked. We are confident that we can yet accomplish our ends if we make use of the proper means.

Our object, more particularly at present, has been to inform our readers what has actually been done, that they may be early informed what has yet to be accomplished before justice is done to the army medical officer, and before the medical profession of the country can say that it is satisfied. But we shall take other opportunities to discuss the general merits of the bill.

Reviews and Notices of Books.

REGULATIONS OF THE UNITED STATES MARINE HOSPITAL SERVICE FOR THE COLLECTION OF HOSPITAL DUES AND THE APPLICATION OF THE FUND RESULTING THEREFROM. Washington, 1873.

ANNUAL REPORT OF THE SUPERVISING SURGEON OF THE MARINE AND HOSPITAL SERVICE OF THE UNITED STATES FOR THE FISCAL YEAR 1873. Washington, 1873.

THE Marine Hospital Service of the United States, which was organized in 1798, has received a new impetus, and has acquired an important position, more particularly as a medical institution, from the intelligent legislation in its behalf in June, 1870. The action then taken placed the Service more nearly on a par with the medical department of the army and navy, and calls for the recognition and respect of all medical men. We are indebted to the Supervising Surgeon of the Bureau of the Hospital Service for the able documents, prepared under his supervision, as evidence of the important work which the Service has accomplished for the benefit of our sick and disabled seamen.

The Marine Hospital Service of the United States was inaugurated in 1798. As a working department of the government it had a varied experience of good and bad for the first seventy years of its existence. Many evils and abuses crept into the organization which it was impossible to correct. It was knocked about from one bureau of the Treasury Department to another, and always wanted unity of purpose and judicious supervision to make it a perfect working agency. Sensible of the needs of the Service, the Secretary of the Treasury, Mr. Boutwell, pending the preparation and passage of the Act of June, 1870, availed himself of the advice of Surgeon J. S. Billings, U.S.A., who gave valuable aid to the Service in the limited time he was able to spare from his duties in the office of the Surgeon-General of the Army. Our merchant marine is, however, most largely indebted to Dr. J. M. Woodworth, the present able Supervising Surgeon, for the fidelity and zeal he has exhibited in working up the department to its satisfactory condition at this time.

The present code provides, in specific terms, for the assessment and collection of hospital dues, and for the proper distribution of the fund so created. It prescribes the proper care to be given sick and disabled seamen, in order to insure their speedy return to their duties. It aims to provide able and competent sur-

geons and assistant surgeons, by examinations similar to those required in the army and navy, who will furnish the most satisfactory relief to their patients, and command the respect of the profession. It will also meet the approval of medical men to know the purpose of the present head of the department to contribute to medical literature and instruction by the publication of well-written articles on the diseases incident to seamen, and to open the hospitals more fully for the instruction of medical students.

During the year ended June 30, 1873, 13,529 seamen were furnished medical and surgical relief, at a cost of \$422,502 98, or at a net cost to the government of \$86,657 03. The table of results obtained by the treatment of the seamen will compare favorably with that of any civil hospital, and the expense for the administration of the service is equally satisfactory. The receipts from hospital dues, which in former years fell far short of meeting the expenditures, under the present organization show a marked improvement, and in a short time will, without doubt, render the Service self-sustaining.

The Marine Hospital Service is the first organization in the country to adopt the provisional nomenclature of the Royal College of Physicians of London. By the adoption of this system the hospital records, hitherto almost valueless for comparative study and consequent profit, will be available in the future in determining many questions as to the effects of seafaring pursuits on health and life, and furnish the sanitarian the basis for important action concerning the seaworthiness of sailors.

The latest report of the Supervising Surgeon contains an interesting article by himself on "Hospitals and Hospital Construction." It is entirely in consonance with the most approved views of the day, in reference to construction, ventilation, air-space, heating, and the like; indeed no better epitome of the subject could be written. Very instructive articles follow, by Dr. Toner, on Yellow Fever, to whose paper is appended an interesting account of the Yellow-Fever Epidemic of 1873, by Dr. Woodworth and the medical officers of the Service at the various ports where the disease appeared; by Dr. Minor, on a case of Double Diaphragmatic Rupture and Hernia, annotated by the Supervising Surgeon; by Dr. Ellinwood, on Urethral Strictures; by Dr. Heber Smith, on The Sailor and the Service at the Port of New York; and by others, on similar subjects of interest and importance.

We cannot fail to notice an evidence of life and energy in the present administration of the service, as shown by the documents before us, which must result in much good to the seaman; and as the merchant-marine of our country must ever be an important element in our national prosperity, we give our hearty encouragement to every endeavor to make its organization more sound and efficient.

Comparing the average figures for the two years during which the present Supervising Surgeon has been in charge of the Bureau, with the corresponding figures for the year ended June 30, 1871—and under the operation of the same act, but before the appointment of a supervising surgeon—it will be found that the economical result of his administration has been—

To *increase* the number of customs districts in which hospital relief is furnished, nearly 27 per cent.

To *reduce* the average daily *per capita* cost of such relief about 20 per cent.

To *increase* the collection of hospital dues about 16 per cent.

To *reduce* the total cost of the service 9.4 per cent.

To reduce the net cost to the Government over 51 per cent.; and, as a consequence,

To diminish the amount of the deficiency appropriation for the current year to only 40 per cent. of that of 1871.

AN ESSAY UPON SYPHILITIC STRICTURES OF THE RECTUM. (ESSAI SUR LES RETRECISSEMENTS SYPHILITIQUES DU RECTUM.) By Dr. EUGENE GODEBERT, Paris, 1873

THIS subject, although largely written upon, is perhaps to-day one of the least clearly settled in syphilography, consequently any opinions regarding it, though they may not be conclusive, are interesting as expressing the views of one who has given attention to it. The present author has taken it as the subject of his inaugural thesis to the Faculty of Medicine of Paris, and he reproduces, in the main, the views of the well-known Parisian surgeon M. Demarquay. As a basis of his work he studies fifty-five cases, which are reported by others, and besides these he adds twelve personal cases, making a total of sixty-seven. Of these he traces a pre-existent syphilis in forty-seven cases. He alludes to Gosselin's theory of the starting-point of the process being specific ulcerations around the anus, which lead to inflammation of the lower parts of the rectum, and consequent contraction, and to the theory of Després, that these strictures result from phagedenic chancres. He divides these strictures into three classes:

1. Those which appear in the secondary period, following mucous patches, and which he thinks may be called secondary strictures.

2. Those of the tertiary period, which are due to deep syphilitic ulceration.

3. Those which appear later on in syphilis, to which M. le Professeur Trélat has given the name quaternary strictures. They consist of a fibrous thickening of the rectal walls, developed under the influence of the syphilitic diathesis. After having detailed several cases, he draws the following conclusions as to the first variety:

1. Secondary strictures result from mucous patches which have involved all the circumference of the anus.

2. They are seated at a variable height, from two to eight centimetres, but they are always more or less accessible to the finger.

3. Their height (up the rectum) does not go beyond usually one or one and a half centimetres.

The tertiary strictures are rare, but still the author thinks that they exist. He reproaches the view of Bärensprung, to the effect that they are due to a scorbutic condition of the blood. The features of these strictures are described as being round, surrounded with a ring of fibrous tissue, having a hard base involving the mucous membrane, and perhaps the muscular coat.

The quaternary stricture is a general neoplastic infiltration of fibrous tissue under the mucous membrane, due to the influence of the syphilitic diathesis. This is the view of M. Demarquay, and is the one entertained by the author. He agrees with M. Guérin as to the fallacy of the view that these strictures are due to scrofula.

Besides the conclusions already given, the author adds the following:

1. The physician should always examine or look for rectal ulcerations, secondary or tertiary, in a syphilitic patient who gives the slightest suspicion of their existence.

2. Besides a local treatment it is necessary to use specific medication.

3. When a stricture is once formed, anti-syphilitic treatment is powerless for its cure.

4. It is necessary, then, to have recourse to surgical

measures: slow and progressive dilatation, internal rectotomy with the instrument of M. Lillaux; sometimes even external rectotomy, or linear *écrasement* (a procedure followed and recommended by Verneuil, which, however, seems to be applicable only in cases in which fistulae exist). Finally, electrolysis, which has been found to be beneficial by Dr. Lefort.

5. Rapid dilatation and the use of caustics should be abandoned.

6. When the rectal touch is performed it is necessary to use the greatest precaution and not to use force.

7. Extirpation of the rectum is not to be practised for cases of stricture.

8. The surgeon need not have recourse to the operation of artificial anus, because in syphilitic strictures of the rectum the retraction is very slow; because the patient applies for treatment before obliteration of the rectum is induced, and finally, because amelioration can always be induced by the means above mentioned.

9. Cancer not being considered, syphilis is the most frequent cause of rectal stricture.

Reports of Societies.

THE NEW YORK SOCIETY OF NEUROLOGY AND ELECTROLOGY.

A STATED meeting of this Society was held at the College of Physicians and Surgeons, on Monday the 18th inst., the President, Dr. Meredith Clymer, in the chair. A large number of members and visitors were present.

An abstract of the minutes of the previous meeting having been read by the Secretary, Dr. A. T. Carroll, and passed,

DR. CLYMER introduced Dr. D. F. LINCOLN, of Boston, who proceeded to the consideration of "The Resistance of the Body to Electrical Force."

Presentation of cases and pathological specimens were then brought before the members, the most interesting of which was one by Dr. Kinnicutt, of a young man, of 19 years of age, suffering from facial paralysis followed by a numbness of the left side of the face. His family history was good, and, until within the last year, had enjoyed good health. At irregular intervals during the past twelve months he had experienced trigeminal neuralgia. Two weeks since he caught cold, combined with sore throat, nasal catarrh, and swelling of cervical glands, which were painful to the touch. He had the sensation of the presence of a plug in the ear. These symptoms continued for three days, with more or less trigeminal neuralgia. On the evening of the third day, in order to relieve the sensations described, the use of an ordinary ear-syringe filled with cold water was resorted to. Instantly on the injection he was seized with great dizziness, accompanied by an inclination to fall on the left side, from which he was saved only by support. This symptom disappeared in from five to ten minutes, but was immediately followed by a feeling of numbness on the left side of the face. He passed a comfortable night; but on looking in the glass the following morning discovered the ordinary symptoms of facial paralysis, with marked paralysis of the facial muscles, inability to close the eye on the affected side, the mouth drawn to opposite side, etc., etc. No deviation of tongue or uvula presented itself, no indication of anaesthesia. There was a slight loss of electro-motive power, contractility of the affected muscles, and marked loss of hearing in the left ear. An examina-

tion of the ear revealed only a depression of the membrana tympani. Subsequent treatment had resulted favorably, though not, as yet, in an entire cure.

DR. CLYMER then introduced Dr. Eugene Dupuy. He remarked that "The physiology of the cerebral hemispheres was still one of the most perplexing and obscure problems in physiology. In spite of much that had been done, there remained much more to be performed; and any experimental researches calculated to throw light upon the functions of the cerebrum were deserving of encouragement. I had occasion to bring before your notice in my inaugural address the recent experiments which have been made with a view to the elucidation of some of these functions by Fritsch and Hitzig, of Berlin, and Dr. Ferrier, of London. Until the practical demonstrations of the German physiologists it was held that the cerebral convolutions were insusceptible to every kind of irritation. They showed by their experiments that when the constant galvanic current was applied to the anterior parts of the brain, that certain muscular movements happened on the opposite sides of the body, and they endeavored to localize in certain definite points in the cerebral convolutions the centres for such muscular movements, regarding the movements thus produced as evidence of the susceptibility of the hemisphere to at least galvanic irritation; and they further observed that this irritation proceeded chiefly, if not entirely, from the anode or positive pole. This was in 1870. Later, in 1873, Dr. Ferrier, of London, following in the path opened up by Fritsch and Hitzig, undertook a series of researches in the same direction, with the view of exactly localizing the supposed motor centres in the cerebral convolutions. His method of investigation consisted in the application of the stimulus of the induced current of electricity directly to the surface of the brain. The conclusions which Dr. Ferrier claimed were the legitimate outcome of his experiments I have recently presented to the Society. The Royal Society of London voted a sum of money to Dr. Ferrier to enable him to continue his experiments. On the 5th of March last, Dr. Burdon-Sanderson, on behalf of Dr. Ferrier, presented to the Royal Society a communication from Dr. F., a further series of experiments, especially on the brains of monkeys, which Dr. Ferrier considered as verifications of points which, in his paper, read six months previously, at the meeting of the British Association at Bradford, he had regarded as only hypothetical. These results, which Dr. Ferrier conscientiously believes to be indicated by the turn of his experiments, may be briefly stated as showing an exact localization in the hemispheres of centres or regions for the carrying out of simple and complex muscular movements of definite character, and described by him as of a purposive or expressional value.

These researches towards solving one of the most difficult and obscure problems in cerebral physiology have excited the very greatest interest amongst physiologists, and several eminent physiologists have set themselves towards making experiments, with a view of testing the accuracy of Prof. Ferrier's researches.

At the last meeting of the Society a member well known in the department of electrical investigation showed you some experiments which he regarded as showing the correctness of Dr. Ferrier's conclusions. In December, 1873, Dr. Eugene Dupuy published his thesis, presented to the School of Medicine in Paris, entitled, "Examen de quelques points de la physique du cerveau," containing a number of experiments he had made on the cerebral hemispheres of dogs, cats, rabbits, and guinea-pigs, to test the accuracy of Dr. Ferrier's experiments. These experiments were re-

peated during the past winter before the Royal Society in London. Before returning to Europe, Dr. Dupuy has kindly consented this evening to favor us with a repetition of these experiments in vivisection, an interesting and valuable contribution to cerebral physiology.

DR. EUGENE DUPUY then proceeded, by the aid of a series of extremely delicate and successful vivisections, to examine the theory of the existence and localization of motor centres in the cerebral hemispheres. His subjects were two small dogs and two guinea-pigs. His object in exhibiting the guinea-pigs, which had been operated upon some time since, was to demonstrate the fact that the absence of the cerebrum did not deprive the legs of the power of voluntary movement. The theories deduced by Dr. Dupuy were diametrically opposed to those of Fritsch and Hitzig and Professor Ferrier, though the experiments were precisely similar in character.

Dr. Dupuy's conclusions from his experiments may be thus briefly summarized:—

I. That it is possible, by exciting certain points of the cortical layer of the cerebrum, to obtain contractions in every limb.

II. That, as a rule, the fore-limb of the opposite side is that affected.

III. That the electric current must be propagated to the base of the cerebrum to excite either the nerves which arise from it, or the base itself, or the pons varolii.

IV. That if the dura mater be electrically excited, contractions are observed in the foreleg, and generally in that of the opposite side.

V. The fact that the galvanoscopic frog is thrown into a state of contraction when its nerves touched some point of the cerebral mass far from the point excited, confirms the view that the electric current is propagated.

VI. Contrary to the effects obtained by Ferrier, Dr. Dupuy has never been able to obtain any effects upon the tongue, either of projection or retraction.

VII. The whole cortical layer of the cerebrum is probably a centre of reflection for a certain kind of sensibility capable of exerting a reflex action on motor or sensory nerves, but that its presentation is not indispensable for the manifestations of voluntary and even intelligent action.

VIII. In the animals on which Dr. Dupuy has experimented, contractions of the opposite limbs can still be produced, even after the ablation of the optic thalami and corpora striata of the opposite side to that on which the irritation has been applied.

DR. ARTHUR FLINT, JR., thought that Dr. Dupuy's periments had proved that Dr. Ferrier's conclusions, which had previously been looked upon as definite in their character, were, in fact, indefinite and unreliable. The portions stimulated were not the portions exposed to experiment. Guinea-pigs were especially liable to diffusion, consequently the movements of those animals differed materially from the movements originated by the stimulation of the motor nerve. He thought the points put forth by Dr. Dupuy were well sustained.

DR. J. W. S. ARNOLD remarked that there must be diffusion, but how much or in what direction it is impossible to determine. It was quite as easy to discover by the galvanometer as by the galvanoscopic frog.

DR. BEARD observed that the current was diffused at a considerable distance from the electrodes. The current contracted the sciatic nerve when it did not influence the brain or cerebral substance. There was a varied susceptibility in several parts of the body.

Dr. Dupuy's demonstrations had not entirely settled the question. He used very weak currents, and the centres were very complex. He had observed movements on the same side as well as on the opposite side.

Further remarks were made by Drs. J. C. Dalton, J. J. Mason, Dr. Lincoln, and others; and Dr. Austin Flint, Jr., moved that the thanks of the Society be awarded to Dr. Eugene Dupuy for his interesting paper, which resolution was unanimously passed.

THE MEDICAL LIBRARY AND JOURNAL ASSOCIATION OF NEW YORK.

TRANSFUSION OF BLOOD.

THIS association held its stated meeting at its rooms, June 19, Dr. J. C. PETERS, President, in the Chair.

After the preliminary business had been transacted,

DR. FREDERICK D. LENTE, of Cold Spring, read a paper on the value of Transfusion of Blood. He stated the main purpose of the paper as a review of the remarks of Dr. B. Fordyce Barker, made at a meeting of the New York Academy of Medicine in January last, and reported in THE MEDICAL RECORD of April 1; and also to refer to the *relative* value of other methods for saving life, when rapidly ebbing from exhaustion produced by hemorrhage, shock, etc. He remarked that though the first experiments in transfusion took place more than two hundred years since, it had never become all popularized in the profession. From the year 1866 to the present time, seventy successful cases had been reported, amongst a much larger number of unsuccessful ones.

Those in New York City, though performed by the most eminent men in the profession, such as Thomas, Van Buren, Flint, Sr., etc. (six in number), had all proved unsuccessful. The non-success was not due to thrombosis. All who have had a large obstetric experience have noted the enormous quantities of blood lost under those circumstances, and also the extraordinarily rapid convalescence, provided full nutrition was maintained. Deny's cases, referred to by Dr. Barker, were just such cases as could have been relieved by other methods. He cited one case in point, that of a young lady suffering under severe attacks of menorrhagia, and at the time of visit was pulseless at the wrist and completely unconscious. He immediately tamponed the vagina to prevent further loss, ordered enemata of brandy, and Liebig's extract of beef. Being some considerable distance from the city, any reliable means for transfusion could not be easily obtained. Prof. Flint, Jr., was sent for, he having just imported an excellent French instrument. For more than twenty-four hours afterward, it was considered unsafe to change her position across the bed, and her recovery was exceedingly protracted, though she eventually recovered. Dr. Flint, Jr., remarks that, "normally, the patient should have from fourteen to eighteen *pounds* of blood *circulating* in the system to properly *sustain* the functions of the body." Is it reasonable, therefore, to suppose that from two to eight ounces, the amount usually employed in transfusion, should do more than *temporarily* excite the action of the heart? Dr. Edward M. Hodder, of Toronto, injected fourteen and twenty-eight ounces of *milk*, in a few hours, into the veins of two patients moribund from cholera, with immediate relief and subsequent cure. The great difficulty in transfusion of blood is the want of *suitable material*, and on this account alone, if on no other, Dr. Hodder's experiment deserves a further trial.

As regards the use of transfusion of blood in blood-

poisoning, further experiments are needed to determine whether the results may not be more permanent, as they have been in one or two cases.

Transfusion has, without question, rescued many lives which would otherwise have been lost, but the treatment will be more successful if it is placed on its proper basis, limited to its appropriate applications, and assisted by auxiliary measures, such as brandy and beef-tea per rectum, elevation of the foot of the bed, warmth to surface, bandaging the extremities, etc. [In support of his views, Dr. Lente cited several interesting cases.]

In gastric cases, the prohibition of all food by the mouth, for days together, except small and regular doses of lime-water and milk; sometimes even prohibiting this, and making the rectum do the duty of the stomach; sometimes the regulated use of *raw* meat, and, more important than all, the use of *induced electricity*, have enabled me to restore the apparently most hopeless cases to life and health. Methodical bandaging (Esmarch's rubber bandage) of the extremities, forcing a large amount of blood from the surface to supply the viscera, digitalis to stimulate the heart, are invaluable both as auxiliaries and substitutes. There is a singular distrust in the minds of the laity and the profession regarding the efficacy of beef-tea, and especially of Liebig's extract and similar preparations. The cases subsequently adduced, however, went far to prove its efficiency, especially in injection, since being more fluid it is more readily absorbed, and its solubility, without sediment, in the smallest quantity of water, renders it possible to give the largest quantity of nutriment in the smallest possible bulk; a matter of no little moment in the case of children or an irritable rectum.

In cases of extreme exhaustion from vomiting during pregnancy Dr. Barker recommends transfusion of blood, but Dr. Lente adopted the ordinary faradic current, passed over the solar plexus behind to the epigastrium in front, or from the *vertebra prominens*, aided by general faradization. In cases of very sudden and imminent danger, when time for transfusion of blood even cannot be had, it might be well to transfuse brandy directly into the veins, or even ammonia slightly diluted.

Gesellius, in a work recently translated by Dr. Janeway, enumerates seventeen cases of transfusion of animals' blood into men, four of which ended fatally, and even those from causes unconnected with transfusion. He also enumerates 145 successful cases of transfusion of human blood to 52 fatal cases. His details are extremely meagre, and consequently not calculated to inspire confidence as to their reliability. One fact in his tables, however, is of great importance, and will doubtless strike us with surprise. It has been a settled question among us that the practice was a dangerous one, and hardly justifiable. The facts here enumerated prove the contrary. The blood of all the mammalia contains round corpuscles, and what is more important and remarkable, *smaller* corpuscles than the human subject. In THE MEDICAL RECORD of May 15 it is stated that Dr. Hasse, of Nordhausen, has transfused successfully with lambs' blood in 23 cases. He transfused *directly* from the artery of the animal to the vein of the patient. The cases of complete recovery by this means include 5 cases of phthisis, 2 chlorosis, 2 cachexia after severe illness, 1 cachexia after caries of vertebra, 1 carcinoma ventriculi, and 1 severe hemorrhage after placenta previa.

Within the past few days J. C. Young, M.D., of the resident medical staff of Bellevue Hospital, and Prof. T. Gaillard Thomas, of the New York State

Woman's Hospital, sent me an account of 2 cases operated on, but never yet reported. In the first, the patient had lost a large amount of blood after amputation, and had sunk so low that transfusion was decided upon. Five ounces of blood were taken from the arm of Dr. Terriberry; it was surrounded by warm water and defibrinated, and by means of a syringe enveloped in warm cloths was injected into the median basilic vein of the patient. Force of the heart and pulse a little increased, and the frequency diminished 10 beats. One hour later 6 additional ounces were injected with about the same result. But shortly after this the patient became delirious, and some few hours after died. The second case was that of a patient who had sustained the removal of a tumor by gastrotomy from the uterus, weighing 50 lbs. The transfusion was performed about 17 hours after the operation, and again at an interval of about 18 hours, but without any effect; and the patient died. Rabbits' blood is dissolved in from 3 to 5 minutes; that of other animals from 20 to 30 minutes. Dogs' and pigeons' blood resist the longest.

Dr. Landois believes that transfusion may benefit the receiver in three ways: 1. By bringing nutritive material into his body; 2. By the oxygen which is derived from the dissolved blood-cells, and in its serum; and 3. By possibly, in certain circumstances, improving the mechanical conditions of the circulation.

A case mentioned by Dr. Barker, and occurring at Bellevue Hospital, is worthy of special notice, some facts regarding it having very recently come to my knowledge. Dr. B. D. Taylor informs me he furnished 16 ounces of blood from his own arm, and another member of staff supplied 3 ounces more—the largest amount of human blood ever used in any one case. This was aided by nutritive and stimulating enemata, digitalis, hypodermic injections of strychnia. She survived about 60 hours, but succumbed at last. The result of this case is very discouraging, and should stimulate a further inquiry into one moot point, whether it is not proper, in all cases, to keep the vessels *filled*, if not with blood, with a proper saline solution added to it, or injected in the intervals of the sanguineous injections *pro re nata*, or with the blood of animals. In 1869 one of the most interesting and successful cases on record occurred. Drs. Buchser and Galeke being the operators. It was reported in THE MEDICAL RECORD for October, 1869. In this case it certainly appears that no remedy short of transfusion of blood would have availed; and, strange to say, only three ounces of blood (not defibrinated) were used. In the very number of THE RECORD (April 1, 1874) containing the report of Dr. Barker's paper is a report by Joseph W. Howe, surgeon to Charity Hospital, of a very successful case, with the recommendation of perhaps the simplest and best method of performing the operation. Here, also, only a small quantity of blood (4 ounces) was injected.

I am aware that these observations have a disconnected and desultory character, partly from the fragmentary way in which the information came to my hands. It was not intended by any means to be exhaustive of the subject, to present any novel facts or theories, or to seek to establish any point of practice, but simply to bring the question fairly before the profession, which has never yet been done.

DR. BARKER, in endorsing the remarks of Dr. Lente, said that there had been in all 126 cases of recovery by transfusion of blood. Transfusion, with the improved apparatus now used, presented no dangers, when direct, except from embolism. It does not depend on the quantity so much as the quality of the blood-corpuscles.

DR. DALTON said the real value of transfusion was as a curative agent. In almost every case the operator traced the recovery to the transfusion. It was principally performed on puerperal women, and successfully. The indispensability of transfusion is one of the most important questions of the day. May not the injection of half an ounce of blood save a man's life?

DR. NEEBEL observed that there was no necessity for using defibrinated blood.

DR. A. SMITH said that it was seldom that an adequate supply of human blood could be obtained. Lambs' blood could be used entirely. He objected to the use of Liebig's extract of beef, that it contained nitrate of potash.

DR. LENTE, in reply, said that the question of embolism in small vessels required further investigation. He did not recommend undiluted food. Soluble beef, in which there is no sediment, is at once converted into blood and received into the veins.

DR. BEVERLY ROBINSON then read a short paper on the Use of the Nasal Douche; but on account of the lateness of the hour it called forth no remarks, and, after the usual vote of thanks to the writers, the session was brought to a close.

Correspondence.

THE HYDROPHOBIA QUESTION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I had intended at the meeting of the Neurological Society, on the evening of the 6th inst., to say a few words upon the subject of Hydrophobia; but being suddenly taken ill, I was obliged to leave before Dr. Dalton had concluded his remarks. As the points upon which I desired to touch are of decided importance, I beg leave to consider them briefly in your columns.

1st. As to the pathological appearances in hydrophobia. A deep interest has undoubtedly been aroused in the profession and in the general community by Dr. Hammond's announcements of his observations in the McCormick case. It appears to me, however, that much more importance has been attributed to the lesions described by the doctor than experience will warrant. Notwithstanding Dr. Hammond's statement that the only accurate microscopical examinations previously made in such cases were those reported by Dr. Allbutt in 1872, there may be found in the Edinburgh *Monthly Journal of Med. Science* for 1850 a case described by Dr. Sidey, of that city—a most accurate observer—in which, during a searching microscopical inspection of the brain and its membranes, the medulla oblongata, the spinal cord, and the eighth pair of nerves in their origin and course, no abnormal appearances were detected. And Fleming, who, as Dr. Hammond justly remarked, has written the best work on hydrophobia, says that more recently several microscopical examinations of the cerebrum, cerebellum, and medulla oblongata have been made, "*but beyond intense congestion nothing could be noted.*" Now, Dr. Hammond laid particular stress upon the fatty degeneration which he had observed in the roots of the pneumogastric, hypoglossal, and spinal accessory nerves, and assumed that the appearances described by Allbutt could have been nothing else than the same morbid phenomena. In Dr. Allbutt's own account of his cases, however, he simply stated that there had been noticed throughout all the cerebro-spinal centres,

in different degrees, "little gaps caused by the disappearance of nerve strands, which had passed through the granular disintegration of Clarke."

Moreover, very extensive post-mortem researches have been made in cases of rabid dogs without any satisfactory results. According to Röhl, a distinguished German authority, the cadaveric lesions observed in canine rabies offer a certain similarity to those which are the consequence of acute poisoning by narcotic substances. In this connection I may say that I visited McCormick two hours before death, at which time he was, in my humble opinion, decidedly laboring under the narcotism of atropine, two exceedingly large doses of which had been administered to him. In this perhaps erroneous conclusion my friend Dr. Allan McLane Hamilton (no mean authority in such matters), who accompanied me, concurred.

Dr. Bruckmüller, the eminent Professor of the Veterinary Institute of Vienna, published in 1869 an elaborate account of very careful examinations undertaken by him upon 375 mad dogs during a period of 20 years. The principal brain lesions which he observed are as follow: Extravasation of blood into the brain substance, 3 cases; hyperemia of brain, 26 cases; oedema, usually accompanied by softening of membranes, 74 cases; hydrocephalus, 37 cases. The conclusion Bruckmüller arrived at, after his long and attentive researches, was, that autopsical appearances in the dog prove of no value in defining or distinguishing the disease.

I am afraid that we must accept similarly unsatisfactory conclusions in the human affection, and agree with Trousseau that in the vast majority of instances "the pathological changes found after death are only those dependent on the asphyxia which occurs in the latter stages."

2d. As to the bite of an enraged, but otherwise healthy dog, being capable of producing hydrophobia, Dr. Hammond was inclined to believe in this singular doctrine, and particularly mentioned that the views of Fleming on this point coincided with his own. But I find on page 112 of Fleming's work the following positive statement to the contrary:

"But surely if the bite given in anger by man or animals not rabid had such an influence, cases of hydrophobia and rabies would be quite every-day events. Curs and other dogs are continually biting each other all over the world; and whoever has struggled, as I have, to sleep through the night in a Turkish locality—Scutari, for instance—in Damascus, in Cairo, or in one of the main thoroughfares of a North China town, such as Tientsin, will be ready to testify that sanguinary battles among the half-starved and mangy canine scavengers are matters of at least hourly occurrence. Besides, in this country (England), so far as our observation has extended, dogs kept purposely for fighting—the notorious bull-dogs—are those least frequently affected with rabies. Certain it is that nothing can be more erroneous or terrifying than the assertion that rabies may be induced by the bite of a healthy animal; and it must be strenuously denied that such a result is possible. *No wound, injury, or bite from a healthy dog will produce the specific disease we term rabies.*"

The most conclusive argument against this absurd theory is the well-known fact that in certain portions of the world hydrophobia is entirely unknown, although dogs abound. Such is the case in Labrador, Greenland, Siberia, Australia, Van Diemen's Land, and New Zealand. A correspondent, "Ahuriri," in the London *Lancet*, of March 2, 1872, states that the inhabitants of New Zealand often wonder at their im-

munity from the affection. They are "greatly afraid that imported dogs will convey the dread disease, which would entail most disastrous results, as the islands teem with dogs tame and wild."

Rabies is unquestionably an affection due solely to a specific virus, and the bite of a non-rabid dog can no more induce genuine hydrophobia than can coition with a healthy but angry female induce syphilis. This latter disease, by the way, in its mode of invasion of the system, and in its indefinite period of incubation, bears a closer analogy to hydrophobia than any other communicable disease—all other diseases dependent upon specific contagion having a very defined period of latency. That of syphilis would appear to be as uncertain as that of hydrophobia. According to Diday, in fifty-two cases of syphilis (not subjected to treatment) the period of incubation ranged from 25 to 105 days; according to Bissereau, the interval between the infecting coitus and the outbreak of syphilitic erythema in 107 cases in which no treatment had been administered, varied from twenty days to five months. Fournier, from an examination of 307 cases, gives an *average* of forty to fifty days. Ricord, as the result of his extensive experience, enunciates the law that when no specific treatment is employed, six months never pass without the period of general symptoms. Sigmund, of Vienna, in 293 reliable cases, gives a maximum of three months. Cazenave goes so far as to estimate the average interval as two years, and relates one instance of ten years; and Vidal approves this statement. Even Bumstead, who endeavors to establish the fact of a definite period of incubation, makes the following statement: "The earliest symptoms of general syphilis (except in cases of hereditary origin and of transmission through the fetal circulation) have been preceded by a chancre, *probably within three and certainly within six months*, provided mercury has not been given;" he also adds that the development of syphilis is hastened by those causes which tend to depress the vital powers. Such circumstances are well recognized as instrumental in setting free the latent rabific virus.

Paget also alludes to the fact of a diathesis, as in cancer and syphilis, remaining undeveloped for a long period, until excited into action by some local injury.

3d. Now, with regard to the period of incubation of hydrophobia in the human subject, Thamhain, in *Schmidt's Jahrbücher* for 1859, gives the following periods in 220 authentic instances: In 2 cases, 3 days; in 33 cases, less than 21 days; in 129 cases, less than 7 weeks; in 52 cases, from 7 to 14 weeks; in 21 cases, from 14 weeks to 6 months; thus 202 occurred within 6 months. He also gives one case in which the interval extended beyond 4 years, and another beyond 5½ years.

I was somewhat surprised the other evening, in listening to a portion of Prof. Dalton's able remarks, to hear that very accurate gentleman state that no good authority believes in such extended periods of incubation as have sometimes been recorded. Dr. Watson, in his *Practice of Medicine*, commits himself decidedly to the opinion that such long intervals are possible, and adduces several authentic instances. He remarks that the virus deposited at the point of injury would appear to be shut up for an indefinite period in a nodule of lymph, or detained in precarious union with the tissues. He cites also several analogous cases of an incubation of several years of vaccine virus. For my part, I have no doubt that the rabific poison may remain *perdu* for many years, and even until natural death, unless liberated by some injury to the cicatrix or by constitutional causes.

4th. As to treatment, Dr. Hammond relies upon excision. I do not believe it possible for the most skillful surgeon to excise the injured part so thoroughly as not to be in danger of reinoculating the wound which he leaves. Dr. Hammond says that he has excised some 30 or 40 cases, in which no symptoms have yet been developed. The number is too small to prove the efficacy of his treatment. In testimony taken on the subject of hydrophobia before a Committee of the British House of Commons, in 1830, Mr. Youatt, the most celebrated of English veterinarians, stated that he had applied lunar caustic successfully to 400 persons bitten by rabid dogs; and a surgeon of St. George's testified that he had similarly treated 4,000 persons without an accident. The mere *supposition* that Mr. Youatt committed suicide on account of the failure of his preventive treatment in his own person proves nothing whatever. As far as we now know, the speedy and thorough cauterization of the injury with nitrate of silver offers the surest chances of success.

In regard to those precautionary measures which should be instituted in order to protect the community against rabid animals, I agree mainly in the efficacy of those proposed in the resolutions offered by Dr. Hammond, and adopted by the Neurological Society. Although it might be desirable that all dogs should be treated according to Bourrel's method of blunting the teeth, yet I do not believe that any constitutional law could "require" it to be done, and I therefore think that the word "recommend" should have been substituted.

Yours respectfully,

CHAS. P. RUSSEL, M.D.

54 WEST 9TH ST., July 8th, 1874.

ESMARCH'S METHOD.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In all the literature concerning Esmarch's method of preparing a limb for the operation for necrosis, I see no plan proposed for preventing the purulent matter that may be in the diseased parts from being pressed into the blood currents while the elastic bandage is applied.

The following plan for isolating the diseased from the healthy tissues will, I think, prevent the occurrence of this accident.

Take a soft rubber ring, a child's teething ring would serve the purpose in some cases, when the diseased bone lies near the surface. Larger and thicker rings made of rubber tubing or cord will be required to surround larger masses of diseased tissue over deep-seated bone; and apply it flatwise to the limb, in such a manner that it will include the mouths of all vessels contiguous to the diseased mass, as well as the ulcerated soft parts.

Now apply the elastic bandage in the usual manner as far as the ring; arriving there, let each turn of the bandage be so firmly applied over successive portions of the ring held firmly in its place, that the latter will form a circular compress entirely around the abscess. The ring should always be so thick that the turns of the elastic bandage will bridge the space included by the former, and in no case press upon the ulcer. By this method we deplete the vessels of every portion of the limb, except that included within the ring, and we drive no pus into the circulation, which is so often the cause of enlargement of glands, abscesses, and pyæmia.

The loss of blood sustained by this plan of bandag-

ing is trifling, and should not be thought of when we consider the danger to the healthy vessels that may be prevented by making use of the circular elastic compress.

Yours, very respectfully,

J. V. LAUDENDALE,
Asst. Surg., U. S. A.

FORT HAMILTON, N. Y. HARBOR, June 5, 1874.

THE NEW BIRTH OF THE AMERICAN MEDICAL ASSOCIATION.

TO THE EDITOR OF THE MEDICAL RECORD.

AS one of the few eastern physicians who attended the recent meeting of the American Medical Association, I wish to call the renewed attention of those who did not attend to the fact, already noticed editorially in *THE RECORD*, that the Association has been reorganized, and substantially on the basis indicated in *THE RECORD* two years ago, and now promises to be an honor to the profession and the country. The delicate and difficult questions of ethics and of social and political economy are now referred to a judicial council, so that the morning sessions of the Association are given mainly to science; the membership has been somewhat limited, so that it will no longer be an entirely indifferent thing to be nominated as a delegate, and the time may come when authors will place on the title-pages of their books, "Member of the American Medical Association."

The quality of the papers read at the Detroit meeting, and the discussions which they called forth, will well compare with the papers and discussions of the New York State Medical Society. The criticisms of the *Philadelphia Medical Times* on the scientific work of the sections seem to me too severe; they were founded on the very condensed reports, I am inclined to believe, more than on personal observation.

My special object in this note is to suggest to those medical men who have any original or important matters to introduce to the profession, to avail themselves of some one of the sections of the Association. I have used at various times strong language in regard to the Association, and have criticised more severely perhaps than any one the crying errors of its past management; I therefore take all the more pleasure in calling attention to the fact of its reorganization, and in urging the claims of the new Association on the original scientific workers of our profession. My faith is strong that the Association of the future will represent far better than the Association of the past has done, the scientific and scholarly elements in the profession of America. This faith is founded in part on the organic changes that have been made in the Association, and in part on the success of the last meeting at Detroit.

A certain proportion of the noisy, the ignorant, and the unscrupulous will probably appear at the future meetings, as in the past; for these bad elements are always with us, and no large body can be wholly free from them; but they will, I believe, no longer be dominant or dangerous.

The question of presidency, which every year causes so much anxious thought and talk, is now of but trifling moment, except to the successful and unsuccessful candidates and their immediate friends. The Association ought to be strong and great, in spite of the weakness and smallness of any one who may happen to be chosen as its figure-head. The official power is so widely diffused that the success of any meeting must depend more on the officers of the several sec-

tions and on the Committee of Arrangements than on the president.

To these words of compliment and congratulation I may add these criticisms:

1. There should be more system in the management of the scientific and literary affairs of the sections. The officers should arrange, beforehand, for papers, cases, specimens, and so forth, from competent authorities, and great pains should be taken to have a variety of subjects in each section.

The time of every speaker should be limited, as at the State Medical Society, so that all subjects and all speakers may have a fair field.

Stupid papers, offered by proverbially stupid men, should be religiously excluded, or politely referred to a committee.

2. Quiet rooms, of moderate size, should, so far as possible, be selected for the meetings of the sections.

Better that a room be too small than so large that very few can hear the speakers. It is always in bad taste to scream and yell in a scientific discussion. If a man declares that two and two make four, at the top of his voice, we are half inclined to question the truth of his statement. The quality of voice that prevails on the stump is precisely that which the scientific and scholarly instinctively avoid. Every year, even those who have good hearing, lose a serious fraction of the papers and discussions of the Association. In Philadelphia it was found necessary to adjourn the open sessions of the Association from a hall, where nothing could be heard, to a church, where only a little could be heard. In Detroit the arrangements were better, but not perfect. The practical difficulties in the way of correcting this evil are very great, as I am aware; but if the acoustic qualities of the rooms in which the meetings are held are carefully studied the evil can, in some cities at least, be reduced to a trifling minimum.

In the management of the social part of the programme, future committees of arrangements would do well to follow, in some respects, the example of Detroit.

The avoidance of close packing and crowding, by having a number of entertainments at the same time and in easily accessible places; the absence of alcoholic liquors, and the presence of ladies—these features of the last meeting—are surely worthy of imitation.

The cohesive power of oysters and ice-cream is not strong enough alone to hold together the best minds in the profession, but, as an adjuvant to science, is not to be despised.

That all this radical revolution in the constitution and management of the Association has been accomplished so easily, so rapidly, and so peacefully, should be a high encouragement to all medical reformers in the future. The result is a direct triumph of special and persistent effort directed mainly through the medical journals. While there had been for years vague and spasmodic complaining against the Association, THE RECORD was, I believe, the first to speak out on this subject loud enough and long enough to arouse general attention, and the first also to suggest in detail and enforce the necessity of those changes that have since been made.

The medical journals of the country have almost unanimously co-operated in this effort to raise the character of the Association; and while there has been a very wide difference of opinion as to the best methods of correcting the evils, few or none have professed that evils did not exist. Those evils have now become mostly historic, and may well be forgotten. The door is now open for the Association

to become the best, as it has long been the largest, medical society in America.

GEO. M. BEARD.

53 WEST 33D STREET.

NOTE ON THE MICROSCOPICAL SLIDES OF DR. OTTO BARTH, ILLUSTRATIVE OF PATHOLOGICAL ANATOMY.

BY ASSISTANT SURGEON J. J. WOODWARD,

U. S. ARMY.

I HAVE so often been asked by correspondents whether it was possible for them to purchase anywhere really useful microscopical slides illustrative of pathological anatomy, that I presume the following brief note on the preparations of Dr. Otto Barth, No. 34 Waisenhausstrasse, Leipzig, will interest many of your readers.

Dr. Barth advertises a series of 100 preparations on general pathological anatomy, and three special series, of 50 preparations each, on gynecology, surgery, and tumors.

One of the sets in general pathological anatomy has just been received at the Army Medical Museum. It consists of 100 handsomely made thin sections, some stained with carmine, others with logwood, others injected, and all permanently mounted in Damar or Canada balsam. These preparations represent a selection of the more important diseases of the nervous system, blood-vessels, respiratory, digestive, and sexual organs, the skin, etc., and form an excellent introduction to the practical study of pathological histology. Looking through the series, I found all the slides instructive, and many of them very handsome, comparing favorably with our own preparations at the Museum. I may mention as particularly instructive the preparations labelled catarrhal and croupous pneumonia, intestinal catarrh, dysentery, typhoid ulcer, cirrhosis, amyloid degeneration, tubercle, and cancer of the liver; fatty, amyloid, and granular kidneys; adenoma and scirrhous of the mammary gland, etc.

The preparations are preserved in a handsome mahogany box, with printed labels (in Latin), and are very cheap, the price in Leipzig being 40 thalers. The agent in this country is B. Westernmann & Co., No. 471 Broadway, New York, who advertises them for \$45 in gold. (This price, however, appears from the catalogue to be based on the original price of the earlier sets, 33½ thalers, which has since been increased by Dr. Barth to 40 thalers.)

The only drawback I have observed is the somewhat inconvenient size of the glass slides on which the preparations are mounted. These are 7 centimetres long by 3½ wide (or 2.750 by 1.375 inches very nearly), instead of three inches by one, which is the usual size of slips employed for microscopic slides in this country.

I have sent to Dr. Barth for the series on gynecology, surgery, and tumors, and will communicate to this journal a brief note with regard to them so soon as they come to hand.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from June 19, 1874, to July 3, 1874.

COOPER, GEO. S., Surgeon.—Assigned to duty at Benicia Barracks, Cal. S. O. 60, Department of California, June 17, 1874.

FRANTZ, J. H., Surgeon.—Granted leave of absence for four months on surgeon's certificate of disability. S. O. 111, A. G. O., June 29, 1874.

DE WITT, C., Assistant Surgeon.—Assigned to duty at Fort Macon, N. C., S. O. 103, Department of the South, June 29, 1874.

DE HANNE, J. V., Assist. Surgeon.—Granted leave of absence for 4 months. S. O. 138, A. G. O., June 23, 1874.

WEISEL, D., Assistant Surgeon.—Granted leave of absence for 20 days. S. O. 103, c. s., Dep. of the South.

Medical Items and News.

HYDROPHOBIA AND THE MUZZLING OF DOGS.—The following preamble and resolutions were adopted at a recent meeting of the Neurological Society:

"*Whereas*, Observation has demonstrated beyond reasonable doubt that hydrophobia is not more prevalent in summer than in the other seasons of the year; that it is a disease much more apt to affect the carefully tended house-dog than the vagrant animal; that the muzzle impedes many natural actions of the dog, the performance of which is essential to its comfort, if not existence; that the apparatus does not prevent the dog upon which it is applied inflicting wounds with its teeth; that from the excitement and irritation it produces it may become an effective agent in originating hydrophobia; that even without these objections, to be efficacious in preventing the spread of the disease, it should be applied without distinction to all dogs, whether domestic or vagrant, and kept continually on them—a manifestly impossible proceeding; that there is some reason to believe that the human subject may contract hydrophobia from dogs not rabid; therefore

"*Resolved*, That the New York Neurological Society respectfully protests against the recent city ordinance, requiring dogs to be muzzled, as being contrary to science, inefficient in preventing hydrophobia, and cruel in its requirements.

"*Resolved*, That in the opinion of this Society the most effectual means of preventing the origination and spread of hydrophobia is by the imposition of a tax upon all dogs kept for use or pleasure; requiring the canine teeth or fangs and the incisor teeth to be blunted as proposed and effected by Bourrel, and the destruction, under proper regulations and by duly authorized persons, of all dogs not licensed, or which may be found with the teeth unblunted.

"*Resolved*, That it would be expedient to arrest all dogs found running at large, even if the teeth have been blunted, and to keep them in custody a short time till the owner can be notified, that a fine be imposed upon each owner, and upon the non-payment of which the dog should be destroyed.

"*Resolved*, That all dogs subject to tax in accordance with the second resolution should be duly registered as licensed, and wear a collar upon which the stamp of the licensing officer and the owner's name should be indelibly impressed."

In the absence of any legal enactment the New York Neurological Society recommends to all owners of dogs to have the teeth of the animals blunted in the following manner, as detailed by Fleming in his Treatise on Rabies and Hydrophobia: "The operation is a simple one. For a large dog two assistants are necessary; for a small animal only one. The creature is seated on a table, a gag is fixed in the mouth, between the molar teeth, by a band passed behind the neck; another band or piece of wide tape fastened

around the muzzle at the back of the gag prevents any movement of the jaws. To blunt the incisor teeth a file is used, and the longer canine teeth or fangs are shortened by sharp nippers and then smoothly rounded by the file. The gag, of course, must be proportioned in thickness and length to the size of the animal."

ELASTIC LIGATURE IN CESAREAN SECTION.—M. Grandesso Silvestri has addressed a note to the *Société de Chirurgie*, on the use of elastic ligatures for the suture of the uterus after Cesarean section, the great advantage claimed by him being that the elastic threads follow the shrinking of the uterus and do not allow the edges of the wound to gape. Dr. Silvestri has used this method in one successful case of Cesarean section.—*Archives de Toxicologie*.

DR. A. B. SNELL, late of Shreveport, La., has removed to Amsterdam, N. Y. Dr. Snell has resided for eighteen years in Louisiana, and was surgeon in Gen. Lee's army during the war. He was also chairman of the committee which made the very able report on the yellow-fever epidemic at Shreveport, 1873.

NEW JERSEY ACADEMY OF MEDICINE.—The organization of the New Jersey Academy of Medicine, as authorized by an act of incorporation passed March 10th, 1874, was perfected at a meeting held in Upper Liberty Hall, Newark, on the 17th of June.

The following are the officers for the current term: *President*, Dr. Theodore R. Varick, Jersey City. *Vice-Presidents*, Dr. J. A. Cross, Newark; Dr. Franklin Gamett, Burlington; Dr. Thomas F. Cullen, Camden. *Recording Secretary*, Dr. Peter V. Hewlett, Newark. *Assistant Secretary*, Dr. R. Gillman, Jersey City. *Corresponding Secretary*, Dr. McGill, Jersey City. *Statistical Secretary*, Dr. A. W. Woodhull, Newark. *Treasurer*, Dr. H. R. Baldwin, New Brunswick. *Curator*, Dr. P. V. Hewlett, Newark. *Librarian*, Dr. B. A. Watson, Jersey City. *Directors*: Dr. Wm. O'Gorman, Newark; Dr. Edgar Holden, Newark; Dr. R. F. Chabert, Hoboken; Dr. F. G. Payne, Bergen Point; Dr. H. H. Abernethy, Jersey City.

The next stated meeting will be held at Upper Liberty Hall, Newark, on the third Wednesday in July.

NEW YORK DERMATOLOGICAL SOCIETY.—At the fifty-seventh regular meeting of this Society, May 12, 1874, the following officers were elected for the ensuing year:

President, R. W. Taylor. *Recording and Corresponding Secretary*, L. Duncan Bulkley. *Treasurer*, F. L. Satterlee. *Executive Committee*, F. P. Foster, E. L. Keyes, F. R. Sturgis, President and Secretary *ex-officio*.

DR. GOUVERNEUR M. SMITH.—The chaste and scholarly memoir of the late William C. Roberts, M.D., read by Dr. Gouverneur M. Smith before the New York Academy of Medicine, has been published in handsome book form by the friends of the subject of the sketch. As a memoir it is a model.

DR. S. CARO, of this city, has been appointed Corresponding Member of the Royal Academy of Medicine, Palermo, Italy.

UNIVERSITY OF THE CITY OF NEW YORK: MEDICAL DEPARTMENT.—The following appointments have been made in the Medical Department of the University of the City of New York: Wm. A. Hammond, M.D., to fill the Chair of Diseases of the Mind and Nervous System; John T. Darby, M.D., late Professor of Surgery in the University of South Carolina, as "Professor of Surgical Anatomy;" and Montrose A. Pallen, M.D., late Professor of Gynecology in the Coll. of Phys. & Surgeons, St. Louis, as "Lecturer on the Surgical Diseases of Women."

NUMBER OF PHYSICIANS IN FRANCE.—The following figures, recently published, on the distribution of medical men over the country, are of interest:—In 1866, in 4 departments of France, there existed 1 doctor to about 2,000 inhabitants; in 21 departments, 1 to 2,000 or 3,000; in 34 departments, 1 to 3,000 or 4,000; in 16 departments, 1 to 4,000 or 5,000; in 2 departments, 1 to 5,000 or 6,000; in 6 departments, 1 to 7,000 or 9,000, and in 1 department, 1 to 10,576. As the mean average of population put down by the reporter as being necessary to secure a livelihood of a medical practitioner is 3,000 inhabitants, it follows that there are sixty-three departments of France where this average is not attained. The total number of medical men appears to be stationary. In 1847 there were 10,643 doctors of medicine, making 1 to 3,244 inhabitants; in 1866 the number was 11,525, and in 1872 (making allowance for the loss of Alsace and Lorraine) the number was only 10,766, being 1 to 3,353 inhabitants, so that as the number of *officiers de santé* has notably diminished, and as that of doctors of medicine has not increased, it follows that the total number of medical practitioners in France is greatly on the decrease. Thus, in 1847, according to the report, the total number was 18,099, being one practitioner to 1,895 inhabitants; in 1866, 17,192, or one to 2,232; and in 1872 only 15,419, or 1 to 2,341 inhabitants.

CREMATION.—According to *The Lancet*, cremation makes progress in Germany, eighty-two cities now possessing cremation societies. The society at Berlin has received intelligence that the new furnace invented for the combustion of bodies by Professors Reclam and Siemens was tested on the 2d of June, and completely satisfied its constructors. Two hundredweights of animal carcase were consumed in about an hour and a half—reduced to white ashes, at no more than three shillings outlay. During the process no sound nor smell was appreciable. Solving as it does the question of cremation, Messrs Reclam and Siemens' contrivance has just met with a rival in the device of Dr. Steinbeis, President of the Central Institute for Trade and Industry, at Wurtemberg. He proposes that the corpse should be placed in a trough made of cement, and be filled up with liquid cement so as completely to cover the dead body. The cement soon hardens and absorbs all the moisture from the body—converts it, in fact, into a preservable mummy at small expense and trouble. As soon as the cement hardens, the square coffins may be piled one upon the other like blocks of stone, and the corpse is literally interred *in* instead of under its gravestone.

CONDENSED MILK IN GERMANY.—In German pharmacies the sale of children's food and condensed milk has so much increased of late that it would seem as if, in the large towns at least, this is the only method employed of feeding infants. In Berlin the condensed milk manufactured by the original company at Cham is in great favor, and the Berlin apothecaries have officially approved this preparation. But other brands, respecting which nothing but good can be said, are also in the market, are cheaper, and find a large consumption.

CARBOLIC ACID is recommended by Elbstein and Müller for internal use in diabetes. Five to seven grains may be administered daily, in divided doses.

DR. H. M. SPRAGUE.—At a special meeting of the Yonkers Medical Association, held June 1st, 1874, the following resolutions were unanimously adopted:

Whereas, Death has, for the first time since its organization, entered the ranks of our association, and

borne from us one of our most valued members, and an esteemed ex-president, Dr. H. M. Sprague; therefore, be it

Resolved, That in the death of Dr. Sprague we mourn the loss of a valued brother, a true-hearted, noble man, a skilful physician, and a devoted student of medical science.

Resolved, That we tender to the friends and family of our departed brother our heartfelt sympathy in this dark hour of their affliction.

Resolved, That we attend the funeral of Dr. Sprague, from his late residence in Fordham, in a body.

Resolved, That a copy of these resolutions be sent to the family of Dr. Sprague, and also published in *THE MEDICAL RECORD*, *The New York Medical Journal*, and the local newspapers.

GEO. F. JACKSON, M.D., *President*.

JOHN PARSONS, M.D., *Secretary*.

A NEW MEDICAL SCHOOL IN INDIANA.—Dissensions among the Faculty of the Indiana Medical College have led to the organization of a new institution, to be called the "Indiana College of Physicians and Surgeons," and to be established also at Indianapolis.

A NEW SIGN OF DEATH.—M. Bouchut, who, in 1849, published a means for discovering the existence of death by cessation of the heart's action, as shown by auscultation and the introduction of an acupuncture needle, has called the attention of the profession to still another sign, viz., pneumatosis of the retinal veins. This is readily appreciable by the ophthalmoscope, and is claimed by M. Bouchut to be an immediate and certain sign of death. The veins show an interruption here and there to the current of blood within them, like that seen in the column of a thermometer composed of colored alcohol.—*Gazette des Hôpitaux*.

THE NEXT MEETING OF THE BRITISH PHARMACEUTICAL CONFERENCE will take place in London next August.

THE TRANSACTIONS OF THE MINNESOTA STATE MEDICAL SOCIETY, ST. PAUL, 1874, have been received. At the sixth annual meeting, held at St. Paul, on the 3d and 4th of February last, Dr. N. B. Hill, of Minneapolis, was elected president, and Dr. J. E. Bowles, of St. Peter, Minn., corresponding secretary. Most of the business of this and the previous semi-annual meeting, held in June, 1873, at Maerkat, appear to have been connected with ethical questions and the finances and business of the association proper. Besides the reports of the various committees, a paper was read by Dr. H. C. Hand on "The Abdominal Branches of the Pneumogastric Nerves, and their Relations to the Treatment of Choleraic Discharges."

CREMATION.—*The Lancet* says that a recent number of *The Academy* contained a paragraph to the following effect, extracted from the *Spreuersche Zeitung*, which, with an eye to possible contingencies, has, with grim facetiousness, inserted in its feuilleton a specimen of the cremation announcements, which in Germany doctors generally, and in England Sir Henry Thompson specially, no doubt anticipate will be of ordinary occurrence among the coming race. The sample announcement reads: "To-morrow, at 3 P.M., I shall burn my mother-in-law."

FOOD FOR INFANTS.—*Appropos* of the recent evidence as to the chemical value, or rather valueless nature, of the foods advertised for infants, the *London Standard*, alluding to the enormous amount of starch contained in these diets, says it is identical with the material

used for stiffening our shirts and collars, and has probably by this time stiffened out a good many infants.

THE LONDON SCHOOL BOARD has passed a resolution in favor of making plain cookery and the household work connected with it part of the education of girls.

ELECTROLYSIS EXTRAORDINARY.—A curious story comes from Whitehall, in this State. Three years ago General Kilpatrick had a remarkable operation performed upon him by a physician in New York, who removed a fleshy formation from the general's neck by filling it full of needles, and then attaching a galvanic battery to it. Ten minutes after the current of electricity was let on, the bunch had entirely disappeared. A more extraordinary operation than this was, however, performed by a Whitehall physician a few days ago, if we are to believe the *Whitehall Times*. A gentleman who had been suffering from a superabundance of adipose tissue consulted the physician, asking for relief from its burden. The doctor told him he could relieve him if he would consent to a painful operation. The gentleman consented, and with the medical practitioner entered the telegraph office at that place. The fat man was requested to remove his coat and vest, after which the physician surrounded him with wires, attaching the ends to a powerful battery. At a signal from the doctor, Manager Eddy let on the current. The patient writhed and twisted when he felt the current passing around him; still he stood like a martyr. Presently he began to shrink; he grew smaller and smaller; his clothing hung in bags about his fast diminishing form; the doctor felt much pleased at the result of his experiment; while the formerly fat man's joy was very great, although he seemed to be suffering acute pain. All of a sudden there was heard a loud clicking at the instrument, as if Pandemonium's great hall were let loose. The operator sprang quickly to answer the call. He ascertained it was from the New York office. He quickly asked, "What's up?" An answer came back as if some infuriated demon was at the other end of the wire. "What in thunder are you about? Cut off your wires quick—you are filling the New York office with soap grease."

LAW TO REGULATE THE PRACTICE OF MEDICINE IN THE STATE OF NEW YORK.—Just before the adjournment of the State Legislature, the following law was passed. We have not learned whether it has or has not received the signature of the Governor:—

"Section 1. Every practitioner of medicine or surgery in this State, excepting licentiates or graduates of some medical society or chartered school, shall be required, and they are hereby commanded, to obtain a certificate from the censors of some one of the several medical societies of this State, either from the county, district, or State society; which certificate shall set forth that said censors have found the person to whom it was issued qualified to practise all of the branches of the medical art mentioned in it. And such certificate must be recorded in a book provided and kept for the purpose by the county clerk of each county in the State.

"Sec. 2. The censors of each medical society aforesaid shall notify all practitioners of medicine and surgery of the terms and requirements of this act, and shall request such persons so notified to comply with those requirements, within thirty days after such notification; and if such persons shall not within the time specified in the notice, or within such further time as may be allowed by special arrangement with said censors, not exceeding ninety days, comply with the requirements herein made of physicians or surgeons, as

the case may be, such persons shall thereafter be subject to all the provisions and penalties prescribed by this act, for any violation of the same, and the president of the society making such request shall, and he is hereby required to, at once commence the proceedings authorized by this act against such person.

"Sec. 3. It is hereby declared a misdemeanor for any person to practise medicine or surgery in this State unless authorized so to do by a license or diploma from some chartered school, State board of medical examiners, or medical society, or who shall practise under cover of a medical diploma illegally obtained; and any person found guilty of such a misdemeanor shall, for the first offence, be fined not less than fifty nor more than two hundred dollars; for any subsequent offence, not less than one hundred nor more than five hundred dollars, or by imprisonment not less than thirty days, or by both imprisonment and fine; and all such fines shall go into the county treasury of the county bringing such action."

PHYSIOLOGY IN CHINA.—*The Scientific American* gives us the following summary of the notions of the Chinese on physiology:—"According to them the chief organ of the human economy is the spleen. Its functions are manifold. It rubs against the stomach and grinds the food; it keeps up the proper degree of heat in the five *taang*; it moves the muscles and the lips, and thus regulates the opening of the mouth; furthermore, it directs our secret ideas so that they become known to us. The liver regulates the tendons, and ornaments the nails of the hands and feet. The heart regulates the blood-vessels, beautifies the complexion, and by its means we are enabled to open the ears and move the tongue. Of the circulation of the blood, the Chinese are profoundly ignorant. The kidneys govern the bones, beautify the hair of the head, and open the orifices of the two *yin*. The diaphragm, being spread out like a membrane beneath the heart, and joined all round to the ribs and spine, covers over the thick vapors, so that the foul air cannot rise. The gall-bladder is the seat of courage; hence the popular belief that whoever eats the gall of a brave man or beast will inherit the valor of its original possessor—a belief which frequently leads to a lively competition for the galls of remarkable animals.

Of the function of the brain the Chinese have but a vague idea, still they think it has something to do with the intellect. In proof of this suspicion, they offer the case of a man of great renown for his learning, whose misfortune it was to fall from a horse with such violence as to break his skull. The physician who was called to treat the case hit upon the happy thought of supplying from the skull of a cow the portion of brain the wise man had lost. The operation was only a partial success, since the subject's eminent powers of mind remained in utter prostration, and from that time forward he was a very different man from what he had been. Whether his residual intelligence exhibited any bovine characteristics our informant unhappily neglects to say.

Hereafter we expect to see this case given as additional evidence that the Chinese are the original discoverers of everything. It is certain that it greatly antedates the operation recently reported from Leipzig for the edification of rural editors: a case in which the brain of a good-natured wine-seller, dead of heart disease, was transplanted into the cranium of a soldier condemned to death for murder, with a corresponding transference of mental and moral traits. The Leipzig surgeon is plainly no better than a skillful imitator.

Medical Department of Life Insurance.

THE POSITION AND DUTIES OF THE MEDICAL EXAMINER.

By DR. J. WILLIAMSON,

OF OTTUMWA, IOWA.

(From a paper read before the Iowa State Medical Society.)

A FEW words on the relation of the medical examiner to other parties.

In these days of money-getting the first question that a man asks himself, or the agent who may be soliciting, is, Will it pay? Will the money which I shall have to pay out from year to year in the way of premiums, return to me, or my legal representatives, with fourfold, tenfold, or a hundredfold increase? If the agent succeeds in convincing him that it will be a paying investment, then he is ready to insure, and the medical examiner is called upon to ratify a contract entered into for their mutual benefit. When I say that the examiner is called upon to *ratify* the contract, I speak of the attitude of the parties to each other and to the transaction. Through the whole affair they have stood to each other in antagonistic relations, as ordinary business men, each bent on getting as good a thing as possible. It is essentially a business transaction, and it is expecting too much to suppose that either one is going to ignore his personal interests, and exclude everything else from his mind except truth and right. Consciously or unconsciously, there come into the mind elements and considerations which have much to do with the decision arrived at. In speaking thus of soliciting agents we would not willingly do them an injustice. As a class we believe them to be honorable men. Neither would we speak too disparagingly of the "average man." But such is human nature and such the position of the parties that, as a general thing, just in proportion as the parties feel they have done a neat thing, will be the difficulties of the examiner in getting a correct idea of the applicant's insurability. Not that I believe all men are liars and swindlers, but we all know how unconsciously the best of men are swayed, by their desires and interests, from the strict line of rectitude. Besides, it is said that corporations have no souls, and it is a curious fact that men of reputed honesty and uprightness of character feel that in dealing with corporations they have a license which they would scorn to use in transactions with their neighbors. The case of the person to be examined is therefore the very reverse of that of the invalid, for the latter comes before the physician revealing, without a question, all his weak points, real and imaginary, that he may be restored to health; and the same is true of the military conscript, who is solicitous lest the examining surgeon should overlook his physical weaknesses.

From this it follows that the medical examiner for life insurance should receive the applicant's statements with a good degree of allowance, and should verify them in every case by a close scrutiny into the working of every bodily function, and a strict inquiry into his family history, and that he should make no account whatever of the desires of the agent.

Another thing follows from what we have said, viz.: that medical examiners should be men possessing a thorough knowledge of medical science, especially of physiology and pathology; they should be men of clear, logical minds, and should have a good deal of the kind of talent found in first-class lawyers. Besides

these requisites he should be conscious of his *entire independence* of the parties to be affected by the examination, and, that this may be the case, his appointment should never be made through the agent, nor the office held contingent on his will. Medical examiners should receive their appointment through a State or District Medical Board or Supervisor, and in no other way. Until then incompetent medical examiners will be the rule.

HALF-WAY MEASURES.

FROM a recent number of the *Baltimore Underwriter* we learn that the representatives of the Southern life insurance companies have lately met in convention and transacted business of importance. The only thing, however, of interest to medical men is the subjoined report, presented to the convention by its "Committee on Medical Blanks and Examiners:"

The undersigned, your committee to whom was referred blank forms of medical examination, and the best mode of securing capable and honest medical examiners, beg leave to submit the following report:

1st. After a careful examination of the various forms submitted, we are of the opinion that each contains all the essential questions necessary to a proper estimate of the risk if truthfully and intelligently answered, and may be safely remitted to the medical advisers of the respective companies; but with a view to secure to all the benefits which may arise from subsequent improvements, and with a further view of establishing comity between the offices of life insurance companies, we respectfully recommend that they interchange their blanks, together with such suggestions of improvement as may be made from time to time.

2d. With regard to female risks. The committee think it proper to say that the data so far furnished are insufficient and contradictory, and that it would be manifestly unfair, as well as improper, to jump hastily to conclusions. In view of this fact, the committee respectfully ask that the subject be referred to the Committee on Mortuary Statistics, to report them as fully as possible at the next annual meeting of this organization.

3d. The chief medical advisers of the Southern life insurance companies shall unite to form an advisory board, which shall, as the medical representative body of the companies, select a thoroughly qualified physician as Supervisor of Medical Examiners for each State, upon the recommendation of the members of the board whose companies are transacting business in such State. He shall be paid a stipulated salary and travelling expenses, and his duties shall be to select competent examiners throughout his district and reject all others, making contracts with the former for the fees for each examination. Said Medical Supervisor, when not otherwise engaged, shall examine for any of the companies composing the Medical Association, and his salary shall be paid *pro rata* by each company doing business in his district. Companies not represented in the association may share the privilege of having their examinations made by said Medical Supervisor and appointees by paying their *pro rata* of his salary and expenses, and the examiner's fees. No examination shall be accepted, under any circumstance, from a physician who has not received the full endorsement of the Supervisor.

4th. Each company represented in this convention shall, on the rejection of an applicant for insurance, immediately inform the others of the fact, together with the reasons therefor.

5th. It is deemed contrary to insurance interests to assign to agents or applicants the causes of rejection.

6th. We further recommend that all answers to questions in the application affecting the insurability of the applicant be filled by the medical examiner.

F. A. ATCHISON,
C. H. PELKROW, } *Committee.*
W. C. ROBINS, }

Upon the first reading of the transactions of the convention, we congratulated ourselves that this excellent report had been adopted and that the course now pursued by a few careful companies in the North, in the selection of medical examiners, was to be pursued hereafter by all the Southern companies. Upon a second reading, however, we discovered the fact that only sections 4, 5, and 6 had been adopted. In other words, it was voted not to lay the axe to the root of the present unsafe and demoralizing system of appointing examiners, but simply to surround it by one or two additional safeguards. The falling of the old tree might stir up a rebellious spirit among the agents of the old régime, and the officers of the various companies hardly cared to face this disturbance in the camp.

As regards section 1, we regret to see that the committee did not improve the opportunity at their command to present to the convention, for study, amendment, and eventual adoption, a uniform list of questions for the medical examiner to answer. It is a source of considerable annoyance to a physician who examines for several companies to fill in correctly so many different forms of blanks; and, on the other hand, there is no good reason why the companies should not all make use of the same style of blank.

Section 2 disposes of the question of female risks in the only manner possible under the circumstances.

Section 3 strikes at the very root of the prevalent method of appointing medical examiners, and offers, in its stead, a very simple and most effective method of elevating and purifying this branch of life insurance business.

Sections 4 and 5 require no special comment; and section 6, though embodying a very sensible and important change, should have been a part of section 1, which treats of medical examiners' blanks.

Let us hope that, by the time the next convention of Southern life insurance companies meets, its timid members will have gathered courage enough to adopt the most important part of the recommendations made by their medical committee, namely, that part which refers to the reorganization of their medical staff.

ON THE WASTE OF LIFE BY PREVENTABLE DISEASE.

By R. BRUDENELL CARTER, F.R.C.S.

OPHTHALMIC SURGEON TO ST. GEORGE'S HOSPITAL.

(Continued from MEDICAL RECORD of June 15.)

UPON the whole, then, I think I am entitled to say that the effect of preventable disease, in this country, every year, is to inflict upon the community a pecuniary tax of not less than three millions sterling, and probably of much more than that sum; to sicken at least six hundred thousand persons; to destroy prematurely at least one hundred thousand lives, many of them of the highest value; to cripple, in some way or to some extent, in mind or body, an unknown number of victims, leaving them to be more or less encumbrances to their own generation, and to be the progenitors of children who will hand down an inheritance of sick-

ness or debility to generations yet to come; and, lastly, besides causing an incalculable amount of merely mental sorrow, to entail physical misery, destitution, social degradation, and even lapse into crime, upon many of those whose main-stay in life it has destroyed. It is often a wholesome mental exercise, with reference to arrangements to which we have become accustomed, to try to stand for a moment, as it were, aloof from them, and to ask ourselves how we should regard them if they were offered to our acceptance for the first time. I think it cannot be doubted, if we could place in this light the evils and calamities that I have endeavored in faint outline to describe, that we should all look upon them as something too monstrous to be endured with patience. We should say that they threw into utter insignificance most of the so-called great questions with which politicians occupy themselves, and that they imperatively demanded the most strenuous efforts of the highest statesmanship for their removal. But so absolute is the dominion of habit over the human mind that we now suffer these evils to flourish practically unchecked, and make scarcely a single earnest effort to control them.

To this statement it may be objected that we have had, during the last few years, a good deal of sanitary legislation, and that the subject is one that has been almost continually kept before the attention of the public. You will, perhaps, remember the old story of Tillotson's appeal to Garrick to explain to him why it was that the stage could sway the emotions so much more powerfully than the pulpit. "The reason is," said the great actor, "that your Grace utters the most sublime truth as if it were fiction, while I utter fiction as if it were truth." Now our sanitary legislation, in most of its parts, has been so constructed as to be almost inoperative; and our sanitary talk, when it has been true, has usually been uttered in the precise manner that Garrick condemned. In mediæval times, in the times of the Plantagenets for instance, several matters of importance for the preservation of the public health were well understood in England; and both Edward II. and Richard II. enacted some curt and wholesome laws, having neither the permissive character nor the ambiguous phraseology of many modern ones, for the punishment of persons who offended against the sanitary lights of those days. The time at my disposal, however, will not permit me to linger over the remote past; and I must come at once to that great measure, the foundation of almost everything that has been done for the diminution of disease in our own day, the Registration Act of 1837. Until this act came into operation, and indeed until it had been in operation for a considerable time, there were no data, outside the metropolis itself, on which sanitary reform could be founded; for no one knew with any approach to accuracy, or in any manner than by conjecture, even the probable extent of the evils against which the law was required to contend. The references of deaths to their causes is still, in many respects, less accurate than could be wished; but the errors probably counterbalance each other to a great extent, and I have been able to-night to place before you certain figures expressing mortality, and to found upon them certain estimates about cost and prevalence, with full confidence that I could not far mislead you. The revelations made by the national death registry speedily had the effect of calling attention to the ravages of preventable disease; but it happened, most unfortunately, that the question somehow became the property of a comparatively small coterie of persons, possessing, indeed, much sincerity and earnestness, but not gifted with minds that could in any high sense be called philo-

sophical, singularly prone to the sins of premature generalization and of presumptuous judgment, and altogether abandoned to the belief that they were the sole depositories of knowledge on the subjects that they had contrived to make their own. Such, I think, is not an unfair description of the curious organization that was denominated the General Board of Health, and that bore sway in England from 1848 to 1858. Its brief reign was characterized, if not by the origin, at least by the first currency of a strange delusion, which has ever since prevailed extensively and which has been the fruitful parent of an infinity of mischief. This is the erroneous belief that the requirements of preventive medicine are of such a nature that they may easily be understood by the people, and easily put in force by any unskilled person. The General Board of Health may be said to have staked its existence on the dogma that dirt is the cause of disease; and wherever disease was rampant, the Board, instead of sending an expert to trace it to its origin, sent an inspector, an engineer, a lawyer, an amateur, or what not, to look for dirt. If he found a muck-heap within a mile of an epidemic, the inspector would feel that he had not only done all that could be required of him, but that he had even exercised extraordinary acuteness of observation, and that he had furnished an exhaustive explanation of the occurrences. It when the muck-heap was removed the epidemic did not cease, it clearly ought to have done so, and the case was so much the worse for the facts. The General Board of Health arrived at the further conclusion that an accumulation of excreta constituted the most noxious form of dirt, and that the best method of disposing of excreta was by means of water-closets. Their inspectors, therefore, whenever they were asked to advise for the improvement of the health of a locality, advised the immediate adoption of a water-closet system. It did not matter whether the prevailing maladies were actually due to faulty methods of dealing with excreta, or to other and wholly different causes; and it mattered still less whether the necessary water-supply could be procured, or what might be the ultimate destination of the sewage. The panacea was in all cases the same, and its perpetually recurring failures were attributed only to its imperfect application. The whole business was like Albert Smith's description of an extinct animal called a "grinder," some specimens of which still lingered upon the earth when I was young, and were engaged in preparing medical students for examination at the "College" and the "Hall." Albert Smith's grinder had told his class that carbonate of lime was the best antidote for certain corrosive poisons, and that, if asked what they would do if chalk was not immediately procurable, they were to say that they would scrape whitewash from a wall with a fire-shovel. "It sounded practical, and would please the examiners." He then turned briskly to a sly and reticent student, and said: "Now, Mr. Meek, what would you do if you were sent for to a man who had hanged himself?" "Please, Sir," said Mr. Meek, "I should scrape the wall with the fire-shovel." And I have no doubt that the prototype of Mr. Meek, if not actually a member of the General Board of Health, was at least one of its most trusted inspectors. Some of us, doubtless, have heard Dr. William Budd describe his inquiries into the origin of the Cowbridge fever. This fever attacked a number of ladies and gentlemen, who, in November, 1853, it being race week at Cowbridge, had attended two balls held at the principal inn there. No less than eight of the sufferers died; and, as they were all people of some wealth

and station, the occurrence attracted much attention, and the General Board of Health sent down an inspector. The ball-room had been made by the temporary conversion of a loft over a large stable; and to this stable the inspector ascribed the fever. Dr. Budd proceeded to the place, as if he were a chance traveller, and discussed the outbreak over a glass of wine with the landlady. He soon ascertained from her that, although the disease had originated in the stable, no horses had died, and no helpers had been attacked. By skilful cross-examination he discovered that a gentleman had been ill with typhoid in the hotel before the balls, and had left, when barely convalescent, in order to escape from them. His excreta had been conveyed into a cesspool that leaked directly into a certain well; and the water from this well had been used in making beverages for the dancers. The members of the Board of Health, however, notwithstanding such evidence as this, had an almost personal hatred for facts that supported a belief in contagion, or in anything but dirt; and they used their whole influence, and their whole printing power, during a period of ten years, for the purpose of discrediting everything that told against the hypothesis they had espoused. They greatly injured and retarded the cause of sanitary reform, by furnishing a signal example of how little those who professed to be authorities might really be worthy of trust, and by supplying a tangible ground for the scepticism of common-sense people. But they, nevertheless, did good service, partly by accustoming the public mind to the idea that some legislation about health was really called for, and partly by directing attention to the enormous prevalence of preventable disease.

About the same time that the Public Health Act, by which the General Board of Health was created, received the sanction of the Legislature, an Act was also passed which empowered the Commissioners of Sewers for the city of London to appoint a medical officer of health. The office was conferred upon Mr. Simon, who held it until 1857, when, the General Board of Health having at last discovered its need of medical advice, he was appointed to be its medical officer. In the following year, when the General Board of Health was extinguished, he was transferred to the headship of the Medical Department of the Privy Council.

It is very difficult, in the case of one who is still living in our midst, to speak with the impartiality of history concerning the quality of his work. But the office with which you have honored me demands that I should at least strive to fulfil its obligations, and Mr. Simon forms the central figure in the picture that I have next to draw. Already, in 1848, a distinguished pathologist, and surgeon to a great hospital, he was not to be deluded by the shallow sophistries that prevailed among men in authority. He saw, with the clear insight of genius, that many of the questions concerning which it was fashionable to dogmatize were insoluble; some, perhaps, from their very nature, some from lack of evidence; and that, with regard to the latter class, the one thing needful was patient and careful investigation, conducted by trained scientific inquirers. He saw that an epidemic outbreak, instead of being at once traceable to the presence of a miasma, was probably the ultimate result of a large number of concurring conditions, among which, indeed, the miasma might play a part, but each of which required to be studied in all its bearings. He saw that this study, in order that it might be conducted fruitfully, required certain kinds of knowledge and certain habits of mind; and that the unverified conjectures which

engineers and lawyers described as their opinions about the causes of disease were simply so much rubbish, impeding the footsteps of the genuine and competent inquirer. During his period of duty, as medical officer of health for the City, Mr. Simon succeeded in removing from his district nearly all the manifestly unwholesome conditions that had before prevailed there, while he yet committed himself to no more than this, that the arrangements which he condemned were necessarily evils in some degree, and that they ought to be altered for the better. He published nine successive annual reports, which have ever since been accepted as types of what such reports should be, and above all, he made no mistakes. During his whole official career, I do not remember a single sanitary matter in which he has ever jumped to a conclusion, in which he has ever gone a step farther than carefully observed and well recorded facts would carry him, or in which his opinion, once given, has either been overturned in controversy or falsified by events. When he became chief Medical Officer of the Privy Council he proceeded to organize a staff of competent observers for the investigation of disease; and, by the aid of such men as Buchanan, Seaton, Radcliffe, and Burdon Sanderson, he set himself to unravel the profoundly difficult and complicated questions that surround the origin and propagation of epidemics. The department of which he was the head became a training school, in which young medical men were taught how inquiries of this kind should be conducted, and by what sources of error they are beset. The junior inspectors, selected on account of their presumed or proved aptitude for scientific research, when employed in investigating the origin and diffusion of local outbreaks of disease, had the great advantage of being able to submit their draft reports to the criticism of their immediate chief, by whom probable sources of error were pointed out, and doubtful questions were suggested as matters for further inquiry, before the reports were laid before the Parliamentary head of the department, and were finally adopted and issued as its work. In this manner was brought about the absolutely unrivalled accuracy for which these documents have been distinguished, and which has caused the yearly volumes containing them to be in a demand far exceeding the supply, as the most precious records of methodical sanitary investigation. Unlike the General Board of Health, the Medical Department of the Privy Council has had no theories, and its function has been only to learn and to declare the truth. Even in such matters as the propagation of cholera and of enteric fever by water contaminated with excreta, it has done nothing more than to establish what has actually occurred in this place and in that, never affirming that a different order of events might not be found elsewhere. Its inspectors, when called upon to advise for the improvement of the health of a locality, have had no universal panacea, either water-closets or any other. They have not scraped the wall with the fire-shovel. They have everywhere inquired into the existing conditions, in the same manner in which they would have inquired into the symptoms of a patient, and they have prescribed with reference to the facts that their inquiries brought to light, meeting local authorities in a spirit of cordial sympathy with their difficulties, and always helping them to do what was best in the actual circumstances of the case. When, for instance, the question has been one of the disposal of excreta, the medical inspectors have told local authorities how similar conditions have been met elsewhere, by what methods and with what success, and have thus brought the experience of all England to bear upon the wants of each place to which

their official duties have called them. As a whole, therefore, the department was both a place of research in which certainties were surely, if slowly accumulated, and a furnace in which sanitary knowledge was tried, and in which the errors of hasty generalization were exploded. At the same time, it was a centre which had established the best relations with local authorities all over the country, and its officers were hailed as friends in council wherever they bent their steps. Besides this, the supervision of vaccination had brought the medical inspectors of the Privy Council into contact with medical men all over England, on a system which ought to have furnished a model for the relations to be established between the Central Department and the medical officers of health. When Mr. Simon took charge of vaccination, it had been brought to the lowest depths of muddle by the mismanagement and the parsimony of the Poor-law Board, and was in many places very carelessly and inefficiently performed. But, after a while, each public vaccinator found himself visited by an inspector of his own profession, whom he was compelled to recognize as being perfectly master of the matters to be inquired into, who supervised his work, who pointed out his errors, who recognized him and was able to reward his merits, who advised him in his difficulties, who guided him along the road which he ought to travel, and who was a consultant to whom at all times he might refer. The result has been that the vaccinators, no longer scattered units, are all working upon the same lines for the attainment of the same ends. The standard of vaccination has been greatly raised, and we may reasonably look forward to a time when the operation will no longer be in danger of falling into disrepute from inefficient performance, or of conveying other diseases from the careless selection of vaccinifers. Such services would, I need hardly say, in any other country, have secured to him who had rendered them an honored position in the State; but with us they have been left unrewarded, and, save by the homage of all capable of appreciating them, unnoticed. Mr. Simon is recognized over the whole civilized world as one of the first of scientific Englishmen, as the greatest authority, past or present, upon everything connected with preventive medicine, and as the source of nearly everything that is certainly known concerning the origin and modes of propagation of epidemic disease. From the height of this eminence he has had to do battle, for the very existence of his Department, with an adversary who is no more than a party politician. Now sanitary legislation cannot be made to play this part, because there is complete agreement with regard to the ends sought to be attained. I know of no party that makes dirt the symbol of its union—I cannot conceive that any politician will ever become a Secretary of State by his pertinacious advocacy of disease. There is no such rallying cry as "Our old fever, and our new epidemic!" And so the good cause languishes for want of opposition; while those who have a pocket interest in any of the causes of pestilence are shrewd enough to hold their tongues. Another difficulty, inherent in the nature of the case, arises from the sort of feeling that men entertain with regard to dangers which they know to be real, but from which, after all, they fully expect to escape, and concerning the details of which they are, and prefer to remain ignorant. Another, and perhaps the most important of all, and one moreover which we are bound to face, arises from the scepticism of the educated public with regard to the conclusions of medical science. Men say, and from this point of view I think they say justly, that doctors often make mistakes, that we confessedly know very little about

many of the questions with which we have to deal—that that we have not cured consumption, or gout, or cholera, that we are unacquainted with the causes of many diseases, and so forth; and on these grounds they feel an unwillingness, not altogether unreasonable, to submit to restrictions, or to spend money, or to do anything that is disagreeable, and that may, they think, after all, perhaps, lead only to disappointment. This sort of feeling seems to me to be on the increase in society; and it has been materially strengthened by the shallow dogmatism of the mere “dirt” school, and by that utter break-down of the Acts of 1871–72 which I have endeavored to trace to its true causes. People in general do not know, and cannot be expected to know that many of the so-called sanitary reformers of a few years since, who attracted attention by their earnestness and self-confidence, and who came to be regarded as the representative men of the movement, were people who had never labored at all at the investigation of facts, who shut their eyes resolutely against everything that did not coincide with their own doctrines, and who never commanded the confidence of the medical profession. Neither do they know that the so-called Local Government Board has acted from the first in total disregard or defiance, not only of medical opinion, but even of medical knowledge; as sagaciously, that is, as one who should try to build a house from the roof downwards, without reference to the law of gravitation. The general belief is, I have little doubt, that the doctors have had their innings, and that they have not only made no score, but that they have shown their inability to play the game. We, in this room, are well assured that we have, even now, positive knowledge by which, if we could apply it, we could greatly diminish disease; and we are also assured that many of the defects in our knowledge, with which we are taunted, are the direct results of the want of certain powers for which we are ready to ask. Take, for instance, the case of the cause of scarlet fever. A distinguished Fellow of this Society holds that scarlet fever can be produced anew by the decomposition of blood, and another, that it is liable to arise spontaneously in any large aggregation of children. I can only meet either of these views by the Newtonian phrase, “It may be so;” and I shall never be able to do more until society will help me by placing scarlet fever under some kind of restraint, by limiting the ordinary channels of its diffusion, and thus by narrowing down the inquiry within practicable bounds. I once lived near to some people with whom I had no acquaintance, but who had young children; and these children were accompanied in their walks by a very pretty, gentle, playful dog, which we came to know well by sight. One day this dog found its way into my garden, where it joined my children in their play, and, as we suppose, gave them all scarlet fever. The children to whom it belonged, we found afterwards, were all down with the disease, and the dog came straight from their beds to us. So, when scarlet fever appears, and we want to trace it to its origin, we have first to consider that it may have been conveyed in some such unsuspected way as this—from a stray dog, from a beggar, from the messenger of some tradesman, in a public conveyance, in a place of amusement, or by casual contact in the street. It may have been put into the letter-box by the postman, or delivered with clean linen by the laundress. As long as we cannot exclude these possibilities, we shall never have any knowledge of the facts; and therefore, on behalf of the medical profession, I say that our demand is not for any fresh sanitary law-making of the customary kind, but for law-making that shall establish conditions

likely to remove our uncertainties. We do not want more power, but more light, and facilities for transforming that light into public opinion as fast as it is obtained. Let us see how these benefits could be secured.

In the first place, perhaps, we should ask politicians to settle, to the satisfaction of the country, a purely political question—that of the incidents of rating. Real sanitary reform, whatever its nature, must cost money, and this money must be drawn from rates.

In the next place, I would impose upon local authorities the same duties as at present with regard to the relief of sickness and destitution, to lighting, paving, and cleansing, to the maintenance of order, and to the protection of property, and I would add to these some others which are now occasionally undertaken, such as the maintenance of a proper gas and water supply, so that no necessary of life in any district should be a monopoly in the hands of a trading company. But in the discharge of these duties I would leave the local authorities, being themselves elected and representative, absolutely unfettered with regard to spending the money of their constituents, and I would also leave them at liberty to frame and enforce any by-laws, not in contravention of the laws of the kingdom, that the circumstances of their several districts might require, or that the public opinion of the inhabitants would warrant. If ratepayers knew that the men whom they elected to be town councillors or guardians would have the power of making by-laws and the power of spending money, the elections would be more carefully conducted than they are at present, the successful candidates would be persons of a very different stamp from some of those who are now returned, and the proceedings of the elected bodies would be subjected to an entirely new kind of scrutiny. While local boards were thus learning the uses of freedom and the elements of administration, time would be afforded for the improvement of the central sanitary organization of the country and for carrying out measures of national importance. Among these the principal would be the complete rehabilitation of the Medical Department of the Privy Council, under whatever name, in such a manner that it might continue to investigate, to advise, and to teach; an improved system of registration, so contrived that it should gradually embrace disease as well as death; and a somewhat close observation of the movements of tramps and vagrants, by whom, I believe, infectious diseases are now largely disseminated. With regard to the first of these requirements I need at present say nothing; but the question of registration is one with which we are less familiar. There can be no doubt, I think, of the great advantages that would accrue from the sort of stock-taking of the public health that would be implied in a complete registration of disease either continuously or at intervals. This is at present impracticable; but Mr. Lewis, of the General Registry Office, has matured and advocated a scheme, which could be easily carried into effect, for the registration of the disease that falls under the notice of public officials, such as the medical officers of unions, workhouses, and jails. The details of this scheme have been published, and are easily accessible; and they have commended themselves, I believe, to all persons practically acquainted with the question, save and except one official, whose work would be materially increased if the suggestions of Mr. Lewis were carried into effect. I feel sure that even this limited registration of disease would prove of immense value in the course of a few years, and that it would pave the way for an extension of the

system. The registration of death might unquestionably be improved in correctness, and the first step to this end would be the payment of a fee for the medical certificate. This fee need only be a small one; and it would not only give the public a claim upon the certifier to be accurate and careful, but it would also form an exception to the systematic injustice by which the Legislature has hitherto compelled the members of our calling to do important professional work for the State without remuneration. Besides these, I have yet another suggestion to make, which will perhaps to some appear startling, but for which I think the time is ripe and public opinion prepared. It is this: that there should be an official declaration to the local sanitary authority, by every medical practitioner, of every case of self-propagating disease that he is called upon to treat. I say "self-propagating," rather than "contagious;" because I should not propose to include any disease that was usually communicated by personal contact only. But I would make it the statutory duty of every doctor, as soon as he saw a case of self-propagating disease, such as fever, scarlet fever, small-pox, and some others, at once to give notice to the local sanitary authority. I would attach a small fee to the notice, and I would punish wilful neglect to give it by a sharp penalty; so that no one could hope to conceal the existence of one of the specified maladies in his family. When a doctor was not called in, the duty of giving notice should attach to the head of the household. I think that the entrance into a district of an infectious disease is a matter of public concern, and necessary to be made known to the guardians of the public health, just as the outbreak of a fire, or the arrival of a gang of burglars, should be made known to the guardians of the public safety. Fires are even more frequent than epidemics; but we do not suffer them to burn unchecked.

With regard to the control or registration of the movements of vagrants—persons wandering from place to place with no visible means of subsistence—I presume the only difference of opinion will be whether the measure is one of sufficient importance to be worth the trouble of carrying it into effect. I think it is, for I believe that a single vagrant, suffering from a mild form of typhoid, may contaminate the water-courses of half a dozen localities. But what I want is, as I have said, knowledge rather than power, or, in the first instance, to be able to track these wanderers with facility, so as to find out and prove the mischief that they do, rather than, without evidence, to arrest their steps.

I have already said that the enforced appointment of a medical officer of health in every district was an absurdity, because there were not a sufficient number of qualified persons to appoint. As a matter of fact, the tenure of office will determine, in every case, after five years; and in many cases, the absurdity has been too manifest to be repeated. But local authorities, in the discharge of their duties, must frequently feel the need of medical advice; and I would have them obtain it just as they obtain any other advice. A board, when in doubt upon a legal question, applies to its legal officer; and he, in case of need, is instructed to obtain counsel's opinion. If this does not settle the point, there remains the resource of an appeal to a central authority; or, in other words, to the law officers of the Crown. Is there any reason why, in like manner, a local authority should not apply, on any question of the public health of the district, to a local medical officer; or why, if he gave an uncertain sound, he should not hold a consultation with some one of larger experience than his own; or

why there should not be an ultimate appeal to the central medical department? Of course, in certain localities, the need for medical advice would be so constantly recurring that it would be wise to appoint a medical officer of health, whose knowledge would always be at the disposal of the sanitary authority; but on this point, as on most others, I would leave that authority unfettered. But a medical officer of health, if appointed, should immediately be brought into relation with the central medical department, and should be made to feel himself an outlying officer of that department; to which, also, all reports of self-propagating disease, or other reports made to the sanitary authority, should be forwarded as a matter of course, so that the department would have full knowledge of the sanitary state of every district. It should be empowered, also, to conduct inquiries in every district, either at its own instance or at the request of ratepayers, and to publish the results of these inquiries; showing, as far as they were ascertainable, the causes of the healthiness or unhealthiness of the locality.

Under such arrangements as those which I have endeavored to sketch in this brief outline, which would render every locality responsible for its own condition, and which, while they relieved it from central control, would leave it subject to central inspection and report, I do not doubt that the public health would soon be greatly improved. It must be remembered that a diminished rate of sickness and mortality in a district would mean a very sensible increase in the value of property, and *vice versa*; so that the potent lever of self-interest would soon become a moving power in the cause of sanitary reform. At first different municipalities would take different courses, and would afford—to borrow a phrase from Cuvier—so many experiments prepared by Nature for the determination of doubtful questions. In one place, for example, the first recorded case of typhoid or scarlet fever would be isolated, and the infection would be suffered to die out, like a match thrown upon a stone floor, at a cost of five or ten pounds. In another place the match would fall as into a straw-yard, and the conflagration would cost, say, a thousand pounds. In one place we should see an enlightened liberality, leading rapidly to a diminution of expenditure, of disease, and of death, and to a corresponding increase in the value of property; in another, a narrow-minded parsimony and a hatred of knowledge for its own sake, leading to extravagant outlay, to sickness, to mortality, and to depreciation of property. These contrasts should be observed in all their features and carefully made known by the central medical department, and they would in time produce their natural effects. Certain places, notably those whose business it is to attract visitors, would always be the pioneers in the path of improvement, and public opinion would in time demand the general adoption of regulations that had proved salutary wherever they had been put in force.

And now, sir, in such brief and imperfect outline as the time at my disposal would permit, I have endeavored to show, first, that the condition of England with regard to preventable disease is such as to call loudly for improvement; and, secondly, that the past failures of sanitary legislation and administration have been mainly due to the neglect, by politicians, of medical science and of medical opinion. I have sketched, also, the methods of procedure which, to my mind, seem calculated to bring about a better state of things. Something I had intended to say by way of peroration; but I have already addressed you for

ninety minutes; and the worst fault of a speaker is to neglect opportunities of leaving off. If my words have been acceptable to this Society, and if they should be endorsed by the mature opinion of its distinguished fellows, they can hardly fail to find favor also with the public. In that case I shall feel that I have done something, however humble, to lighten a burden that presses heavily upon the happiness and the prosperity of our beloved country.

A NOTE ON LONGEVITY.

BY THE EDITOR OF "PUBLIC HEALTH" (MAY 16, 1874), LONDON.

IN an interesting paper on the Law of Longevity, with special reference to life assurance, written by Dr. Nathan Allen, of Lowell, Mass., U. S., and published in *Public Health* of February 16th, great stress is laid by the author upon hereditaryness, or, in other words, long-lived ancestry, as one of the prerequisites of longevity. Dr. Allen remarks: "The influences of hereditary descent have as yet received but little attention, compared with their importance, even from the medical profession, and before they can ever be thoroughly understood, it will be found, if we mistake not, that there exists in physiology, as a fundamental principle, a general law of propagation; and, as a part and parcel of the same, will also be found this law of longevity. In the matter of life insurance a thorough knowledge of these hereditary influences is of the utmost importance."

Several of our correspondents took exception at the time to Dr. Allen's views on this point, regarding them as rather theoretical than actual. It is one of such great importance that any practical light that can be thrown upon it will not be without benefit.

I therefore propose to briefly describe the history of a family which has recently come under my notice, in which this principle of hereditary influence is strikingly illustrated.

The immediate subject of my note is an old man, one David Jenkins, whom I have lately seen professionally, as a matter of charity, he being ill and in necessitous circumstances. Upon visiting him I found a remarkably hearty-looking person, evidently suffering more from debility induced by insufficient nourishment (5s. weekly, out of which 2s. have to be paid for rent, being all the assistance that he and his wife, also aged, receive from the parochial authorities), and from the injurious effects of the unusually cold weather, than from any senile disease, although he is ninety-three years of age. None of the more prominent signs of decay from old age are present. Until a recent date he has picked up a trifle occasionally by doing little odd jobs of work, such as mending chairs (he was formerly a cabinet and chairmaker) and carrying parcels or letters; when in health, the old man is tolerably sound on his legs, and can walk fair distances.

He was born at Swansea, where he passed the first fifteen years of his life; subsequently he went with his parents to live at Bath, where he learned the business of chair and cabinet maker; and during the last thirty-five years he has resided in London, nearly twenty having been spent in the same house.

But the principal point of interest about this case is that David Jenkins is the great-grandson of Henry Jenkins, who would have considerably puzzled disbelievers in centenarianism, if any existed in his time, for he lived to the patriarchal age of 169 years. The best account of this venerable old man is that given

by Mrs. Saville, a lady of position, who resided at Bolton, in Yorkshire, where Henry Jenkins also lived. "When I came to Bolton," says she, "I was told several particulars of the great age of Henry Jenkins; but I believed little of the story for many years." One day, however, he happened to call at her house, to ask for some assistance, when she "desired him to tell her truly how old he was. He paused a little, and then said that to the best of his knowledge he was 162 or 163; and I asked what king he remembered. He said Henry VIII. I inquired what public event he could longest remember. He said Flodden Field. I asked whether the king was there. He said, no; he was in France, and the Earl of Surrey was general. I asked him how old he might have been then. He said, 'I believe I might have been between 10 and 12; for,' added he, 'I was sent to Northallerton with a horse-load of arrows, but they sent a bigger boy from thence to the army with them.' All this agreed with the history of that time; for bows and arrows were then used, the Earl was named general, and King Henry VIII. was then at Tonnay. It is observable that Jenkins could neither read nor write. There were several old men in the same parish, some reputed to be nearly 100 years old, but they all said that Jenkins was an elderly man ever since they knew him. He told me, too, that he was butler to the Lord Conyers, and remembered the Abbot of Fountains Abbey very well, before the dissolution of the monasteries."

Henry Jenkins died on December 8, 1676, at Ellerton-on-Swale, in Yorkshire. The battle at Flodden Field was fought September 9, 1513, so that, assuming he was 12 years old at that time, he lived to the "amazing age of 169" (as was stated on a monument subsequently erected to his memory by a subscription amongst the inhabitants of Bolton), and thus attained to 16 years' longer existence than old Parr.

I need not discuss the question whether he really reached the great age of 169, or whether he died at a few years under that period. It is sufficient for the purpose of this Note that he lived longer than any other person whose case has been authentically put on record since the commencement of the Christian era.

Of Henry Jenkins's descendants, the particulars are, as might be expected, from their humble position, only slight; but there is no room for doubt upon one point, viz.: that they were all long-livers. David Jenkins tells me that his grandfather was a very old man at the time of his death; and that his father died at the age of 93, from the effects of a rupture through overstraining himself in his work as a chairmaker. Had it not been for this accident he would probably have become a centenarian; and we see that, despite of poor David Jenkins having to contend with the drawbacks of bitter poverty—rendered none the less poignant by the fact that, years ago, he succeeded in elevating himself into a position of comfort and independence as a master-tradesman, which position he subsequently lost through a series of unavoidable misfortunes—he has attained the great age of 93, in the full possession of his faculties, and free use of his limbs, with every prospect of living many years longer, if he should not be crushed under the heavy weight of adversity.

Surely, in the history of this family, there is enough to show that Dr. Allen was not mistaken in his views upon the importance of hereditaryness in connection with the subject of longevity.

THE Chamber of Life Insurance will hold its next meeting in this city during the coming week. It has work before it of importance to medical men.

A LAYMAN'S VIEW OF THE QUESTION.

(From "The Chronicle.")

No subject connected with life insurance is at present receiving more, or more thoughtful attention, than that of medical examiners, their qualifications, their relation to the companies, the manner of their appointment, and the measure of their compensation. This will be one of the principal topics of discussion at the approaching meeting of the Chamber of Life Insurance, it having already been referred to a competent committee. And it is a subject of transcendent importance to every life insurance company in the land. It has been incompetent medical examiners quite as much as malarious influences that have made the southern business of our life companies unprofitable. And generally, because of incompetency or carelessness on the part of medical advisers, the mortality among insured lives has been of late frightfully increased.

Applicants for insurance are the food upon which life insurance companies subsist—the pabulum of which their future safety, efficiency, and usefulness are built up and perfected, just as the food which man eats gives him strength, repairs the waste attendant upon the performance of the natural functions, and so prolongs his life.

No less care should be used in the selection of the food required in the one case than in the other. Nature's careful guardians in the case of the human body are the organs of special sense. A like supervision over the safety of a life insurance company should be the office of a skilled medical examiner. He it is alone who can decide whether the food presented and ingested will build up into healthy, vigorous bodies, or degenerate into a sapless and decrepid corps of invalids. He alone passes judgment upon its hurtful or beneficial qualities, and thus wields an influence potent for good or evil, not only upon the companies which he may represent, but upon the community at large; for life insurance is a business from which man, in any position in life, may derive benefit.

Every risk assumed upon a recommendation not made by skilled judgment, and based upon strict and conscientious examination, is a fraud upon each and every policy-holder, and another cause of want of confidence on the part of the insuring public.

It needs no acute reasoning to prove that a company which receives and accepts unworthy risks is not a safe company, and outsiders, as they are termed, are by all odds the first to discover such a fault, and seeing it, to avoid involving their fortunes with those of the recklessly managed company which commits it.

Surely no company can be blind enough to its own interest to fail to realize how greatly it is dependent upon the clear judgment of its corps of medical examiners, neither should any medical gentleman assume the duties of this office without conscientious self-inquiry into his own fitness to fill the position, and a clear understanding of the weight of responsibility borne by his shoulders, and the manifold interests affected by the faithful or unfaithful discharge of his duties.

Not only is it work of mere professional acumen, but it is a work which will add more to his own credit, and to the honor of his profession, than any other which he can be called upon to perform; for here it is that the medical examiner should gather the data based upon which the benefits of the good work of which he is the guardian may be disseminated broadcast, and the results of his labor redound to the welfare of mankind in future years.

But still more, and greater than all, the medical man should consider his labor of the most purely philanthropic nature. The fee which he receives will never repay him for the labor expended, scarcely for the time occupied, if he performs his duties conscientiously,—does it so as to show a just appreciation of the confidence reposed in him by the managers of the company,—does it in such a manner that no certificate shall bear his signature without showing him to be master of the teachings of his art, and without reflecting honor upon himself and his professional brotherhood.

To labor solely for the interests of his company is a sacred duty which he has pledged himself to perform, in accepting the appointment of medical examiner; and no consideration of time, business, or pleasure should ever cause him to gloss over an examination, or fail to make a clear, skilful, and satisfactory diagnosis of every case brought under his investigation.

Both the manner of appointing and the method of compensating medical examiners has hitherto been almost as incompatible with the procuring of such trained skill and conscientious fidelity as if they had been especially contrived to defeat it. There is but one fair and reasonable way of compensating the chief medical officers of life companies, and that is by a percentage of the "mortality gains." This will act as an incentive for them not only to be keen and careful in their scrutiny of risks and applications, but discreet in their selection of local examiners as well. And if all the companies doing business in any one locality could be brought to unite upon the same physician as examiner in that locality, he too might be partially compensated in the same way, *i.e.*, by a percentage of what experience should show he had saved to his clients by keeping the average mortality in his district below the tabular mortality.

It is not claimed that this method of compensating medical examiners can be successfully adopted in all places or under all circumstances; but we believe that its adoption in the case of the chief medical director, and his assistants in the larger cities and more important districts, would be a long step and a brave one in the right direction.

Miscellaneous.

LONGEVITY OF MEDICAL MEN.—According to Casper the average age of clergymen is 65; of merchants, 62; clerks and farmers, 61; military men, 59; lawyers, 58; artists, 57; and medical men, 56. The medium duration of life in Russia he states at about 21 years; in Prussia, 29; in Switzerland, 34; in France, 35; in Belgium, 36; and in England, 38 years. It has been calculated by some statisticians that, under ordinary circumstances, man can live six or seven times longer than the years required to attain puberty. Taking this at the fourteenth year, from 84 to 98 years of age would be the natural life. The *Medical Times and Gazette* lately argued that medical men in England stand high on the scale of longevity. The united ages of twenty-eight physicians who died last year amount to 2,354 years, giving an average of more than 84 years to each. The youngest of the number was 80, the oldest 93; two others were 92 and 89 respectively; three were 87, and four were 86 each, Sir Henry Holland being one of the latter. There were also more than fifty whose average age was between 74 and 75 years.—*Doctor*, April 1.

Original Lectures.

ON EXTERNAL HÆMORRHOIDS.

A CLINICAL LECTURE DELIVERED AT CHARITY HOSPITAL.

By ERSKINE MASON, M.D.,

ADJUNCT PROF. OF SURGERY, UNIVERSITY MED. COLLEGE, NEW YORK.

THE affection of the rectum to which I shall call your attention to-day, no doubt is the most frequent disease to which this organ is subject, and one which you will constantly meet in daily practice. I allude to hæmorrhoids, or, as they are commonly spoken of, piles. In clinical lectures such as these it will not be my intention to give you a minute description of these affections in all their phases; but I shall touch slightly on some of these points in order that you may better comprehend the nature of the cases that are presented to you, dwelling, however, chiefly upon the more practical points in reference to their surgical treatment. Before presenting to you these patients who are suffering from hæmorrhoids, I must tell you first that all are agreed in dividing piles into two classes—external and internal—and that these tumors are often very different as to their minute anatomy, as well as location, symptoms, and indications with respect to treatment. While following this common division of hæmorrhoidal tumors, you must also know that cases present themselves where it may often be difficult to say to which class they belonged, if indeed they could be placed exclusively in either. I am well aware that some authors have laid down rules for your guidance in this respect; but I fear that in your practice you will find many exceptions, which may be of service perhaps only in proving a rule. While these two varieties are very commonly met with in the same individual, you are often to see them separate and distinct. More frequently you will observe external hæmorrhoids unassociated with internal, than internal without the presence also of external. Indeed it would be a rare case, were it of any duration, to find the internal variety devoid of some external growth.

Now, where are we to look for these different varieties of this affection? External hæmorrhoids are those which are seen just at the verge of the anus, and for the most part form just at the lower border of the sphincter, and project outside the verge of the anus. Internal, those that form above the sphincter, and remain either in this locality, hidden from casual observation; or from various causes they too may project outside the external sphincter. Bear in mind it is the situation in which these tumors first arise, not the locality in which the eye may at first perceive them, that places them under one classification or the other. This being the case, are there any reasons why they should arise just at these situations, and not within that portion of the bowel which is surrounded by the circular muscular band which we call the sphincter? The solution of this question, I think, was given by Mr. Brodie, and is to be found in this fact: the hæmorrhoid veins, which is the part chiefly involved in this affection, run on the inside of the sphincter, and while this muscle preserves its tone, dilatation of these vessels is not permitted. It will be only in old standing cases, I think, that a varicose condition of these vessels will here be found.

Before speaking of the causes that give rise to hæmorrhoids, it is perhaps better to consider the nature of these tumors. Though I shall tell you presently that

we classify these growths, as to their appearances and pathological tendencies, as well as the locality in which they arise, we may say that no matter whether they be called external or internal hæmorrhoids, they are made up chiefly of a varicose condition of the hæmorrhoidal veins, though sooner or later other elements enter into their formation, such as capillaries, arteries, products of inflammation and integument, according to the particular kind of tumor which we meet with. And here it may be well to enumerate a few of the appearances these tumors present, and the respective characters of each.

First, as to those which are spoken of as external hæmorrhoids. If you examine the anus of a patient with this form of trouble, as for example in the case of this man before you, you will find around the verge of his anus several tumors varying in size from that of a large pea to those of the size of a Lima bean, and in many instances these may be of a much larger growth. Their bases are large, and by separating the sides of the anus, either by the fingers or speculum, you will observe that they run up the sides of the bowel somewhat like pillars. The extent they ascend will vary much in different cases. Some of these tumors are seen to be quite distinct from others, while, again, others merge into one another. The color of these growths is of a bluish appearance at their most dependent portion, a little more of a purple color above, and they may be covered by both mucous membrane and the thin integument which surrounds the anus. This will present to you a fair case of what is known as external piles. In other instances, as with this patient, you will also observe surrounding and hanging from the anus several tags of thickened hypertrophied integument. Some would place these patients in two separate classes of external piles; but I think that this is a useless refinement, regarding, as I do, that these patients exhibit but two stages of what is known as external hæmorrhoids. For let a patient who suffers from varicose external hæmorrhoidal veins neglect himself, then hypertrophies of the integument surrounding the anus will sooner or later be developed. This variety of hæmorrhoids which I have just shown you, is what patients will sometimes speak to you of as blind piles, because they are not so liable to bleed as a class, which we will presently consider.

Let us now examine these tumors as to their anatomical nature, and we find this will vary according as they are examined just after their formation or after some interval has elapsed, and they have undergone pathological changes. At first they consist solely of an enlarged varicose hæmorrhoidal vein. After a time, if neglected and they become the seat of frequent inflammation, we will find that lymph has been poured out in the areolar tissue around these veins, and as a result the size of the growth has increased, and the vein may be so compressed as greatly to diminish its calibre, and at times entirely to obliterate it, so you may find nothing but infiltrated tissue and hypertrophied integument, such as you see in the patient before you. Again, these veins may rupture, extravasating blood into the areolar tissue, giving rise to a tumor in which you will find no vein entering into its formation—merely coagulated blood. This condition, if properly cared for, will often disappear by absorption; yet if constantly subjected to irritation, we shall find that as a result these hypertrophies, or tags of integument, which we so often see about the verge of the anus, will likewise be formed.

With this affection, as with all others, we will meet with them in different conditions. When subjected to little or no irritation, patients will often disregard

them, they perhaps giving rise to little or no inconvenience. When attacked by inflammation the case will be very different, and the appearance of the parts will be different from those we have described. You will then observe:

The tumors very much swollen, of a reddish hue; the mucous membrane somewhat prolapsed, or rather everted and oedematous, and the parts extremely painful to the touch, and the neighboring organs, such as the uterus and bladder, at fault, through what we term sympathy, and to so great an extent that often these latter organs are regarded as the ones diseased, while the true source of trouble is neglected. How common is this affection, you will soon discover when you commence to practise, if you already are not aware of it. You will examine very few patients who have reached the middle period of life without finding some trace of hemorrhoids, should you seek for them. Yet in a large portion the affection may be so slight as never to have given any great inconvenience.

Now, what are the causes that will give rise to so frequent a trouble? The list might be made a very numerous one; but it can be condensed into this—anything that will offer an impediment to the venous circulation of the pelvic organs will sooner or later cause hemorrhoids. Thus you observe it in connection with pregnancy, enlargement of the uterus from any cause, displacements of that organ; affections of the bladder, prostate, or urethra; constipation; the abuse of drastic cathartics, or the irritation of the anus from prolonged riding in the saddle, or the use of improper substances for detergent purposes. A very common cause you will find to be want of proper exercise; hence its frequency in those of sedentary habits, as well as in those whose occupation keeps them standing for many consecutive hours.

The symptoms which announce the presence of external hemorrhoids are various. It may be only the presence of the tumor which the person detects, or a sense of uneasiness in walking or sitting down; uneasy sensation while defecating; the presence perhaps of a little blood; a sense of weight or bearing down, or perhaps itching about the anus, and this is a symptom which in some patients is most annoying. In some it occurs chiefly after they have retired to bed, while others are often annoyed by it through the day.

In the management of this affection, you will find a great many remedies—so called. In very many of your cases you can relieve, if not entirely cure, your patients, by properly seeking for the exciting cause of the trouble in each individual case, and then subjecting your patient to the proper treatment for that. If it be due, for example, to stricture of the urethra, relieve the stricture and the hemorrhoids will soon cease from troubling. Do not imagine for an instant that every patient who labors from hemorrhoids must be subjected to an operation before he can be relieved from his trouble. Not at all; though in very many instances I grant you that nothing short of an operation will offer any promise of permanent relief, and in these instances all the remedies that patients apply of their own accord, and which physicians often advise, tend but too often to perpetuate the trouble.

For the treatment of an ordinary case of external piles, when they are not inflamed, a little care on the part of your patient in avoiding those causes which so frequently give rise to them, viz., constipation, the use of stimulating drinks and highly seasoned food, with frequent ablutions, will often be all that is requisite to relieve unpleasant symptoms; and if it be the first intimation of hemorrhoidal difficulty, under such a plan of treatment the tumors may altogether disappear.

Under the head of remedies, I should place the free use of cold water, used both externally and as an enema. As an enema I believe you will find it most efficacious when used in the morning, just before the bowels are moved. When constipation is the habit of your patient, you may resort to saline aperients, such as potass bitart., the different preparations of magnesia and sulphur. If you combine several of these remedies in your prescription, and give it in dessert-spoonfuls in a tumbler of water before breakfast, you will often find that they will act very pleasantly. Indeed with some a glass of cold water, taken the first thing upon rising, will often be all-sufficient to cause a regular movement. Avoid all drastic cathartics, and make your patient abstain from all stimulants, either in food or drink. With some the free use of mineral waters, as Kissingen, Vichy, or Pullna, will be found useful. The confections of senna, sulphur, and black pepper, either separately or in combination, are also useful and agreeable remedies to many. A dessert-spoonful of these is usually given in the morning. Few patients will come to you but have made use of local applications, and these, for the most part, will have been astringent ointments, and perhaps the most commonly employed is the gall ointment, with or without the combination of opium. That these are at times serviceable, I do not deny; but that in many instances they are harmful, is equally true. For my part, gentlemen, I am not partial to applying our remedies in this way. It is a dirty mode at the best, and I only resort to it in exceptional cases. Where we have bleeding it may be well to use persulphate of iron in this way, and the strength that is used may be from a scruple to two drachms to the ounce of cerate. So, too, where there is much itching, the red or white precipitate applied around the anus at night may be found serviceable. Where it becomes advisable to resort to topical applications, you may often accomplish your object by the use of lotions, and certainly it will be found both a more cleanly and agreeable method. Among these local applications you will find a solution of tannin, or any mineral astringent, as the sulphate of zinc, either in water or glycerine, serviceable; and you will find equal parts of the liquor plumbi diacet. dil. and the liquor ammonia acet. a useful wash, when acute inflammation is subsiding. When your patient is suffering acutely from inflamed external piles, you may relieve him by the application of a few leeches around the verge of the bowel, by the application of poultices, or in some instances what will be found preferable, the application of ice, and the ice should be placed either in a bladder or bottle. In this way you may use it without keeping the person or bedclothes wet. Opium and belladonna suppositories may also be required to relieve the pain. In these cases you must not neglect to inquire in reference to the bladder, for in many instances this organ may be but partially if at all emptied, your patient's agony being increased by retention, which will require the catheter for its relief. Under this head arises the question, Shall we operate while the piles are in an acute state of inflammation? It is somewhat difficult to give you set rules for your guidance in all these cases, as they will be found to differ materially. The older surgeons unhesitatingly forbid operating upon inflamed piles, fearing that pyæmia would result; while more modern writers rather advocate operating at once. Until you have become more familiar with the disease, and are better prepared to discern different shades of this inflamed condition, I think it would be better, if not safer, for you to abstain from operating till after the acute stage has passed. When, however, you find

a blue tumor projecting beyond the verge of the anus, and this is hard and tender to the touch, and for a day or two has given great annoyance, you may incise this, squeeze out a clot, and then apply a piece of lint dipped in some astringent wash, and you will thus at once relieve your patient.

The subject of itching piles deserves more than the mere references which I made to it a moment ago, for it often is one of the most distressing symptoms to which our attention is called. The remedies that have been suggested for its relief are perhaps as numerous as those for the purpose of "curing piles." I have alluded to the white and red precipitates. Citrine ointment, drachm to the ounce, and the use of sulphurous acid diluted with equal parts of water. This latter is an extremely valuable remedy, especially where we find an eczematous condition of the verge of the anus, which is often due to the presence of a parasitic plant; and for the knowledge of its use I am indebted to Dr. Van Buren. Yet in spite of all these applications I have seen many cases where nothing sufficed short of the removal of the hemorrhoids by surgical means.

In spite of all your medical treatment and care, you will often find that nothing short of the removal of these hemorrhoids will suffice. And though you may have carried a patient pleasantly through an attack of inflamed piles, and a long interval elapse without his suffering any inconvenience from hemorrhoidal tumors, he is almost sure, sooner or later, to have a return of the trouble, and these attacks often will grow more frequent till operative interference is resorted to. You may remove these external growths by various means, such as the ligature, actual cautery and scissors; the various modes of applying these you will see me do upon these patients. My preference here is for the ligature and scissors. If the tumor be a large one, you may pass the curved needle, armed with a double ligature, through the base of the tumor, and then you may tie the base of the tumor on either side; if small, it will be all-sufficient to use a single ligature. On this subject I shall have more to say to you when I come to speak of the treatment of internal piles. Where the tumors are partially surrounded by integuments, be sure to nick this with your scissors and sink your ligature well down into the groove you there make; for if you include integument in your ligature you but cause your patient much unnecessary pain. Those pendulous masses of hypertrophied skin you can best remove with the scissors; the hemorrhage will not amount to much, and should it become necessary to resort to means for its control, the parts are always accessible. Yet see that it has been checked before you leave your patient. In removal of these growths do not be too free with your scissors and encroach upon the verge of the anus, else as a result you may find, after the parts have healed, you have left your patient in a worse condition than before, by giving him a troublesome stricture of the anus. When you operate upon external piles, be sure you examine if the internal form of this trouble does not also exist; for if it does, and you neglect these, your operation will prove of but little avail.

CASES PRESENTED AT THE CLINIQUE

OF

T. GAILLARD THOMAS, M.D.,

PROFESSOR OF OBSTETRICS AND DISEASES OF WOMEN IN THE COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK CITY.

CASE I.—MENORRHAGIA AND METRORRHAGIA.

Mrs. K., aged 24. Has been married two years. Has had one miscarriage at the middle of the third month of pregnancy. Her miscarriage occurred nine months ago, and she dates the commencement of her sickness at the date of the occurrence of that accident. It is a noticeable fact that a very large proportion of uterine diseases date their beginning at a parturient process, occurring either at full term or as an abortion.

Symptoms.—The chief annoyance to this patient is a prolongation of her menstrual periods, which are accompanied with great loss of blood, pain in the back and through the body. Consequent upon this is a constant feeling of weakness and prostration; otherwise the patient feels very well.

What is the condition which gives rise to the symptoms for which this woman seeks relief?

Physical Examination.—Position and surface of cervix uteri normal, cervix slightly increased in size.

Conjoined manipulation detects the presence of a round body just behind the symphysis pubis.

This is proved to be the body of the uterus, and not a fibroid growth attached to its anterior surface, by the introduction of the uterine sound. This instrument is found to pass directly into the mass detected by manipulation. The body of the uterus is somewhat enlarged and in an anteфлекed position.

The enlargement in this case probably depends upon a prolonged congestion incident to a continued obstruction to the circulation caused by this condition of flexion. The arteries to a considerable degree resist the flexion, and still permit a free flow of blood to the organ; but the veins being less resisting, are more or less overcome by the flexion, and cannot conduct the blood from the uterus; hence the organ is kept in a constant state of engorgement. When, therefore, this flow of blood to the uterus is increased by the process of ovulation, this regular and constant engorgement is increased, the flow of blood is exaggerated, and menorrhagia is developed.

The increase in size of the organ might be explained in another manner. It might be said to be dependent upon a condition known as sub-involution; but that cannot be satisfactorily proven at this remote period from the abortion. A condition of prolonged congestion is the most reasonable explanation for the increase in size in the present case. The pain which the woman suffers is properly explained in the same manner.

Treatment.—Treatment should consist in placing the organ which has become flexed in such a position as will permit the free flow of blood to and from it. The condition in which the uterus is found is essentially a mechanical one, and not a condition of chronic inflammation.

Leeches, rest in bed, etc., would undoubtedly give the patient relief; but such measures would be illogically applied, if applied with the view of subduing a chronic inflammatory condition.

First, reduce the dislocation or displacement. This is to be accomplished by introducing the uterine sound into the cavity of the uterus, bending it in such shape as will permit its easy introduction, and then placing the uterus in a straight position by simply elevating the handle of the sound towards the sym-

THE Board of Examiners appointed by the Regents of the University of New York, in accordance with the law passed in 1872 for the purpose of examining candidates for the degree of Doctor in Medicine, opened their first session at the Fifth Avenue Hotel.

physis, at the same time making a fulcrum with the other hand at or near the middle of the instrument. When the organ has been placed in a straight position, then the sound may be turned upon its axis and the uterus placed in a position of *complete retroversion*, and there retained for a minute, unless the patient complains of pain.

Next, a firm wad of cotton is to be placed anterior to the cervix. Repeat this operation every five or six days, retaining the uterus in a retroverted position with the sound—at the second sitting, if possible, a much longer time.

Continue this treatment for one month. When the uterus has become accustomed to being thrown backwards, use an anteverision pessary to retain it in its proper position. The use of a stem introduced into the cavity of the uterus is a dangerous method of treatment, because of the liability of its producing not only intense agony, but of producing pelvic peritonitis and death. It should be resorted to only when all other measures have failed. Carefully remove all constrictions about the waist which shall have any tendency to press the abdominal viscera downwards. With proper treatment continued for three months, the prognosis in the case is good.

CASE II.—EPITHELIOMA OF THE CERVIX.

Mrs. B., aged 48 years, married. Three years ago this patient presented herself at the clinic in an emaciated condition, with rapid pulse, face expressive of great distress and anxiety, and a constant metrorrhagia. She could do nothing in the way of labor on account of the great hemorrhage which followed the most trifling exertion or movement of the body.

Physical Examination revealed the existence of cancer of the entire cervix. The cervix was removed by means of the galvanic cautery. The disease appeared in the stump in about one year. It was then destroyed by the use of nitric acid. The patient recovered rapidly, and now presents all the appearances of a woman in perfect health. Now, at the end of three years from her first appearance, there is not a vestige of the disease left. This form of cancerous growth should be regarded as curable, to a certain extent at least, and treated in accordance with that view. Conception, after amputation of the cervix, is rare. I have never seen an instance.

CASE III.—REMOVAL OF HYMEN.

Mrs. R., aged 25 years, married, and has never borne children.

The patient complains that there is some obstruction to sexual intercourse.

Physical Examination.—The hymen is found firm and unyielding, and is in such a condition as necessitates an operation for its removal before the patient can obtain relief.

Diagnosis of a condition of the hymen which obstructs sexual intercourse should be easily made. The proper method of treatment in such cases consists in its complete removal, and not simply splitting it. Seize it with a pair of forceps, and with a pair of scissors completely sweep it from its attachments. If profuse hemorrhage follows this operation, ligate the vessels.

Do not apply a roll of cotton wet in an undiluted solution of persulphate of iron, because a disagreeable accident is quite liable to attend its removal, namely, the removal of all that portion of the vaginal lining with which it has been in contact.

Complete removal of the hymen is advisable, because it is usually an irritable hymen that gives rise to diffi-

culty in sexual congress, and if permitted to remain, as by the operation of slitting, its irritability not only remains, but is very liable to become increased.

CASE IV.—ENLARGEMENT OF THE ABDOMEN.

This patient, aged 48, and the mother of a family, came to be advised with regard to a supposed ovarian tumor. Her abdomen has been gradually enlarging during the past two years, and has now attained an uncomfortable size.

Physical Examination.—There is apparently an abdominal tumor. Let us see what are the conditions connected with the abdominal walls which may give rise to an apparent abdominal tumor.

Rigidity of the abdominal walls may develop a condition resembling tumor. There is no rigidity present in this case. More, however, will be said with regard to that condition in connection with another case. Edema of the abdominal walls may cause enlargement.

Pitting upon pressure cannot be developed; nor are there any evidences of dropsy in other parts of the body.

This cause will therefore be set aside.

Elephantiasis will cause enlargement. This affection is exceedingly rare as occurring upon the abdomen, and will not be further considered.

Deposit of adipose tissue is not an infrequent cause of abdominal enlargement.

This deposit takes place between the skin and abdominal muscles; is sometimes supplemented by a like deposit occurring in the omentum, and perhaps in the mesentery. In females this deposit is quite liable to occur about the time of the menopause.

Diagnosis of fatty deposit in the abdominal walls is not always easily made.

In the present case, where there is considerable laxity in the parts, it is very easily arrived at by placing the hands upon the sides of the abdomen, and then, by a kneading, rolling, motion approximating them as near as possible in the median line, when a huge roll of fat is worked up, which can be grasped in the hand, leaving no reasonable doubt regarding its nature. There is no tumor within the abdominal cavity, for the reason that the fingers can be carried lower and lower at the end of each expiration, until they finally touch the posterior walls.

The enlargement of the abdomen is therefore due to deposit of fat, and not to the presence of an ovarian tumor.

Treatment.—Support the abdominal walls, without compressing them. This can be accomplished by a broad abdominal supporter.

CASE V.—ENLARGEMENT OF THE ABDOMEN.

This patient comes seeking advice with regard to the proper time for the operation of ovariectomy for a supposed ovarian tumor. She is an exceedingly nervous woman.

Physical Examination.—Before thinking of the operation of ovariectomy, it is of the utmost importance that correctness in diagnosis should be established beyond question. This has not always been done.

You will notice, gentlemen, that we have here a large conical tumor, causing the abdomen to assume very much the appearance of the abdomen in the advanced stages of utero-gestation. Indeed such a condition as is present in this case has, more than once, been mistaken for utero-gestation, and physicians have not only been called, but have remained in anxious attendance, hourly expecting the delivery of the woman. This tumor can be firmly grasped, and when moved it carries the whole abdomen with it.

What are the causes that may give rise to abdominal tumors?

First. Abnormal conditions connected with the abdominal walls.

Second. Abnormal conditions arising in the peritoneum.

Third. Abnormal states connected with the abdominal organs.

Fourth. Certain conditions that may arise post-peritoneum.

The first class of causes has been somewhat considered in connection with Case IV.; but it is to be brought to our assistance in the examination of the present case. Under that head *rigidity* of the abdominal walls was mentioned as a cause for abdominal tumor. This case is probably as good an illustration of that condition as you will ever see. You will notice that, as I press upon the walls in any direction, there is a rigidity manifested which is boardlike. There is no solid tumor here, for the reason that there is resonance upon percussion over every portion of the abdomen.

The tumor is not due to an accumulation of fluid in the abdominal cavity, rendering the walls tense, for there is absence of the wave of fluctuation, and presence of resonance upon percussion.

You will still further notice how easily the tumor can be outlined, and how it rises into this conical form when I gently irritate the recti muscles. Now, let us percuss the tumor when it is fully developed, and you hear a full and clear tympanitic note. This tympanitic percussion note is due to tympanitis, or accumulation of air in the intestines, and the hardness and rotundity are due to spasm of the abdominal muscles. This spasm is not voluntary upon the part of the patient, but is a peculiar spasm which occurs in hysterical women, and gives rise to what has been termed *phantom tumor*.

The administration of an anæsthetic would dispel the tumor entirely, which would not be the result if it was due to simple accumulation of air in the intestines without muscular spasm.

Both cases just shown you illustrate the importance of thorough and exhaustive examination before venturing upon a diagnosis.

CASE VI.—SUB-INVOLUTION OF UTERUS AND VAGINA.

Mrs. F., æt. 30, and the mother of two children. The youngest child born eight years ago. Sterility has existed since that date.

Has been sick during the last three years. Her chief complaint has been of burning pain upon both sides in the hypogastric region and extending down the thighs. Menstruates every two or three weeks. No leucorrhœa. Pain in the bladder. Backache. The backache is a greater source of discomfort than any other single symptom. Loses considerable blood at each menstrual period.

Physical Examination.—The drawing upon the black-board will represent the condition when the patient is placed in the erect posture.

Ostium vaginæ open. Cervix farther back than it should be. As the finger passes along the anterior wall of the vagina the body of the uterus can be distinctly recognized in a position of ante-flexion. Cervix is slit up to the vaginal junction upon both sides. The walls of the cervical canal, however, lie in close contact. It very frequently happens that, when the cervix becomes ruptured in this manner, the lips of the womb become everted, and rub against the vaginal walls, giving rise to excessive irritation. The vagina is very voluminous. The perinæum is ruptured. The

conditions present in this case are not at all infrequent.

They are four in number. (1.) Ruptured perinæum. (2.) Sub-involution of the vagina. (3.) Rupture of cervix uteri. (4.) Sub-involution of uterus, with displacement.

The body of the uterus is very much enlarged. It is in a condition of sub-involution, which has been present during the past eight years. It is displaced for the reason that its weight is very much increased, and it has lost its normal support on account of the ruptured perinæum, which takes away the support of posterior wall of the vagina, the anterior wall, and the bladder.

The cervix was torn through at her last delivery, which arrested the subsequent normal process of involution of the entire organ.

The ruptured perinæum and torn cervix uteri have been followed by sub-involution of uterus and vagina.

Treatment.—There are three indications to be met in the way of treatment:

- (1.) Restoration of the uterus to its normal size.
- (2.) Restoration of the vagina to its normal size.
- (3.) Supporting the bladder.

For the first the systematic use of ergot should be adopted, and continued perhaps for two years. The systematic and long-continued use of ergot undoubtedly has the power of diminishing uterine engorgement by diminishing the volume of uterine fibre. Fld. ext. ergot ʒss. twice daily. Employ an ante-flexion pessary to lift the uterus from the bladder. Continue this treatment for some time, and when an improved condition of the uterus has been established, replace the perinæum by surgical means, and give more permanent support to the bladder, which will fulfil the third indication.

It must not be expected that we can give perfect support, such as was present when the parts were in a normal condition, but much better support may be furnished than now exists.

Her condition may be improved so that perhaps pregnancy may again occur. The process of uterogestation, and the subsequent process of absorption, may give the patient yet additional benefit, by giving the uterus and vagina a second opportunity to undergo involution.

Closing the torn cervix is not recommended, because no harm attends its existence in this particular case, but in most it is decidedly advisable.

CASE VII.—SUB-INVOLUTION OF THE UTERUS.

Mrs. Q., æt. 24, been married three years, and is the mother of one child. The child was born two years ago. Has never been well since the birth of her child; a very common history.

Menstruates entirely too freely. Has constant fixed pain in the back, and dragging sensation about the pelvis. Exercise causes excessive fatigue. Has leucorrhœa. These are symptoms from which she wishes to be relieved.

Physical Examination.—Uterus lies upon the floor of the pelvis, and can be touched at the distance of a single phalanx from the external opening of the vulve. Cervix is very large, and the body of the uterus measures nearly an inch more than it should.

There is an ichorous irritating discharge from the external os. The ovaries are slightly enlarged and somewhat tender. The perinæum is ruptured. Such are the results of physical examination.

What is the diagnosis? The uterus is enlarged and in a condition of chronic engorgement. Some would call it chronic inflammation of the parenchyma of the organ.

The uterus is upon the floor of the pelvis. Many would regard it as a case of displacement.

There is some enlargement and tenderness of the ovaries present. Some would pronounce it a case of enlarged and tender ovaries, and that the condition of the uterus was secondary to ovarian affection.

For my own part, I believe the case can be most satisfactorily explained upon the ground that it is one of sub involution; and further, that it is a typical illustration of a large class of cases which are often regarded as chronic inflammation, displacement, etc., etc. Her sickness dates from her last parturient process. During that process, or subsequent to it, it is probable that conditions were developed which interfered with the proper completion of the process of involution. Consequent upon this the organ has remained of more than normal weight. This increase in weight, together with loss of support sustained by rupture of the perineum, has caused the displacement.

The constant tension produced upon the ligaments of the uterus, arising from the displacement, causes the constant pain in the back and dragging about the pelvis.

The increased size and constant congestion of the organ, particularly the lining membrane, accounts for the too free menstruation.

Treatment.—Place the patient in bed, where she will remain for two weeks at least. Replace the organ as perfectly as possible with the hand. Keep the bowels quite open. Use warm vaginal injections three times a day, for twenty minutes at each time. Continue this treatment two or three days. Then, after pushing the uterus up as high as possible, tampon the vagina with cotton soaked in glycerine, and permit the tampon to remain for 36 hours. Remove and replace the tampon at the end of that time, and continue that treatment for ten days. It is quite probable that at the end of that time she may be able to wear a uterine support. If so, fit one accordingly, and place the patient upon the use of ergot in half-drachm doses of the *fid.* ext. twice a day, which is to be continued, it may be, for a long time. Remove all pressure upon the organ from above. This can be accomplished by wearing an abdominal supporter or a belt. Sustain the general condition of the patient with iron and bitter tonics. There is one other condition which demands attention, and that is the fungoid condition, or little warty growths, so called, upon the inner surface of the uterus, which are almost invariably present in this class of cases. These are to be removed by gently scraping the internal surface of the uterus with the eurette. When these bodies are all removed, carry the *co. tr.* iodine up to the fundus of the uterus, and pass it over the entire internal surface.

This condition of the internal uterine surface is a prolific cause of menorrhagia, and by its cure the woman will be relieved of both the menorrhagia and leucorrhœa, which are present in her case.

When the uterus has been materially reduced in size, and the general condition of the patient improved, the perineum may be replaced.

“A NEW PLEASURE.”—Under this caption *The British Med. Jour.* quotes the following from *The Times*: “Should this meet the eye of the lady who got into the 12.30 train at New Cross Station, on Friday, May 15th, with two boys, one of whom was evidently just recovering from an illness, she may be pleased to learn that three of the four young ladies who were in the carriage are very ill with the measles, and the health of the fourth is far from what her relations could desire.”

Original Communications.

THE NASAL DOUCHE: WHAT IT ACCOMPLISHES AND WHAT IT DOES NOT.

By BEVERLEY ROBINSON, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL (DEPARTMENT OF THE THROAT) PHYSICIAN TO THE DENTIL DISPENSARY, ETC.

Read before the New York Medical Library and Journal Association.

SINCE ROOSA, MOOS, KNAPP, PARDEE, and other well-known specialists have made known to the profession the evil effects upon the organ of hearing which may and do result from the use of Weber's douche, in applying medicated solutions to the mucous lining of the nasal passages, its employment has become more restricted.

A few practitioners, it is true, have persistently denied that unfortunate sequelæ are ever directly caused by this convenient appliance. Others, more numerous, admit that inflammation of the middle ear, followed by purulent discharge, may infrequently be occasioned by the douche; but they add that, when properly used, viz., when the patient does not swallow during the period which the operation consumes; when due attention is paid to the temperature and degree of concentration of the solution employed, to the force of the jet of liquid and the duration and frequency of the application, objection to its use are rarely, if ever, valid.

Others, again, in their writings, bid their colleagues to beware of employing the nasal douche, no matter how imperative the indication of its use may appear to be, and consider its adoption, as a method of treatment, to be ever attended with danger to the ears of the patient. Amongst these latter Professor ROOSA stands forth prominently; and as he is of the opinion (*Treatise on Diseases of the Ear*, p. 291) “that its use should be discontinued by the profession,” no doubt, when his work appeared, many of those physicians who still remained faithful to the douche, abandoned it, though loath to do so, “as it is thought to be so thorough in its work of cleansing the nostrils and pharynx.” (*Loc. cit.*)

Against this received opinion, which we deem to be a great though generally accepted error, we here desire to enter our protest.

The nasal douche *does not*, in our estimation, do what it purports to do, viz., cleanse thoroughly the nasal passages and naso-pharyngeal cavity, but in reality leaves a considerable space untouched by its action. If such be the case, those members of the profession who gave up its use with reluctance need at present have no regrets.

We will now endeavor to demonstrate the truth of the above assertion. The diameter in all directions of the jet of liquid which flows from the nozzle of the ordinary Weber's douche is certainly not more than $\frac{1}{4}$ to $\frac{1}{2}$ of an inch. The anterior openings of the cartilaginous portion of the nose (nostrils) in the adult, and during normal respiration, are of oval form, and, speaking generally, from $\frac{3}{8}$ to $\frac{1}{2}$ of an inch in the lateral, and from $\frac{1}{8}$ to $\frac{1}{2}$ in the antero-posterior diameter. The posterior openings are likewise somewhat oval in configuration, and about half an inch in the short, or transversal, and 1 inch in the long, or vertical diameter. The depth of the nasal passages at their median portion is nearly double this latter measurement; whereas the lateral diameter in this region measures,

upon the floor of the fossa, or inferiorly, only 6 lines, and becomes rapidly narrower as we approach nearer to the roof, or superior part of the nose, where it has only about 1 line.

This lateral diameter does not vary much antero-posteriorly, but remains nearly the same on a given horizontal plane. These data being accepted as true, let us see how the douche acts. When the nozzle is introduced into one of the anterior openings of the nose, and the stream begins to flow, but a few seconds usually elapse before a jet of water of like calibre with the entering one makes its exit from the opposite nostril. Now, the physiological fact upon which the use of Weber's douche is based is, that one side of the nasal and the entire naso-pharyngeal cavity being filled with liquid by hydrostatic pressure, the soft palate is raised up by the contraction of the levatores palati muscles, and perfect coaptation between its posterior border and the walls of the pharynx is effected, and thus the passage-way for the escape of any quantity of liquid downwards into the pharynx is completely intercepted. The injected liquid must, therefore, of necessity, make its exit by the other side of the nasal passages, and in doing so comes in contact with all the parts contained in or limiting the side of these cavities through which the stream enters.

To this we reply that if, during the operation, one-half the nasal passages and the entire naso-pharyngeal space were flooded with liquid, we doubt not that the whole of the interior of these cavities would be cleansed and rinsed very completely. But, practically, is this often or ever the case?

We put aside temporarily, without considering them, those cases in which the passages are so much obstructed by the swollen and infiltrated condition of the mucous membrane, or from some other cause, that the stream either *cannot* pass, or flows slowly and imperfectly; and we would draw attention to the following propositions:—

1. Inasmuch as in the majority of cases the column of water escapes in equal volume, and with as great force and rapidity as the entering jet, how can the passages be flooded?

2. Water naturally seeks its level, and when it can pass freely around the posterior border of the nasal septum, how can it be made evident that it goes so far upwards as the vault of the pharynx, or penetrates to the depth of the nasal cavities?

3. We must remember that, in using the douche, the patient is told to bend his head over a basin or receptacle for containing the issuing liquid. The floor of the nasal passages thus becomes a plane inclined forwards and downwards, and the medicated solution employed has, by the mere force of gravity, an impelling tendency to go around the septum narium and flow out by the lower meatus.

We may now return to the cases where the passages are greatly obstructed; and, first, we question whether—and though the calibre of the stream be sufficient to fill up one of the anterior openings of the nares, and be used under the conditions of hydrostatic pressure ordinarily employed with the douche—whether, we say, in like case the remaining portion of the side of the nasal cavities by which the stream of liquid flows in would be entirely filled. When we penetrate a short distance into these cavities their dimensions are greater in the different diameters than those of the anterior nares, and with similar calibre of orifice of exit to orifice of entrance, both being placed on the same level, the liquid must take the shortest and most direct road towards the opening of escape outwards.

It, however, the force and rapidity of the current be

very great, and if, owing to excess of obstruction on the opposite side to that of the entering fluid, this latter cannot so quickly leave the nasal passages as it flows into them, one side, at least, of these cavities may be entirely filled with liquid; but even in that case it would only be during a few seconds.

For, admitting the possibility of the case supposed, is it not apparent that the subjective sensations of the patient would become so unpleasant, or the pressure in the nasal cavities and naso-pharyngeal space be such that the soft palate would give way almost immediately.

Some liquid would then pass into the stomach by an effort of deglutition, or else, owing to confused breathing, get into the larynx and produce a violent paroxysm of cough. In the last-mentioned event the whole of the inflowing liquid would be violently rejected through the mouth and nose, whilst the operation itself would of necessity be suddenly interrupted.

We do not believe, therefore, for our part, that either the vault of the pharynx, the superior and middle turbinated bones, or the superior meatus, are cleansed *at all* by the nasal douche. True it is that a great deal of inspissated mucus, hard crusts, and soft, fetid secretions, are frequently brought away; and we were disposed, for a long while, to console ourselves in the belief that the nasal cavities were effectually rinsed at the termination of each operation. Experience, however, has taught us the fallacy of such a belief; and now that we inspect the nares anteriorly after one of these washings, and, what is still better, make a rhinoscopic examination posteriorly, when it is possible, we find at times there still remains at the top of the pharynx, or around and contained in the posterior openings of the nose, strings of viscid mucus which have been left untouched. Whenever this proof is wanting we shall have to consider the striking clinical fact of a crust or large muscle-shaped bit of mucus being expelled from the nose after what we inferred wrongly had been a most complete cleansing.

The explanation of this phenomenon is readily found. Large pieces of mucus have become detached from the roof of the nose, and more particularly from the cribriform plate of the ethmoid bone, the posterior surface of the nasal bones, and the upper turbinated bones, owing, no doubt, to increased temporary secretion, brought on by the use of the douche, and have fallen to the floor of the nasal cavities. Here they have been the occasion of more or less unpleasant and abnormal sensations, and a strong effort of expiration is sufficient to expel or throw them off altogether. Whilst much of the irritating and concrete mucus is thus got rid of, a certain amount remains behind, and, by the morbid alterations which it assumes, is the source of further disease, or, at all events, by its constant contact with parts already diseased, protracts or renders impossible the return of these latter to their normal state.

We would not have our readers believe that the foregoing remarks originated *wholly* with ourselves. They have been suggested partly by the perusal of an interesting communication from the pen of Thomas F. Rumbold, M.D., which appeared in the number for September, 1873, of the *St. Louis Medical and Surgical Journal*, partly by a short article in *Archiv für Ohrenheilkunde* (vi. Bd., 4 Heft, 1873), by Ludwig Schultze, of Leipzig, and partly, we feel free to add, by our own individual thought and experience. The subject of these brief remarks is assuredly one worthy of attention.

Affections of the nose are not infrequent with us. Nasal catarrh especially is met with each day and on all sides.

It becomes, therefore, the duty of every practitioner of medicine, and not merely of the specialist in diseases of the throat and nose, to know how this last-mentioned and other analogous affections may be treated prudently and efficaciously; and true it is, unfortunately, the treatment of them has hitherto been most unsatisfactory. So much is this the rule, in point of fact, that already, amongst unprofessional persons, "catarrh" is classed with other "opprobria medicorum."

May not the secret of this lack of successful therapeutics be found in the statement, we ask, that thus far no instrument has come into *general* use which meets the one evidently essential indication in the treatment of every case, viz., to thoroughly cleanse the *entire* nasal cavities.

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

THIRD MEDICAL DIVISION.—DR. PERRY, HOUSE-PHYSICIAN.

ELECTRICITY IN VOMITING.

This means of controlling obstinate vomiting had succeeded admirably in all the cases which had presented themselves since its first adoption in this branch of the service. For arresting the vomiting which attended some cases of puerperal fever, it had operated in a manner perfectly satisfactory. The method of using the remedy is to place the positive pole over the seventh cervical vertebra, and the negative pole over the stomach. The strength of the current is varied according to the susceptibilities of the patient.

DIGITALIC STUPES

was used in a case of chronic Bright's disease. As long as urine was secreted freely, the woman felt very well, and did not lose ground. Infusion of digitalis, used in the form of stupes, accomplished all that was desired in the way of keeping up a free flow of urine. She had been using the remedy in this manner for some time with the same result.

PNEUMONIA.

The special feature of interest in a case noticed was the extent of the consolidation, and the paucity of rational symptoms. Dyspnea was absent. There was but very little increased frequency of respiration. Pulse somewhat increased in frequency, but not markedly so. Temperature only *slightly* elevated. There was complete consolidation of one lung and the lower lobe of the opposite lung. After a few days' duration of this condition, dyspnea, hurried respiration, and other symptoms of constitutional disturbance became quite well developed. Recovery took place.

PILL FOR CONSTIPATION.

The following pill is found to be quite serviceable in correcting constipation.

R. Aloes soc. pulv. grs. vi.
Ext. belladonna. grs. iij.
Confection sennæ. q. s.

M.

Div. in pill No. xii.
S. One morning and night.

CHRONIC CYSTITIS.

Silicate of soda one part to two hundred of water has been employed upon this Division for washing out the bladder in cases of chronic cystitis. The results obtained have been somewhat more satisfactory than those attending the use of solutions ordinarily employed in the treatment of this affection.

OAKUM FOR DRAINAGE.

The requirement, after operation for excision of hip-joint, is to secure free discharge from the bottom of the wound. Under such circumstances the opening should never be plugged with cotton. It is *necessary* to use some substance which will permit free discharge, and, at the same time, help to absorb it. Oakum meets these indications better than any other substance that can be employed. If cotton is used, immense damage may be done by infiltration of the discharges into the tissues surrounding the wound. Such is the doctrine taught in this hospital. Another item which is regarded as being of special importance in dressing the class of cases just alluded to, after the operation, is to maintain *firm compression* about the wound, in order to give additional security against infiltration of the tissues with the discharge. Oakum again serves the surgeon most admirably. Cover the surface of the limb about the wound with a thick layer of oakum, and compression can be made to any degree required by means of a roller bandage without endangering in the least the life of the tissues beneath it.

DEFORMITY AFTER FRACTURE.

Deformity after fracture is very apt to occur, more especially in the lower extremities, if the soft callous thrown out for the repair of a fracture is not properly protected for some time after union has taken place. If supporting apparatus is not used when the patient commences to walk around, the soft material will commence to yield, and not infrequently ugly deformities will be developed, much to the annoyance of both patient and physician.

RE-FRACTURE.

Breaking up a fracture which has united with deformity should hardly be undertaken when the union is older than four months.

Apply very powerful extension while making the movements necessary to break up the adhesions. The counter-extension band should be very carefully padded before making such powerful extension, for, the patient being under the influence of an anæsthetic, the surgeon has no knowledge of the amount of pressure upon the parts except by the effects produced upon the tissues. Break the bone thoroughly, but, at the same time, with great care. Break the adhesions thoroughly, both upon the inside and outside of the bone.

FRACTURE OF RADIUS AND ULNA IN A CHILD TWO YEARS OLD.

The fracture was dressed with the arm in the extended position, and held by a long splint made of binders' board, wet, completely moulded, thoroughly padded, and reaching from near the axilla to the palm of the hand. This manner of dressing was employed, because of the difficulty which arises in splinting the forearm of a child of this age, on account of the shortness.

NEURITIS.

The patient was an able-bodied man. He had received a blow upon the deltoid muscle about seven weeks before, and had felt an uneasy pain extending down the arm ever since the accident. The case was

regarded by the visiting surgeon as one of *neuritis*, probably due to injury of the circumflex nerve at the time he received the blow. The difficulty had already affected other nerves. It was painful and troublesome. Time is a great element in the treatment. Counter-irritation was said to be useless. Friction and stimulating liniment was about all that could be reasonably done for such cases.

HOSPITAL FOR THE RUPTURED AND CRIPPLED.

THE special object of this hospital is the cure of those cases which, for obvious reasons, do not come within the ordinary medical and surgical treatment of public hospitals in general.

To the resident physician and surgeon and his assistant we are indebted for the following items with regard to treatment of the affections named.

CLUB-FOOT.

These cases are uniformly treated by applying a shoe constructed in accordance with the following general plan: The sole of the shoe is made of sheet-iron. A heel-cap about an inch and a half high is attached. A strap of iron half an inch wide, more or less, is attached to the edge of the sole opposite the heel, having a lateral joint opposite the tibio-tarsal articulation, and at its upper extremity a padded band to go around the leg just above the calf. The heel of the foot is made fast within the heel-cap by a pad, having pieces of tape attached, which is applied to the instep; passing the pieces of tape through the heel of the shoe and bringing them back, they are tied over the instep. A roller bandage is passed around the ball of the foot, and thence around the sole of the shoe in such a direction that the foot is drawn into its proper position and retained upon the sole of the shoe. The whole apparatus is covered with leather, and is to be applied over a stocking. It is changed twice a day for the purpose of giving both motion and relief to the foot. It is worn at night. It is customary to apply some lint and a roller bandage over the foot, where pressure previously has made the skin tender or even excoriated, before applying the stocking and shoe.

When the talipes is equinus, the motion of the joint is limited to motion *forward* from a perpendicular. When the talipes is calcaneus, motion is limited to *backward* movements from a perpendicular. The idea is to leave motion free in the direction which will permit any step the patient takes to assist in overcoming the deformity, by having a tendency to bring the toes down and the heel up in calcaneus, and the heel down and the toes up in equinus.

It is not believed that a majority of cases can be cured by any apparatus *alone*, however early the treatment may be instituted. Tenotomy therefore is necessary. The success of treatment by means of the shoe is to determine whether the cutting operation is to be performed.

It is the faithfulness and persistency with which the treatment is carried into effect, either before or after the operation, that is to remove the deformity. The plan of determining whether a contracted part is to be cut or not, by applying the test of placing the contracted tissue upon the stretch, and then making an additional point of pressure to determine whether reflex contractions can be produced or not, and if present cut is regarded with some favor.

HIP-JOINT DISEASE.

The operation of exsection is condemned. Hygiene and constitutional treatment are chiefly relied upon. The local treatment is regarded as quite important, and consists in the application of a *spica* bandage to the hip, thus giving some rest and support to the parts involved, and then let the child run about all it may choose consistent with prudence. A moderate counter-irritation is maintained, such as can be secured by the following liniment:

R. Lin. saponis.....	℥ vi.
Liq. iodini co.....	℥ i.
Fl. ext. belladonnæ.....	℥ ss.
M.	

The diet of the patients within the institution is especially regulated; the meals are given with regularity four times a day. The food is of the most nutritious quality, and that which can be easily digested. Medically, the treatment is alterative and tonic.

POTT'S DISEASE.

A case which we saw was one in which there was a double angular curvature, one in the dorsal region and the other in the lumbar region. In addition to these, and doubtless dependent upon the disease of the spine, was a large, doughy swelling upon the outer anterior aspect of the left thigh.

It has been found that when these swellings contain more or less of *serum*, pressure and tr. iodine will sometimes remove them entirely. Fluid, probably purulent, may be present, but they are not opened.

CHRONIC SYNOVITIS.

This affection is treated chiefly by means of pressure, tr. iodine, and the iodine liniment already mentioned.

Pressure, in all cases in which it is necessary, is made by means of a *lacing* apparatus. A stocking, or knee-cap or leggin, large enough to nearly encircle the limb, is made of strong cloth, and lined with buckskin. The lining is only loosely attached to the outside, which permits of the introduction of cotton over various points, if desirable to make circumscribed pressure, or give an extra protection to the tissues. Eyelets are introduced along the edges, and a lacing cord can bring to bear any degree of pressure required. It forms a very convenient and serviceable method of applying pressure.

PARAPLEGIA WITH POTT'S DISEASE.

This is a condition occasionally met with, and it is of some interest to know that, with treatment of the spinal trouble, the paraplegia is usually cured, or is removed in from six to ten months.

Some cases in this institution have recovered from the paraplegia, which has been in existence for *five* years.

WATER.

During the hot weather the quantity of water given to the children is limited. It has been found that, if they are permitted to drink all their thirst craves, it is done at the expense of disturbing digestion and exciting bowel complaints. A reasonable quantity of fluids is allowed at stated times, and only at such times as designated. The desire for immoderate drinking is soon overcome in this manner, and a better degree of health is maintained than to permit an unlimited drinking of water.

Progress of Medical Science.

ON VALERIANATE OF AMYL AND ON AMYL ETHERS.

—Dr. W. F. Wade writes to the *British Med. Jour.*, concerning the value of new preparations of valerian, viz., valerianic ether, valerianate of amyl, and amyl ethers: "Notwithstanding that valerianic ether is less disagreeable to patients, as testified by those who have taken both, than the ordinary valerianic preparations, it has its drawbacks, the principal one being the diffusion of the smell through the apartment or ward when a dose is being taken, or through the shop when it is being dispensed.

"It occurred to me that possibly the valerianates of amyl might be more elegant than the ethyl preparations. . . . The methyl one is not much superior to its predecessor, but the amyl one is incomparably more agreeable. A spirit of the valerianate of amyl, to which a few drops of a spirit of acetate of amyl (known in commerce as essence of Jargonelle pear), have been added, is, without any qualification or exception, not only the most elegant preparation of valerianic acid, but intrinsically an agreeable drug. All these spirits improve in odor by a little keeping. I find that, to some stomachs, ethers are repugnant, unless well diluted; and six or eight drops of the compound spirit are, generally speaking, sufficient for an ounce of water, and also an adequate dose. I think that the effects of the amyl valerian are quite as good as the ethyl preparation. This latter will be called, in future, valerianate of ethyl, instead of valerianic ether. The new preparation will be called compound spirit of valerianate of amyl (sp. amyl valer. co.), and will consist of one part of ether to nineteen of spirit. To two ounces of this are added twenty minims of a spirit of acetate of amyl, made in like proportion, viz., one in twenty. The simple spirit will also be procurable.

"I take this opportunity of saying that, by my direction, the oxide of amyl or amyl ether has been prepared. This is a more agreeable preparation than the ordinary (ethyl) ether preparation of the *Pharmacopœia*. I have not yet had time to try its therapeutical effects, but should this equal those of the valuable old drug, it will probably be superseded. A spirit of amyl ether, to an ounce of which one drop of oil of gaultheria has been added, is a singularly fragrant and agreeable drug. Spirit of amyl, with a little acetate of amyl, is also very elegant."

TREATMENT OF VARICES BY LOCAL APPLICATION OF

PERCHLORIDE OF IRON.—Dr. Linon, of Verviers, has used perchloride of iron locally, with great success, during the past three years, in the treatment of varices. The strength of the solution is about two and a half drachms to eight ounces of water. Compresses of flannel are steeped in the water, then wrung out, and applied by means of a flannel bandage, which is only to be moderately tightened. This application is to be kept on twenty-four hours, and on removing it the surgeon will be much surprised to find that the venous dilations have almost entirely disappeared. The applications are to be renewed as above during seven or eight days successively, after which time the bandage is to be kept on without any further wetting, till it becomes loose. It is to be then wetted with the solution again, and applied until the varices have disappeared, which generally takes place after eight days or a fortnight, according to the size of the swelling. These simple means have removed in a few days enormous varices, accompanied by violent pain, with dark spots on the surface, and have restored to the patients

the use of their limbs. By the unsuccessful application of dry bandages only, Dr. Linon has been able to show that it is not compression, but really the local action of the iron, which is efficacious. The local action of thermal waters containing magnesia, on the skin, is similar to the perchloride. Thus at Luxeuil, patients affected with varices derive great benefit from the Benedictine pond.—*The Lancet*.

ANTIDOTE OF RABIES.—Dr. Jitzki communicated, in January, 1874, to the Imperial Society of Wilna (Russia), a fact of some interest. A very savage dog was in the habit of killing vipers (*Coluber berus*), and his mouth and neck were covered by the wounds inflicted by them. This animal was bitten by a mad dog, which had already bitten several horned cattle and another dog; these all perished from rabies. The owner of the first-mentioned dog, not wishing to destroy him, determined, however, to watch him, and made up his mind to kill the animal on the appearance of the first symptoms of rabies. Nothing, however, happened, and the dog remained quite well.

The case struck Dr. Jitzki, especially as he learned that a woman of the same locality had been bitten by a viper, and some time afterwards by a mad dog, without suffering from hydrophobia. He was thus led to suspect that there is antagonism between the virus of hydrophobia and the virus of vipers. If this were true young dogs might be protected by inoculation.—*The Lancet*.

NATURE OF THE FLUID DISCHARGES IN CORYZA.—At a recent meeting of the Société de Biologie, M. Ranvier stated that, on examining with the microscope the fluid discharged from the nose at the commencement of coryza, he found that it contained a large quantity of cellular elements; some of cylindro-conical form, with a flat surface crowned with cilia; others strongly granular and turgid, in which the flattened surface and cilia had disappeared. Rindfleisch was of opinion that these cells were colorless corpuscles, covered with cilia. It was of great importance to determine if these were really leucocytes, or only deformed epithelial elements. On warming them some of the cilia could be seen to recommence their movements, but no amoeboid motions were observed. They are, therefore, not colorless corpuscles of the blood. M. Ranvier has become still more satisfied of this after examining them in iodized serum. The use of the amniotic liquid of the sheep, highly iodized, enabled him to recognize the fact, in conformity with the statements of M. Bernard, that the colorless corpuscles of the blood, or the lymph corpuscles, contain considerable quantities of glycogen. In fact, when leucocytes are immersed in iodized serum, they may be seen to acquire a characteristic violet-brown color. But the cells with vibratile cilia met with in the mucous of coryza, though assuming, indeed, a yellowish tint under the influence of iodized serum, do not give the peculiar reaction of glycogen. It would hence appear to be clearly made out that these are not young elements proceeding from the blood, but that they are the epithelial cells of the mucous membrane.

A NEW OPERATION FOR CLEFT PALATE.—In a recent number of *THE RECORD* we noticed a modification of an operation for fissure of the bony palate, performed by Sir Wm. Fergusson (and described in *The Lancet*, vol. ii. p. 784), after the failure of the ordinary operation of Langenbeck. *The Lancet* of June 20, 1874, contains a description of still another improvement by the same surgeon. The operation, as

before described, consists in paring the edges of the mucous membrane on each side of the cleft, and then, by means of a chisel, splitting the hard palate on each side, and forcing the two portions of bone thus obtained towards the middle line. The osseous fragments are then bound together in the middle line by two or three silk ligatures, each of which passes through the nasal cavity. The results of all the cases operated upon up to that date were reported at page 298 of the current volume. Although the operation has hitherto been remarkably successful, considering the severity of some of the cases in which it has been employed, it had one drawback. The two bony fragments were liable to become tilted. To obviate this Sir William recently followed this course:—After paring the edges of the mucous membrane, he pierced the hard palate with an ordinary shoemaker's awl in two places on each side of the cleft, close to the margin, in such a manner that the holes on one side of the fissure were, directly opposite those on the other side. A separate silk suture was then passed through each hole on one side, carried into the nasal cavity, and brought into the mouth again through the holes on the opposite side of the cleft. When the sutures were thus secured, the hard palate was divided on each side outside the apertures, by means of the chisel, in the manner described. The silk sutures were then drawn together, and the two fragments of bone brought into gentle apposition. Sir William remarks that since first performing this operation he has found that it had been previously recommended by Dieffenbach.

EPILEPSY INDUCED BY HEAVY POTATIONS.—The same authority says: "Epilepsy and epileptiform seizures are induced in many instances in recruits by indulging in heavy potations; indeed, among soldiers generally, the inordinate use of alcoholic drinks is a potent cause. The gorging of the stomach, usually with beer, was found by Dr. Balfour (Aitken's Science and Practice of Medicine, vol. ii. p. 356) to bring about attacks; and the same is my experience. Indeed I have known instances of soldiers who never had attacks except after filling their stomachs with intoxicating drinks, more especially the vile potations used as substitutes for spirits in foreign countries. No doubt many cases of so-called sunstroke in India are induced by these poisonous liquors which in bygone years caused such maddening effects that men were known to mutilate themselves when under their influence."

INFLUENCE OF ALCOHOL AND TOBACCO ON THE HEART.—Nowhere can thoracic sounds be better studied than at a large recruiting depot. . . . It is indeed curious as well as interesting and instructive, to note the vagaries in cardiac sounds alone. These, although in no ways so varied as the causes to which they owe their existence, are sufficiently conflicting. Thus, frequently, between exciting and depressing influences of one kind or another, it is very difficult to say how far abnormalities are ascribable to temporary and to organic derangements. Under such circumstances, cases often occur apart altogether from the morbid sounds when the heart's rhythm is perverted. I can give no better definition than a muffling of the two sounds, or what might ordinarily be called "a variety of irritable heart," occurring, however, occasionally in subjects not naturally of an excitable temperament. From these persons it was very often readily elicited that they were given to an excessive use of tobacco, either by smoking or chewing, or the two combined, accompanied, in many instances, by drunken habits.

The amount of tobacco consumed daily, was ordinarily half an ounce, and often nearly a whole ounce. From constantly observing cases of this description, and invariably associating them with the above causes, I desired several recruits to abstain entirely from tobacco and alcoholic drinks for a week, and return for inspection. In three or four instances out of ten all the symptoms disappeared; whilst in the cases where there was little or no improvement it was more than probable that the injunctions were not carried out properly. I do not know if this want of clearness in the systolic and diastolic sounds is to be detected in every instance of the excessive use of tobacco or of alcoholic drinks; but judging of the prevalence of the state in question among Londoners (chiefly in-door workmen and persons leading sedentary lives) it would seem to be pretty general.—A. Leith Adams, M.B., F.R.S., Surgeon Major, London Recruiting District, in *The Lancet*.

AN UNNATURAL POSITION OF THE HEAD A CAUSE OF DEATH FROM ANÆSTHETICS.—An interesting paper by Dr. G. W. Copland appeared some time ago (Feb. 26, 1874), in the *Boston Medical and Surgical Journal*, on the "*Styloid Muscles and Anæsthetics*." In this article the cause of impeded breathing during anæsthesia was attributed to the action of the styloid muscles closing the glottis. It was also there shown that the difficulty could always be relieved by simply tilting the head forward so as to relax these muscles, without making traction on the tongue. In a further contribution by the same writer to the *Philadelphia Medical Times* of May 30, it is claimed that death from chloroform and other anæsthetics is often caused by an unnatural position of the head, the latter being thrown back and the styloid muscles put upon the stretch. Circumstances in a number of recorded cases of death from anæsthetics are cited which favor this opinion. It is asserted "that all the deaths from nitrous oxide gas, and a large number of those from other anæsthetics, have taken place while the patients were in a sitting posture, which would allow the head to fall back farther than if they were lying down; thus favoring the theory that interference with the free action of the lungs may have been the primary cause of death." The cardiac syncope would be of course more readily induced "in patients suffering from shock or fatty degeneration, or already reduced by disease."

Another point advanced is "the importance of elevating the head sufficiently to compel the patient to inhale the anæsthetic through the nares entirely. If deep inspirations be taken through the open mouth, the lungs are inflated instantaneously, and just as rapidly emptied, leaving a long interval while no vapor is in the lungs. If the inhalations be through the nares, it takes a much longer time to inflate the lungs, and a much longer time to empty them, leaving no interval. Now the number of respirations per minute is the same either way; hence it follows that it will require a longer time to effect anæsthesia through the mouth than through the nose."

TRANSFUSION FROM THE LOWER ANIMALS TO MAN.—In the *Medical Examiner* of June 15, 1874, Dr. Grady reports two instances of successful transfusion from lambs to patients affected with phthisis. The cases were in the practice of Dr. Proegler, of Addison, Illinois. The success of Hasse, of Nordhausen, in Germany, in treating phthisis by transfusion from lambs, induced Dr. Proegler to repeat the experiment, and his cases are the first instances of the performance of this operation in this country. The record of the cases furnished us serves only to demonstrate the prac-

tibility of the operation; sufficient time had not elapsed when the report was made to give any positive therapeutical results of the procedure.

Cannulae were inserted into the carotid of the animal and the median basilic vein of the patient, and connected by a rubber hose. Before the connection was completed, the blood current was made to displace a weak, warm solution of carbonate of soda, with which the apparatus was filled. In the first case operated on, the stream of lamb's blood having been permitted to flow into the patient's circulation for ninety seconds (representing about eight ounces of fluid), the effect is thus described: "Immediately a sense of warmth spread from the incision over the patient's entire surface; the face became flushed; the pulse *slackened*, but full and firm; a slight *fullness* in the head increased to excessive vertigo; in the ears was heard; vision became indistinct; *snorflakes* seemed to appear before the eyes, while a constantly increasing dyspnoea indicated the discontinuance of the transfusion. All symptoms disappeared in a few minutes, and nothing was observed until, after about two hours, rigors set in, giving way after fifteen minutes to a rather high fever, the temperature rising to 104°, the pulse to 115 beats, leaving the patient towards the middle of the night in a sound sleep."

The urine, though high colored, was not bloody, and was not examined for albumen, which Hasse had always found. An urticaria appeared after eight days, as in Hasse's cases. Its subsidence was accompanied "with the vanishing of a strong odor of *lamb*, which had haunted the patient until now."

In the second case the details were similar; 10-12 ounces were transfused, and the subjective sensations were much as in the previous case. The general condition was not notably altered in either case up to the time of writing the report.

AN EXTRAORDINARY CASE.—The *Irish Hospital Gazette* records an extraordinary case recently brought before the Dublin Pathological Faculty by Professor R. W. Smith, of Dublin University. The disease under which the woman succumbed, whose skeleton he exhibited, was one of rare occurrence, and difficult alike to diagnose, treat, or even name. At the time of her death the woman was forty-five years old. Fifteen years previously she had been sent to jail for some offence, which was probably committed while insane, as shortly afterward she was transferred to a lunatic asylum. During the first ten years of her residence there nothing remarkable about her was noticed, and she was employed in washing the floors, etc. At the end of this period she ceased to be able to work, and remained in bed for the remaining five years of her life, gradually becoming more feeble, and dwindling away in stature until she became about one-half of the height she was originally. She did not complain of any pain; her limbs became coiled up in every possible shape, and she seemed gradually to disappear from off the face of the earth. She died, possibly, from constitutional disease of the osseous system. He (Professor Smith), however, looked upon the condition of the bones not as a disease, but as a manifestation of an as yet unknown diseased condition. Professor Smith had weighed all the bones individually; the total weight of the skeleton (including the cranium) was two and one half pounds, which equalled about the fourth part of the weight of a child at birth. The bones were extremely light, soft, fragile, and atrophied in every respect. The number of fractures were prodigious. The ribs were in a hundred fragments. The head of the humerus was bent; the

fibulae were curved; the thigh-bones and pelvis were huddled up together; and the bones of the vertebrae thinned and worn away across the front of their bodies. The lower jaw was atrophied and broken into three fragments; the base of the skull was cribriform all through; and he (Professor Smith) believed that if the woman had lived longer not a vestige of a bone in her body would have been left. As to the nature of this disease he (Professor Smith) believed that it was identical with rickets occurring in the adult; and although that opinion might appear heretical to some, yet he was glad to find that in the last volume of Trousseau's Lectures on Clinical Medicine, that distinguished author had expressed his opinion that osteomalacia and rickets were one and the same disease.

CHLORAL HYDRATE AND CAMPHOR AS A LOCAL APPLICATION IN NEURALGIA.—It is said that the intimate mixture of equal parts of chloral hydrate and camphor will produce a clear fluid which is of the greatest value as a local application in neuralgia. Mr. Lenox Browne states, in the *British Medical Journal*, that he has employed it, and induced professional friends to do so, and that in every case it afforded great, and in some instantaneous, relief. "Its success does not appear," he says, "to be at all dependent on the nerve affected, it being equally efficacious in neuralgia of the sciatica as of the trigeminus. I have found it of the greatest service in neuralgia of the larynx, and in relieving spasmodic cough of a nervous or hysterical character." It is only necessary to paint the mixture lightly over the painful part, and to allow it to dry. It never blisters, though it may occasion a tingling sensation of the skin. He has found it also an excellent application for toothache.—[We have used this remedy in several cases of neuralgia of the trigeminus, but with no good result.]

DR. GEORGE BAYLES develops, in a recent number of *The New York Observer*, a scheme of practical benevolence which well merits consideration. It is a plan for temporary exchange of the poor between city and country churches. Every town parish has a number of sick and feeble persons on the lists of its visitors who are pining for country air; and almost every rural church has at least a few poor whom it would be a charity to send to the city for medical attendance or other special purposes. Why should there not be an interchange of Christian care for the benefit of these two classes? Each congregation entering into the arrangement might establish an asylum, or house of reception, or make arrangements for supporting its guests at private homes. "What system could be devised," says Dr. Bayles, "that would more certainly restore to the churches the Christ-like spirit of humility and self-denial?"—From the *Tribune* of July 6th.

We have known that for a long time people from the country were in the habit of coming to New York, and, with the slight expense of paying their board or "sponging" on relatives, have attended at dispensaries and out-door departments of hospitals and received medical attendance gratuitously, but Bayles out-Herods Herod. He not only proposes to board them while they are here, but would establish a regular system for keeping up an uninterrupted supply of pauper practice. This is one way of helping the young and struggling practitioner—what next?

DR. A. H. SMITH, of New York, informs us that he has used his "extemporary aspirator" with complete success in a case of hydrothorax.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, August 1, 1874.

HYDROPHOBIA.

A CURIOUS excitement has of late seized upon the community in this city—a Lyssomania, if a word may be coined for the occasion—an aberration of public common-sense—for which (unless the vicinity of the comet to the dog-star has anything to do with it) some of our brethren of the daily press are in no small degree responsible. Columns upon columns of commentary upon the subject of hydrophobia have emanated from the versatile and all-absorbing intellect of the reporter—that ubiquitous professional interviewer of all professions. In our mind's eye we behold that insinuating individual glide past the servant at the front door, like some Italian bandit summon the distinguished physician from the social board, point at his head the interrogatory lead-pencil, and wring from his reluctant (?) tongue the knowledge of life and death. Then retires the interviewer to his reportorial cave and prepares a draught which, on the morrow, shall curdle the blood of his victim—the public. Not to mention, besides, the heavy editorials, full of abstruse speculation, we would more particularly deplore the admission into newspapers of innumerable senseless communications upon the subject from every credulous ignoramus who is able to wield a pen in the cause of charlatanry.

There is probably no disease within the whole range of medical literature which has a more ancient history than hydrophobia, or which has been more earnestly investigated by scientific men. It has been well described by many distinguished ancient physicians in works still extant—by men whose observations upon the phenomena of many affections are still accepted as models—and in modern times by the most eminent medical and veterinary authorities. Its peculiarities in the dog more especially have been thoroughly studied in the Paris, Lyons, Toulouse, Berlin, and Vienna veterinary infirmaries, with all the minute par-

ticularity so characteristic of the enthusiastic French savant and the careful and cautious German observer. Whatever its origin, it is acknowledged to be *incapable of propagation save by specific contagion*, and, as Dr. Russel pointed out in our last number, it bears a very close and striking analogy to syphilis in the mode of its communication and its uncertain period of dormancy before development. In France and Germany rabies is not an uncommon disease; in the wooded districts rabid wolves and foxes constantly exist, and epizootics of the disorder are almost periodical among dogs in both country and city. The same, to a limited extent, is true of England. Notwithstanding these indubitable facts, there are some persons who actually deny the existence of such a specific disease in either animals or men, and others who declare canine rabies to be so rare as to be almost unknown. Others still assert that the affection may be communicated by healthy but irate animals—even by angry men (and perhaps by viragoes!). Husbands and wives, take warning, and, children, agree together as do the birds in their little nests!

On the other hand, while acknowledging the existence and comparative frequency of canine rabies, we would discommence the senseless panic which, fostered, as we have said, by a portion of the daily press, has completely demoralized the public mind. Every morning we read a list of "mad dogs" destroyed in the streets after having bitten numerous people. Probably not one, or at least a very small number, of these animals were suffering from rabies. The dog, in hot weather, is more than usually liable to epileptic attacks; he falls down suddenly—loses his natural perceptions—struggles—froths at the mouth—snaps without aim—and in a few minutes staggers to his feet and often rushes wildly away. If let alone he soon recovers—but during his returning consciousness he may snap at those who molest him. All dogs, moreover, are apt to be irritable in hot weather, and it requires little provocation to render them dangerous. Street dogs are particularly exposed to annoyance by children, against whom their resentment is naturally directed, and when angry they will sometimes attack others than those who vexed them.

Such are the poor brutes which are pursued by hooting crowds, and after being despatched by the pistol or the club, receive the compliment of obituary notices in the newspapers.

The question of humanity to animals is, of course, to be considered with that of human safety. But if the two can be easily reconciled—if almost complete immunity can be insured to man, and at the same time his sagacious and loyal friend can be protected from fanatic persecution, we shall have "a consummation devoutly to be wished." The measures lately taken by the Board of Health in this direction have our warmest sympathy. The recommendations embodied in the recent communications to the Board from Drs. Dalton

and Russel are evidently the result of careful reflection by gentlemen who, on account of their special acquaintance with the subject, are best qualified to speak for the Department which they represent. It is assuredly important that the community in general should be authoritatively informed upon matters pertaining to life and health; that undue and unnecessary excitement should be allayed, and that every precaution consistent with law and humanity should be observed.

The agitation, therefore, of the subject of hydrophobia by the secular press has perhaps been productive of some good in enabling the public to be properly instructed by capable authorities; and it is consequently pardonable to some extent. But the *professional sensationalism* which has been developed at the same time we cannot but regard as inexcusable, and we propose to exercise our function of independent criticism in a matter not altogether removed from the sphere of medical ethics.

With reference to the pathological appearances which are said to have been discovered in the McCormick case, we confess ourselves "a little mixed." In *The Tribune* of July 1st we were somewhat startled by an announcement, as follows, in big type:—"Dr. Hammond's Wonderful Experiments in the McCormick Case! Structural Changes in the Medulla Oblongata," etc., etc. We read this article with deep interest, and gazed with proper respect upon the doctor's picture illustrating the extravasation of blood "at the origin of the pneumogastric nerves." Next morning, however, we were intensely disgusted to learn, in a letter from Dr. H. to *The Tribune*, that we and the public in general had been hoaxed by some facetious reporter, inasmuch as the diagram which the doctor had published the previous day represented "a section of the medulla oblongata at a level of *one of the roots* of the spinal accessory nerve, and not the pneumogastric, although similar appearances of extravasated blood were present higher, at the level of the latter nerve." Good gracious! what a revolution in public opinion must have taken place after this statement; and what a gnashing of editorial teeth must have been heard in the precincts devoted to *The Herald*, *The Times*, and *The World*! And how youthful, inexperienced microscopists must have envied the "scientist" who was able, by "sufficiently thin sections," to demonstrate these remarkable distinctions in a specimen "kept in absolute alcohol 18 hours." These last, however, may have derived some consolation from the professor's admission during his lecture before the Neurological Society, in speaking of the cells of the pneumogastric and hypoglossal nerves, that "of course it was not possible, in a fresh and unprepared preparation, to form any definite idea of the relative proportion of nerve to nerve-like cells," etc. And yet, upon such a preparation, from which, with a one-quarter inch objective, it was ascertained that

the cells "had almost entirely disappeared," we are requested to rely for "accurate" microscopical appearances.

The illustrations supplied by the late Surgeon-General to *The Tribune* of July 7th were, no doubt, as faithfully reproduced in that enterprising journal as was possible under the circumstances; and yet, though they might have made the unskilful stare, they could not "but make the judicious grieve." One of them reminded us of a *Herald* war map, another was filled with fiends like those of Gustave Doré, while in a third we traced a close resemblance to a representation of superannuated spermatozoa in "Reflexions sur la Mariage," or a similar work. Is it possible that the satyriasis, which is frequently a symptom of hydrophobia, underwent, in McCormick's case, a metastasis to the vicinity of the cerebellum, without actually reaching that organ? Perhaps if some other of the specialists present at the McCormick autopsy had enjoyed the opportunity of participating in Dr. Hammond's microscopical researches, more faithful drawings might have yielded more satisfactory results. It was scarcely fair in Dr. H. to appropriate all of interest in McCormick's brain, as we understand he had likewise done at the Entwistle post-mortem, before the arrival of the curator of Bellevue made it necessary for him to deliver up two or three thin slices. In the latter case Dr. H. discovered no extraordinary lesions.

Dr. Hammond deserves and can scarcely fail to receive from a grateful community many substantial acknowledgments of his concern "pro bono publico" (which, in dog-Latin, might be translated "for the public bone"). It is only proper that his efforts to illuminate the vulgar mind by light from his scientific stereopticon, as it reflects his views of hydrophobia, should not be unremunerative. Certainly it has somewhat alarmed Mrs. Jones to be informed that her Skye terrier, Jip (an irascible little cur under any circumstances), may at any time lose his temper and deposit rabific virus in baby's finger; but Jones has consoled her with the assurance from his morning *Tribune* that there is at least one scientific physician in the city both able and willing to avert the calamity which might ensue were baby treated by us or some other disciple of Yonatt with caustic proclivities. Although Jip may thus become a very expensive animal, Jones has determined to keep him as long as he can afford it.

Seriously, we are sorry to be obliged to differ with any of our medical brethren as we have deemed it our duty to do in this matter. But we are not alone in our opinion. The last clause of the verdict of the Coroner's jury in the McCormick case reads as follows:

"To the direct question of the Coroner, whether the post-mortem investigations made in this case are of any scientific value in determining the pathogeny of the disease, we answer in the negative."

This jury was composed of ten medical men, speci-

ally selected for the occasion. Six out of the ten agreed in the opinion expressed. But the reputation of the six who carried the resolution is sufficient to give their views a very positive value in the profession.

Reviews and Notices of Books.

CONSUMPTION AND ITS TREATMENT IN ALL ITS FORMS.

By DR. CARL BOTH. Published by Alexander Moore, Boston; Lee & Shepard, Boston and New York; Trübner & Co., London. 1873.

THE first two chapters of this book embrace a history of the opinions held with regard to the nature of the disease and its treatment. The third chapter considers the nature and application of the cellular principle. The conditions for normal cellular life are (1) correct place, (2) correct nutrition, (3) correct pressure. The fourth and fifth chapters are devoted to the anatomy, physiology, and general pathology of the lungs. Under the latter head the movable or blood-cells are regarded as the most important subjects for observation. Primary or real tubercle consists of blood-globules escaped into the connective tissue of the lungs. These occur only in the points of the lungs, for the reason that they are more directly exposed to loss of pressure than any other part of the body. Inherited consumption is due to *innate atelectasis*. The existence of any such disease as consumption, as such, is positively denied, and all that is necessary for successful treatment is an exact understanding of the anatomy in question, and the logic of common sense. The latter item is probably a good thing to have.

In the fifth chapter the stethoscope is set down as being useless for the examination of lungs. In the sixth chapter whooping-cough is regarded as being caused by atelectasis in a majority of cases. In the seventh chapter emphysema is spoken of as a positive preventive against tuberculosis. The three succeeding chapters are devoted to the disorders of the capillary blood-vessels. Under this head the author discusses the various forms of consumption, congestion, and oedema of the lungs, and pneumonia, acute and chronic. The cause of acute pneumonia is set down as abnormal excitement, either physical or mental. The process is always an active one, and rupture of blood-vessels is always present. Chronic pneumonia always has its beginning in the acute, and is invariably the result of neglect in treatment. It is probable that 50 per cent. of the cases of consumption in this country are chronic pneumonia. A slow and hearable expiration under the clavicles is regarded as a certain sign of tubercle formation. This variation in the expiration is produced by irregular passage of air in the neglected bronchi, and the crackling which appears afterwards is caused by arrest of the motion of the hairs of the epithelium, which is owing to the formation of tubercle directly near it. To secure artificial calcification of the tubercles is the aim of the entire treatment. The author describes at some length the measures to be adopted in order to accomplish this, and arrives at the conclusion that, if the management which he recommends is followed regularly, any kind of tubercular affection of the lungs will *invariably and readily* become arrested.

The subsequent chapters of the book are devoted to the consideration of the disorders of other anatomical elements of the lungs, disorders of the pleura, disorders which may be mistaken for consumption, and disorders from external causes.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, May 13, 1874.

DR. J. LEWIS SMITH, VICE-PRESIDENT, in the Chair.

A CASE OF CANCER OF THE LIVER, SECONDARY TO VILLOUS CANCER OF THE GALL-BLADDER.

DR. JANEWAY presented a specimen of the above, with the following history:

This patient was admitted to Bellevue Hospital March 8th, 1873, and in the service of Dr. Clark, as visiting physician; Drs. Fleming, Steurer, and Chapin house staff.

Mary Graff, æt. 39, married. She was in such a condition on admission as to give but a poor account of herself.

She gave no history of hereditary disease.

She had till the date of present illness been healthy and temperate.

Six weeks before admission she became jaundiced while suffering from nausea and vomiting. Shortly after her feet became oedematous. She also had occasional chills. The jaundice has persisted since its inception. Her bowels have been constipated.

Pulse on admission, 120; Th. elevated.

March 10th, Pulse, 140; Th. 105°; R. 50.

" 11th, " 120; Th. 102°; R. 44.

On this day she had a violent chill, and died.

During her stay in the hospital she was deeply jaundiced. A systolic murmur was heard at the base of the heart, and also a murmur in the epigastrium.

I saw the patient once, and then found that her liver was much enlarged; that over it a plain friction sound could be heard, and on palpation a plain friction fremitus could be felt, and a few small nodules be made out occupying the liver substance. I thought the most probable diagnosis cancer of the liver. She had also enlarged glands at the root of the neck on the left side.

I made the autopsy on the 12th, with the following results:

The lymphatic glands at the root of the neck, on the left side, are enlarged, rather firm, and on section give to the knife a little whitish fluid; but here and there show little spaces containing a mucous-like fluid. The glands around bronchi and in the mediastinum are in a similar condition.

The heart and lungs were normal. The liver was much enlarged, and on its surface presented several whitish tumors, and in the centre of some of the larger a depression existed. On the lower part of the right lobe the surface is rendered rough by old thickenings. The nodules are disseminated in the liver, the larger ones 1½ inch in diameter, the smaller of the size of a pea. Beside these nodules the new formation also existed in some of the portal canals as a thickening of sheaths.

The ducts within the liver were much dilated, and contained more or less bile-stained muco-pus; and at one point the liver tissue is honeycombed by these dilated ducts, and partly gangrenous.

On section of the nodules they showed a grayish-white color, and a mucous-like matter escapes to a slight extent, and small spaces are seen containing this.

The gall-bladder is thickened, enlarged, and contains several biliary calculi and muco-pus; at the centre it is much thicker throughout its circumference, and its

surface is covered with numerous elongated villositities. The section of tissue below is of a whitish color.

This tumor divided the bladder into an upper part, which communicated with the duodenum, just below the pylorus, by a round ulcerated opening. A large mass of cancerous glands are situated in the gastro-hepatic omentum, and these occluded the hepatic duct.

A mass of enlarged glands surrounded the lower portion of the abdominal aorta and the common iliac artery; also the accompanying veins. A large antemortem thrombus was found in the lower part of the vena cava ascendens, and in the left common iliac vein. This formation was probably due to pressure effected by the above-mentioned glands.

The kidneys, uterus, ovaries, etc., normal.

A microscopic examination showed the gall-bladder to be covered at the thickened part with villositities, covered with a single layer of cylindrical epithelium; that at the base these villositities became approximated, and so short spaces containing epithelial cells arose; also that alveolar spaces existed in the thickened walls of the gall-bladder, containing cells without marked cylindrical character.

The nodules in the liver present spaces containing cells of epithelial character. In some places the space is only lined by a layer of epithelium, which has in some places more of a polygonal, at others cylindrical character. In some of the alveoli a slight projection into the latter happens, looking like a miniature villosity.

The glands present much the same phenomena as the liver.

This case and the one which I presented at the last meeting serve to show that cancer of the liver is not so often primary as might be imagined. Here are two cases in which the gall-bladder was the primary site; and this is just the situation which is most frequently overlooked. I have understood that Virchow, in his unpublished lectures, draws attention to this point.

A CASE OF BILIARY CALCULI AND OBSTRUCTION OF THE DUCTUS COMMUNIS CHOLEDOCHUS.

Mary Quilk, *act.* 70, Irish, a domestic, was admitted to Bellevue Hospital on November 27th, 1873.

The following notes of her case have been preserved in the Hospital Record Book by the then house staff, Drs. Fleming, Steurer, and Chapin. Her mother died of phthisis, but with this exception the family record was good. Her health was good until ten years ago, and then, owing to a strain while lifting, suffered from synovitis. There has been some swelling of legs and abdomen, which disappeared, and has not recurred lately. Recently she has been feeble, and only earned enough to supply her wants.

On the Thursday preceding admission she began to have a heavy feeling in the head and sickness at the stomach. By evening her abdomen became swollen, and severe pains manifested themselves in the loins and back. These persisted until Sunday morning, and then gradually disappeared, leaving her feverish.

She complained also of cold chills each night preceding the fever.

When admitted she was quite jaundiced; but owing to the darkness of her rooms could not tell about its time of origin.

At this time the lungs, heart, and spleen were found normal. The liver was of normal size, not tender on pressure.

The urine contained bile pigment, but nothing on microscopic examination.

Nov. 29th. Pulse 99; Th. 101° F.

Nov. 30th. Patient delirious last night.

Dec. 1st. Th. 102° F.; P. 92; R. 24.

Dec. 2d. Th. 102½° F.; P. 92; R. 32.

Patient restless during the night, had chills and fever alternately, no pain.

From the 3d to the 8th the evening temperature was from 102½° to 104½°, and the morning from 99½° to 100½°.

From the 8th to the 13th, only 101° or 100° at night, and nearly the same in the morning.

At this latter date bronchitis occurred, which occasioned a slight rise for a couple of days.

16th. Desquamation of the cuticle and slight improvement in the symptoms.

The temperature from the 15th to the 23d was 99° or 99½° A.M., 100½° P.M.

On the 17th the jaundice became slightly increased, and from this date, especially after the 20th, the patient was troubled with severe coughing at night.

For the first time since admission into hospital, bile occurred in the feces on the 23d, and from this date the jaundice diminished.

On the 27th, nausea and vomiting of greenish matter occurred, and a small faceted calculus of cholesteroline was found in the feces; and on the subsequent day several similar calculi.

On the 7th of January a pneumonia commenced in the lower lobe of the right lung, and of this she died on the 13th.

At the time of death the jaundice had for the most part disappeared; an occasional examination of the urines showed granular and epithelial casts. The nuclei of the cells were stained by bile pigment.

I watched this patient very closely during her life, and early made a diagnosis of obstructive jaundice, due probably to calculi, and in consequence examined the feces daily from a few days after admission till the 28th of December. Previous to this a difference of opinion had existed as to the cause of the jaundice, and at one time the occurrence of considerable tympanites with some fluid made the area of liver dulness apparently considerably diminished; and this apparent diminution continued to some extent to death. For a little while I was afraid that the calculi were producing sufficient irritation to produce abscess of the liver, the hectic fever apparently pointing in this direction.

Autopsy.—On post-mortem examination I found the brain normal. Lungs—Gray hepatization of the lower lobe of right lung; a small spot of red hepatization in the upper lobe of the left lung. Heart, normal. Peritoneum—Ascites of moderate amount. Liver—The left lobe was of normal size, but tilted upwards by a tympanitic condition of the colon beneath. The right lobe was a little smaller than the average. A section through the liver showed the bile ducts in the canals dilated almost to the size of the portal vein in the same situation, and these dilated ducts contained a thick mixture of pus, mucus, and bile. The centre of the lobules was bile-stained. The gall-bladder was small, contracted, its walls thickened, and adherent to transverse colon and duodenum. It contained twenty-eight small calculi, the size of small peas, with facets, and two large ones about the size of marbles. Externally these are white, internally yellow. The cystic duct was dilated so as to admit the little finger, and the hepatic duct was capable of holding index finger. The common and cystic duct contained twenty-two calculi similar to those in the gall-bladder. Two of these were of larger size, the rest small. There was a catarrhal inflammation of the ducts and bladder. The opening of the common duct in the duodenum was slightly enlarged, and just back of it a small calculus, not ob-

structing, was found. The kidneys were large, of a deep green color, and showed lesions of parenchymatous nephritis. Spleen slightly enlarged. The stomach and intestines appeared normal.

The post-mortem examination shows: 1st. That jaundice owing to obstruction from calculi may disappear, owing to removal of calculi, which were probably at the opening into duodenum; whilst others, some of them of considerable size, were present in the ducts. That the dilatation produced by the obstruction was sufficient to dilate the ducts so that the bile flowed around the others. Though, if she had not died of the pneumonia, it is probable that the large calculi would have produced another attack when they reached the narrow terminal portion of the duct.

2d. That the hectic fever in the earlier portion was due to the catarrhal inflammation of the ducts.

3d. How a tympanitic condition of the colon may so displace the liver as to produce apparent diminution in its size, and though I had during life considered this to be the cause of apparently small size of liver, others had considered the liver really as small.

ROUGH CATHETERISM.

DR. MASON presented the genitalia of a man, aged 45 years, for the purpose of exhibiting the results of rough self-catheterism. The patient, who was an inmate of Charity Hospital, had had syphilis for a number of years; was, at the time Dr. M. saw him, suffering from hemiplegia, the result of syphilitic disease of the meninges, and was covered with a pustular eruption. The scrotum was the seat of elephantiasis, and contained an abscess which opened through a sinus into the perineum. In addition to these troubles, he had stricture of the urethra, with cystitis.

The house-surgeon was directed to use the catheter whenever it was required, and to administer tonics. The patient thereupon declared that he could do the former operation himself, to prove which assertion he drew from under his pillow a number six catheter, and commenced the operation. To the astonishment of all but himself he jammed the instrument past every temporary obstruction until the bladder was reached, declaring that he had practised the same manœuvre two or three times daily for a long time.

The patient died the day afterwards, and the autopsy examination of the urethra showed the existence of a dozen false passages, while the mucous membrane at one point was ploughed up in such a condition as, at first sight, to resemble a polypus. The bladder was much thickened, and was a classical representation of cystitis in an advanced stage. The spinal cord could not be examined.

PYO-NEPHROSIS, NEPHROTOMY, ETC.

DR. LOOMIS presented some fluid removed from a male patient at Bellevue, more for the sake of placing the history of the case on record than for any peculiarities which the fluid itself possessed. The man, aged 35, was admitted into the hospital on the 11th of February last; was a seaman by occupation, of moderately temperate habits, who never suffered from syphilis, as far as could be learned, and who gave a good hereditary history. He had, in fact, always been in robust health, up to three years ago, with the exception of two slight attacks of subacute rheumatism and one attack of facial erysipelas. Three years ago he was, for the first time, seized with intense pain in the left lumbar region, extending round to the corresponding inguinal region, and accompanied by a tingling pain at the end of the penis and retraction of

the left testicle. This pain was paroxysmal in character, and continued for about twelve hours, and its subsidence was followed by the passage of a considerable quantity of milky urine. From this time he went on perfectly well, passing his urine without difficulty, until fourteen months before his admission into the hospital, when he noticed, for the first time, in the left lumbar region, a tumor the size of his fist. This tumor was movable, and was not tender on pressure; in fact, he never suffered any inconvenience from its pressure, except considerable soreness after violent exercise. There was nothing worthy of remark until two weeks before his admission, when the tumor had so increased in size as to become troublesome, and his general health became so much impaired that he was unable to gain his livelihood. Physical examination of the chest showed the lungs healthy, and the heart slightly hypertrophied, the second sound being heard with the greatest intensity at the right side of the sternum. The arteries throughout the body, so far as they could be reached, were tense, but there was no particular disturbance to the systemic circulation. A tumor was found in the left lateral segment of the abdomen, extending forwards (the patient lying on his right side) nearly to the median line, and backwards to the lumbar region. This tumor was ovoid in shape, with long diameter transverse, was nodulated and irregular in its outline, was not tender on pressure, and gave a sense of fluctuation when the hand was placed posteriorly, and slight taps were made to the anterior portion of the tumor. The quantity of urine passed was ninety ounces in the twenty-four hours, and was albuminous. He was somewhat emaciated, but not markedly. His countenance was quite healthy, and did not suggest the idea of malignant disease.

When Dr. Loomis saw him, on the 27th of March, he made the diagnosis of pyo-nephrosis, and at the same time he suggested the propriety of aspirating the tumor anteriorly. It was aspirated by Dr. Farrington. Previous to this, about the 7th of March, an hypodermic needle had been introduced into the tumor and a small quantity of the fluid was withdrawn, which was found to contain granular matter and pus. Dr. Loomis was not aware that this had been done at the time he made the diagnosis. The needle of the aspirator was introduced two inches above the crest of the ilium anteriorly, and twelve ounces of pus were withdrawn. After the aspirator was used the tumor was much smaller in size, but there was still left a hard mass in the lumbar region. The swelling soon after began to increase, and its size gave the patient much inconvenience. His urine, examined from time to time, was found to contain albumen. Sometime after the second aspiration it was examined by Dr. Janeway and found to contain hyaline casts and pus.

The temperature of the patient during this time never rose above 100°, and his pulse barely reached 96. On taking charge of the ward in which the patient was, Dr. Loomis called a consultation for the purpose of deciding whether it would not be best to enter the tumor from behind, in the situation in which lumbar colotomy was performed, and after the manner recently and successfully practised by Dr. Lente, of Cold Spring, N. Y. The consultation decided in favor of such a plan, and the operation was accordingly performed by Dr. J. J. Crane, the afternoon of May 12th. Dr. Crane made his incision two inches above the anterior superior spine of the ilium, extending it back very nearly to the spinal column. After reaching the quadratus lumborum muscle he entered the sac and drew off forty ounces of fluid, a portion of which was exhibited to the Society. After entering the sac a

drainage tube was introduced, and retained in situ by adhesive straps. The fluid had been examined, and was found to contain pus, hyaline casts, and blood. At the time of reporting the case the man was in a very comfortable condition; the pus was discharging through the drainage tube, the pulse was 101, and the temperature 101°.

At the request of Dr. Loomis, the President asked Dr. Lente to give an account of the steps of the operation and other particulars.

REMARKS OF DR. F. D. LENTE.

I will merely state, Mr. President, that the operation is precisely that for lumbar colotomy, only instead of opening the colon we open the distended kidney. I made my incision *transverse*, midway between the last rib and *crista illi*, in order to avoid division of the lumbar arteries; the incision was three inches in length, commencing three inches from the vertebral spines. This gives just room enough in a spare subject, but hardly sufficient in a very muscular or fat one. The objective point is the edge of the *quadratus lumborum*; on drawing this aside you should come directly upon the dilated kidney. Mr. President, I claim that my case, to which Dr. Loomis has referred, is the first instance in which *nephrotomy* proper has been performed, so far as very extended researches in German, French, and English medical literature, made by several medical friends and by myself, enable me to judge. To learn the true signification of the term, we must go back from fifty to two hundred years, and to French writers mostly, though Velpeau, in his *Operative Surgery*, gives a correct history of it. The operation, and indeed the disease for which the operation is performed, has been almost ignored by the writers of the last fifty years. And the term is indiscriminately applied to the opening of an abscess pointing in the loins; to the cutting down upon and removal of a calculus, ascertained by the touch to be present in an abscess; to the entire removal of the kidney, and to such a case as that now under consideration. To show how loose the ideas of the profession are on this point, I may state that within the last twenty-four hours I have been referred, by two of our best anatomists and surgeons, both teachers of these branches in this city, to what they considered undoubted instances of this operation. I read from the pamphlet handed me by one of these gentlemen Mr. Anandale's account of his operation, and his comments upon it, to show how completely unlike it is to true nephrotomy. In fact, as you see, Mr. Anandale expressly says: "I have not called my case one of successful nephrotomy, although similar cases have been so named, for I think this term ought to be confined to those cases in which the surgeon makes a special incision down through the loins, and lays upon the ureter or kidney." But to make the definition sufficiently comprehensive, he should have added: "And where no abscess has formed external to these parts, and where the kidney is free from inflammatory adhesions to the superjacent structures." He goes on, as you see, to mention the most distinguished surgical authorities, as Tulpius, Benj. Bell, and Benj. Brodie, as ridiculing the idea of this operation, and denouncing it as absurd and dangerous. The other instance brought to my notice is Mr. Bryant's, in his recent work on surgery. But I fail to find any more evidence of his having seen or performed the operation than in numerous other cases to which my friends and acquaintances have referred me. It is more than probable that the operation to which he alludes, but does not even attempt to describe, was similar to the numerous others where abscesses external

to the kidney have formed, and even pointed, in the loins before having been opened. However, I will write to Mr. Bryant to ascertain the precise facts of his case. Another important point, to which I desire to call the attention of the Society, is the plan for maintaining a free egress for the pus and other matters. I used a tube, first of gum elastic, then of tin, then of silver, of one-quarter inch diameter, two inches in length, and with flanges for securing it to the skin by means of adhesive plaster. This maintenance of a free and direct outlet for matter has been almost uniformly neglected by the numerous surgeons who have ventured to open *peri-nephritic* abscesses; and the openings, having degenerated into sinuses, allowed a reaccumulation of pus, necessitated a new operation, or dilatation; or, as a general rule, offered but a feeble barrier to the almost uniformly fatal result. As the only exception to this rule, I find, since my operation was performed, that Civiale, in his work published in 1819, recommends just what I used first, because I had no better, a piece of old gum elastic rectal tube. He says an inelastic tube could not be borne so well; but here he is mistaken; it is far better. I will only add now, as I propose to give a full history of this important matter at some future time, that my patient is now in her twelfth week, has been walking about the street for some time, and has felt no pain or any inconvenience even from the tube, saying that she will be perfectly content to wear it the rest of her life if there is the least danger in leaving it out.

HEMORRHAGE INTO THE OVISACS—AN INTERESTING QUESTION IN PATHOLOGY.

DR. MARY PUTNAM JACOB presented the ovary of a woman, inmate of the Magdalen Hospital, who had succumbed to pneumonia after complete hepatization of the right lung. Menstruation had occurred two weeks previously, and a recent corpus luteum existed in the healthy right ovary. In the left the fimbriae of the Fallopian tube were adherent to the ovary, and near the surface were two hemorrhagic clots, one the size of a filbert, the other rather smaller. The clots were the color of currant jelly, and somewhat more consistent, easily enucleable from the cavities containing them. The wall of these cavities was smooth and reddish. Microscopical examination, after hardening in alcohol, showed in the clot masses of blood corpuscles and granular fibrine, and in the wall of the cavity two layers: 1st, an outer, composed of fine conjunctive tissues; 2d, an inner, consisting of a narrow, yellowish band composed of small, round, nucleated cells. These two layers evidently corresponded to the conjunctive tissue-wall and the *membrana granulosa* of a Graafian vesicle or ovisac, and the examination showed therefore that the hemorrhage had been a simple exaggeration of that normal to the menstrual period, and not an apoplexy into the stroma of the organ, a lesion much more rare, if indeed it ever occur primitively.

It would be of interest to ascertain whether the hemorrhage had occurred during the pneumonia, or at the period of the last menstruation, that preceded the invasion of the disease by one week and the death by two. In the latter case, no obvious cause for the accident existed, unless it were that thickening of the peritoneal coat of the ovary prevented the escape of the ovule and raised the tension in the ovisac. The adhesions between the ovary and the Fallopian tube indicated this possibility. The career of the woman, previous to admission to the hospital, suggested, however, other conditions that might have abnormally increased the afflux of blood to the

ovaries during the last menstruation, and thus favored excessive hemorrhage into the ovisacs.

On the other hand, such hemorrhage was well known to occur rather frequently in the course of febrile disease, and often to be accompanied by uterine hemorrhage—the "uterine epistaxis" of Gubler.

The consecutive relations of these lesions were as interesting as their etiology. Hemorrhage into the ovisacs was one,—according to Gallard the lesion that initiated retrouterine hæmatocele, whenever the effusion of blood was sufficient to tear the peritoneal covering of the ovary, and continued long enough to fill up the cul-de-sac of Douglas. Again, it was generally admitted that at least one kind of ovarian cysts developed from the ovarian follicles, enlarged by excessive secretion into their cavity. The specimen suggested that in some cases such secretion was preceded by hemorrhage, and replaced the clot when this had been absorbed.

The absence of pain in this and other cases of ovarian apoplexy was very remarkable in its bearings on the theory of pain during menstruation. It was one of many facts showing that the pain does not depend upon the quantity of blood present in the ovaries, but upon modifications of their nerves, and in the mode of circulation. The same remark held true of the uterus.

CANCER OF OMENTUM, AND FIBRO-CYSTIC DEGENERATION OF UTERUS.

Dr. BRIDDON presented a specimen with the following remarks: On the 1st of February, 1874, I was requested by my friend Dr. Stephen J. Clarke to meet him in consultation, and was furnished with the following history:—The patient was a lady of forty-one years. She was accustomed to high living and the intemperate use of wine. Married at the age of seventeen, she had one child at term, and had aborted on twelve different occasions. She had frequently been under treatment for uterine ailments, viz., ulceration and endometritis.

Dr. C. had been called in a few days before my seeing her, and found his patient suffering from acute pain and tenderness in the lower portion of the abdomen. Her uterus was retroflexed and exquisitely sensitive, and he came to the conclusion that she was the subject of metro-peritonitis complicating old displacement. The patient regarded herself as pregnant, though she assured the doctor that she had menstruated regularly. I was only able to verify the conclusion already arrived at. She had an accelerated pulse and exalted temperature. Her abdomen was considerably distended, universally tender, but more so in the hypogastric and inguinal regions than elsewhere. I found the os and fundus uteri on the same plane, the body considerably enlarged and immobile. She certainly was not pregnant. I advised a continuance of the treatment which had been instituted by her physician, and under which the acute symptoms rapidly subsided.

On the 13th I was requested to see the lady again. I found a moderate amount of fluid in the peritoneal cavity, and Dr. C. directed my attention to a tumor which he had discovered in the umbilical region. It lay with its long diameter across the abdominal cavity; its vertical diameter was determined to be about four inches; transversely it was more difficult to estimate, but was probably six or eight inches; its edges could not be made out, and it was not movable; it was not bossy or nodulated, and had no resemblance to the incarcerated contents of a sacculated colon. I expressed the opinion that the ascites was probably due

to cirrhosis, and that possibly the tumor might represent malignant disease of the omentum.

Subsequently this patient was seen in consultation by several professional men. One suggested the probability of the tumor being a floating kidney; another gentleman, deservedly distinguished for his acumen and skill as a diagnostician in the abdominal diseases of women, expressed his opinion that the patient had ovarian tumor and an extra-uterine fetus. Explorations with the aspirator were suggested, but she would permit no operative interference of any kind; and though during the month of April she suffered much from the accumulation of fluid in the cavity of the peritoneum she would not consent to its removal by the trocar. During the last two weeks of April she had profuse and frequent alvine discharges of a very offensive odor, and of the consistence and appearance of tar. On one occasion she vomited a small quantity of blood. She died on the 4th day of March.

Autopsy, eight hours after death, in the presence of her medical attendant, Dr. Clarke, who had tapped immediately after death and removed a pail and a half of thin, straw-colored fluid. Rigor mortis, moderate; surface of skin, pale; abdomen, collapsed; a fusiform swelling could be seen lying transverse in the upper portion of the umbilical region. On opening the abdominal cavity a large mass was seen lying across the space between the stomach and transverse colon; it was composed of the omentum, in a condition of cancerous degeneration; its transverse measurement, ten inches; vertical, four; and its average thickness one inch; its surface, irregularly nodular, was of a pale, pinkish yellow, and its consistence firm. There were small whitish nodules here and there over the visceral and parietal peritoneum; these varied in size from the dimensions of a pin-head to that of half a pea.

The small intestines were collapsed and markedly hyperæmic; colon was in some parts distended with flatus, and at the angles of junction between ascending, transverse, and descending contracted to a considerable degree.

The liver was small, weighing two pounds and a half, its surface drab-colored; on the convex surface of its right lobe were two puckered cicatrices, and a small white subperitoneal nodule; the cut surface presented the appearance met with in the atrophied form of nutmeg liver (red atrophy), the intralobular spaces of a dark red hue, and the intervening or interlobular spaces white; the gastro-hepatic omentum was the seat of the same deposit as that met with in the gastrocolic fold.

Spleen and kidneys were perfectly healthy. On looking into the pelvis it was not possible to distinguish any of the viscera belonging to that cavity. Old and probably repeated attacks of para- and peri-metritis had obliterated everything; the superior strait was roofed in by old false membrane, forming a concave diaphragm, unbroken by anything save the passage of the rectum behind and to the left; no appearance of fundus, ovaries, or anything else; the contents were removed in mass. After dissecting away a considerable amount of connective tissue, the uterus was found to be retroflexed and considerably enlarged; length of cervix, one inch and a half; of body, three and a half; a neoplasm, either fibrous or myomatous occupied, or rather had developed, at the expense of the posterior wall of the body; there was considerable hypertrophy of that portion of the cervix that joins the body; the walls of the body itself, in front, could be traced up to top of the tumor, where they became thinner, and be-

hind were entirely lost or absent; the canal of the cervix appeared to be occluded at the os internum, or, at all events, after faithful search I was not able to make out the channel of communication. On the os itself was a small vascular polyp about the size of a pea.

The uterine tumor measured two inches and a half in its largest diameter; it was composed of a number of more or less spherical masses united in one. On opening the cavity in which this mass was contained, and which I supposed to be the cavity of the uterus itself, about two ounces of serum escaped. Whether this was secreted by the uterine mucous membrane confined by the impermeable os, or whether I had opened into a cyst, I shall leave for the members of the Society to determine.

Stated Meeting, May 27, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

NEPHROTOMY AGAIN.

DR. LOOMIS presented an abdominal tumor and made the following remarks:—

MR. PRESIDENT: At the last meeting of the Society I presented a specimen of fluid taken from an abdominal tumor during an operation upon a patient in Bellevue Hospital. The history of the case was then given, and the manner of operating described. (174th page 409.) I am now able to give the results of the operation, and an account of the lesions found at the post-mortem examination.

The operation was performed on the 12th of May, at 2 P.M. At 4 P.M., after the patient had been removed to his ward, he complained of pain in the left side of the abdomen—vomited almost constantly a greenish matter. His temperature was $97\frac{1}{2}^{\circ}$, his pulse 96, and his respiration 18 per minute. Two drachms of the sol. morphia were administered, which relieved the pain and caused the vomiting to cease. During the night he coughed very frequently, and expectorated a muco-purulent material. In the morning, May 13th, patient complained of pain in the abdomen; vomiting recommenced, temperature $101\frac{1}{2}^{\circ}$, pulse 104, respiration 26; breathing hurried; cough troublesome; expectoration muco-purulent, and streaked with blood; patient restless; urine scanty; pus discharges freely through the drainage-tube. The external incision below the tube was reopened, to allow more perfect drainage from the external wound. In the evening of the same day the temperature was $102\frac{1}{2}^{\circ}$, pulse 120, and feeble; respiration 32; abdomen tympanitic and tender; bowels not moved since the operation; patient continues to vomit a greenish material.

The following morning, May 14th, the temperature was $100\frac{1}{2}^{\circ}$, pulse 108, and very compressible; respiration 26; countenance anxious; tongue dry and brown; patient still vomits; bowels still constipated; respiration difficult; cough troublesome, and expectoration tenacious and blood-stained. Subcrepitant râles are heard at base of both lungs; patient is too feeble to undergo a careful physical examination. Four ounces of urine drawn by catheter found to be highly albuminous; abdomen excessively tympanitic and tender; discharge from tube is free and abundant.

At 2 P.M. patient was rapidly sinking, and died at 6 P.M., fifty-two hours after the operation. Stimulants were used from the time of the operation until his death; also quinine and opium in sufficient doses to keep him free from pain.

Autopsy was made by Dr. Murray, directed by Dr. Janeway, in presence of Drs. Wood, Smith, Loomis, and the house staff. Brain not examined; lungs,

some congestion, with slight œdema; a small spot of red hepatization in right lung, in the upper part of posterior lobe; heart normal; a slight calcification of internal coat of aorta above one leaflet of aortic valves. Abdomen: There is a large tumor occupying the left lumbar region, extending upwards into hypochondria, and toward the median line from this region. Over this tumor the descending colon passes, being quite closely connected to it by the layer of mesocolon. The posterior line of peritoneum corresponds to a line drawn from the anterior superior spinous process obliquely upwards and backwards to the ribs; and the line of reflection is two inches anterior to the incision made in the lumbar region into the tumor.

The peritoneum covering the outer part of tumor, and that reflected from this to the abdominal wall, is irrigated and coated with a little sero-pus, and some slight amount of the latter exists in the pelvis. The other intestines appear normal. Liver presents nothing special. Spleen normal. Right kidney nearly twice as large as usual; waxy degeneration, with some interstitial nephritis, and epithelium in tubes is in some places fatty. The tumor was removed, with bladder and left ureter. On dissection, the tumor is found to consist of renal tissue markedly atrophied. Three sacculi, representing dilated infundibuli, and great increase of fat tissue, both outside of tumor, and in hilum. When the fat was removed the size of the tumor was reduced one-third, and measured 10 inches by 6. The three sacculi are independent of each other. The largest is below, and filled with thick pus, with some mucus and cheesy matter. Into the middle one an incision, one inch in length, had been made during life. Between this incision and the fascia is a layer of fat, which was infiltrated with pus, and from this point pus could be traced to the peritoneal reflection above mentioned. The pelvis communicates with the upper of the three sacculi, and is thin at this point. This sac contains thinner pus than the others. The ureter admits the index-finger, and the walls are much thickened. One inch above entrance into bladder complete occlusion exists. Bladder normal in size and appearance. Ureter admits No. 14 catheter. Testicles: The epididymis on each side is thickened, and its cavity dilated—on one side affecting only the tail, and in the other extending into the body.

DR. LENTE: This specimen presents many points of practical interest from a surgical standpoint, and will also render a brief reference to the history of this important disease, and of the operations which have been proposed for its relief necessary to a proper appreciation of the subject. At our last meeting I made some allusions to these points, and do not wish to repeat what I then said. But in a discussion with my friend Prof. Mason, after the adjournment of the Society, he repeated his assertion that the operation of *nephrotomy* had been performed by one and perhaps two surgeons previous to my attempt, and again referred me to the sources of his information. An examination of these, which I had already made, and a further conversation with him, convinced me, and I may say himself also, that we were differing only in the *name*, and not in the *nature* of the operation; he contending, like many other modern surgeons, that any incision down to an abscess originating in the pelvis of the kidney, or even outside of the kidney (for he classed Bowditch's *peri-nephritic* cases in his category), constitutes *nephrotomy*. Now, what I have ventured to claim, after a very extended research, aided by several medical friends, through French, German, and English literature, in public and private

libraries, extending back more than two hundred years, is, that the operation which I successfully performed some three months ago,—that is, the cutting down upon a kidney *entirely free from peri-nephritic disease or adhesion*, with no guide except the anatomical relations of the parts, *had never before been attempted*. Not only so, but had been almost uniformly denounced, by the most distinguished surgeons of the last and the present century, as dangerous and reckless, as will hereafter be shown by a reference to the bibliography of this subject. It is only within a comparatively few years that one or two surgical writers have recommended the operation as a means which desperate circumstances ought to justify. Even Mr. Bryant, to whose operations, as I have already said, Prof. Mason so confidently referred me as examples of my operation, thus speaks of it on p. 452 of his last edition, but recently issued from the Philadelphia press: "When suppuration of the kidney takes place, with or without a calculus, and any external evidence of abscess exists, an opening should be made; and it is a *moot question* (italics are mine) with surgeons at the present day whether it is not better practice to anticipate this *pointing* by an early incision." This renders it certain that he has not performed nephrotomy proper himself.

It is not merely a matter of personal pride which induces me to insist so strenuously on a proper discrimination between this operation and others which have been resorted to for the relief of this fatal disease, and especially that for the *removal of renal calculi*, which latter operation is more frequently confounded with nephrotomy than any other,—a want of precision in terms likely to lead to fatal errors in practice, since a careful study of the numerous histories of this disease, and of the operations undertaken for its relief, scattered among the medical records of the last and the present century, indicates that it is a most uncertain and hazardous practice to cut down on these abscesses, even if pointing in the loin, *with a view to extract the calculi* supposed to be there; and even when the abscess has been successfully opened, that the safer practice is not even to probe for calculi, or to make too free even with the finger, since both procedures have been followed by fatal hemorrhages and other accidents. Even when the calculus is discovered, it is often so irregular, and attached so firmly by prolongations into the structure of the kidney, as to render attempts at extraction exceedingly hazardous. Another important reason for discriminating between this operation and others is, that the *delay* which is necessitated, if we wait for external evidence of abscess or pointing, is very dangerous in various ways. The sac, being thin and tense, may burst at any time, with a fatal result, or may work its way into some dangerous or inconvenient locality; or the other kidney, on the integrity of which the patient's chance for life hangs, may, in consequence of extension and long-continued suppuration, take on waxy degeneration. An *early* operation, which can only be nephrotomy proper, is therefore, and for many other reasons, of the first importance.

We thus see that it is not unimportant that the name of this operation should be preserved in its original signification; and any one, who will take the trouble to consult Rayer's *Maladies des Reins*, tome iii.; Civiale's *Traité de l'Affecton calculieuse*, Paris 1838; P. I. Desault's *Traité des Maladies des voies urinaires*, or the *Mémoires de l'Académie de Chirurgie*, Paris 1812, will be convinced that the true meaning of the term nephrotomy is what I have stated; and that it only causes confusion, and, as I have said before, tends to

errors of a serious nature in practice, to apply it so indiscriminately to various dissimilar operations. This subject is, however, too extensive and important to be embraced in a short article like this, but will be fully elaborated, in all its interesting details, in connection with the history of my case (now doing well) and of the Bellevue Hospital case; of the *post-mortem* examination of which I now proceed to notice the most interesting and important points, as bearing upon the question of the propriety and safety of *nephrotomy*.

In the first place, it is noted that the ascending colon is firmly attached to the anterior surface of the tumor. This was not detected during life, and should make us careful in the use of the aspirating tube, especially one of the larger sizes. In fact, aspiration is of little service in this disease, as the diagnosis is usually clear enough without it, and as a curative agent it is of no value whatever. The *large size of the tumor*, after so large an evacuation of pus at the operation, is noteworthy. After removal of the *fat*, which reduced it one-third, it still measured ten inches by six; this was due mostly to solid material constituting its walls, but partly to two large independent cysts containing pus. By some it may be thought that we gain but little by the operation if we still leave large cysts unopened. But, in all probability, especially if the operation is undertaken, as it should be, early, before the cyst-wall has become notably thinned, these cysts will, sooner or later, burst into that which has been opened, and so discharge themselves safely. In my own case, now some three months after operation, there is still a large, solid tumor, which caused me some uneasiness until I inspected this specimen, for this leads me to expect no *rapid* diminution of this swelling. In my case there is probably no cyst remaining of any size, because, first, there is no fluctuation, and secondly, it is stated in the post-mortem description of this specimen that the cysts consist of dilated infundibuli, whereas, in my case, I could feel the infundibuli only exaggerated, but not irregular or converted into cavities. This extremely irregular and dilated and sacculated condition also teaches us how likely futile our efforts at fuding a stone would be, even if more than one should exist, as our finger could not touch bottom, and our probe would almost certainly fail to find them. A most important point to be noted is the fact that the *peritoneum* was pushed, by the growth of the tumor, entirely beyond the reach of the knife, in the operation, even if the incision had been far more free.

It is noted that "between this incision (that by which the sac was opened at the operation) and the fascia is a layer of fat, which was infiltrated with pus, and from this point pus could be traced to the peritoneal reflection above mentioned" (that is, where it had been pushed from the abdominal wall by the tumor). In planning my operative procedure, the principal fear with me was of this very purulent infiltration, owing to the very loose connection of the kidney with this fascia, and it was this which led me to adopt a large, straight, inelastic tube as a *thorough outlet for the pus*. And this fact constitutes the principal anatomical distinction between nephrotomy proper, as the older writers have defined and limited it, and all the other operations which are so constantly confounded with it. In all of these the adhesions, which have *invariably* formed by the inflammatory processes outside of the kidney, have entirely precluded this danger. This revelation of the autopsy also teaches us that this operation should be conducted with the greatest care, and on a definite plan; especially that after the patient has been turned on

his side a cushion should be placed under the flank sufficient to cause the tumor to be somewhat salient in the lumbar region. In my case the kidney could not be felt at all after the patient had been turned on the opposite side, its great weight dragging it thither, but was fixed, and made perceptible by a folded pillow which I placed under her. In the second operation, this was not done, consequently some time was lost in finding the sac; and after the opening was made, in the efforts to find the latter, in order to enlarge it, the finger injured the loose cellular connection with the fascia above mentioned, and left a tract for the gravitation of the pus. However, this had nothing to do with the result of the operation. Another important point is the condition of the ureter and the cause of the disease. There was no calculus, and this, with the reasons already adduced, should render us chary of probing for calculi. The complete occlusion of the ureter near the bladder gave rise to considerable discussion, as to its probable cause, between Professors Loomis and Janeway, the latter supposing that it was due to the extension of gonorrhoeal inflammation, owing to the fact that both epididymes were found to be diseased. But the history of the case hardly seems to warrant this deduction. It remains a very interesting though inexplicable pathological fact. In deciding upon the propriety of this operation, the condition of the other kidney is a matter of the greatest moment, as upon its integrity depends the life of the patient. In this case the physician in charge of the case, Prof. Loomis, was fully aware that it was seriously affected; but it was thought that life would be prolonged by removing the cause of its degeneration. It is a fortunate and a very remarkable and unexpected fact that, as a very general rule, even when one kidney has been for years affected by very extensive suppuration, the other organ is almost perfectly healthy. This is established by the records of a very large number of autopsies. The drainage tube used in this case was one of tin, which I had first employed in my case. I had established the proper length (two inches) by careful examination, and though contrary to the opinion of some of the surgeons engaged in this second case, the autopsy showed that the end was engaged in the sac after death.

DR. JANEWAY also exhibited a specimen of adenoma of the breast, removed by Dr. A. B. Mott, more for the sake of exhibiting a beautiful and characteristic display of the gross appearances of the disease than for any particular rarity as a case.

SAWDUST BRANDY.—An American journal of high moral principles is sorry to learn that a German chemist has succeeded in making a first-rate brandy out of sawdust. We are friends to the temperance movement, says the editor, and want it to succeed, but what chance will it have when a man can take a rip-saw and go out and get drunk with a fence-rail? What is the use of a prohibitory liquor law if a man is able to make brandy smashes out of the shingles on his roof, or if he can get the *delirium tremens* by drinking the legs of his kitchen chairs? You may shut an inebriate out of a gin-shop and keep him away from taverns, but if he can become uproarious on boiled sawdust and desiccated window-sills, any effort at reform must necessarily be a failure. It will be wise, therefore, if temperance societies will butcher the German chemist before he goes any further. His recipe ought not to be made public. He should be stuffed with distilled board-yards until he perishes with *mania a potu*.

Correspondence.

SHORTENING OF LIMBS AFTER FRACTURE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—In THE RECORD of June 1st, 1874, is a letter from my friend and colleague, Dr. Frank H. Hamilton, criticising my remarks on "Fracture," as published in THE RECORD of May 1st, 1874, wherein I said: "The law, however, that shortening must necessarily attend the union of a fractured bone, is incorrect, as can be satisfactorily proved by practical demonstration."

Dr. Hamilton says, in his note of June 1st: "I am not aware that any one has ever laid down a law of this kind. If any one has, he has rendered himself a proper subject of ridicule."

"Believing, however, that Dr. Sayre has been incorrectly reported, or that in an oral lecture he has spoken inadvertently, I wish to call his attention to the paragraphs above quoted, and to ask him how they are to be understood."

In explanation I will say, first, that I did not speak inadvertently, nor was I incorrectly reported. On the contrary, Dr. Carpenter, who reported my lecture, is one of the most accurate medical reporters that I have ever known.

I make no pretensions to having cured *all* my cases of fracture without shortening, but know that many of them have been thus cured; and believing that a student will make a better result if he *tries* for perfection (although he may not attain it) than if he commences to treat a case of fracture with the belief that it must recover with shortening, I *tried* to impress them with the importance of trying for perfection.

That this belief in shortening after fractures is quite general, I am confident, from the number of physicians and students who have spoken to me on the subject, and from the discussion on fractures at the recent meeting of the American Medical Association in Detroit, where Drs. Hodgson, Gregory, and others stated that "union of a fractured bone without shortening was impossible," and most of these persons have referred to Dr. Hamilton as their authority for this belief. I am therefore delighted to know that they cannot quote him in future in order to sustain this erroneous doctrine.

I presume they have, like myself, inferred that Dr. Hamilton did not believe in the possibility of an oblique fracture of a long bone uniting without shortening from reading his published works; and that the inference was a correct one, I quote from page 74 of a work entitled "Deformities after Fractures," published in 1855, by Frank Hastings Hamilton, M.D.

He says: "In conclusion, I wish to say briefly, that in view of all the testimony which is now before me, I am convinced—

"*First*, That in the case of an oblique fracture of the shaft of the femur occurring in an adult whose muscles are not paralyzed, but offer the ordinary resistance to extension and counter-extension, and where the ends of the broken bone have once been completely displaced, *no means have yet been devised by which an overlapping and consequent shortening can be prevented.*

"*Second*, That in a similar fracture occurring in children, or in persons under fifteen years of age, the bone may sometimes be made to unite with so little shortening that it cannot be detected by measurement; but

* The Italics are mine.

whether, in such cases, there is in fact no shortening, since with children especially it is exceedingly difficult to measure very accurately, I cannot say.

"*Third*, That in transverse fractures, or oblique and denticulated, occurring in adults, and in which the broken fragments have become completely displaced, it will generally be found equally impossible to prevent shortening, because it will be found to be generally impossible to bring the broken ends again into such apposition as that they will rest upon and support each other.

"*Fourth*, That in all fractures, whether occurring in adults or in children, where the fragments have never been completely or at all displaced, constituting only a very small proportion of the whole number of these fractures, a union without shortening may always be expected.

"*Fifth*, That when, in consequence of displacement, an overlapping occurs, the average shortening in simple fractures, where the best * appliances and the utmost skill have been employed, is between one-half and three-quarters of an inch."

And in a later work, "Principles and Practice of Surgery, by Frank H. Hamilton, 1872," on pages 291 and 292 is the following:

"In reference to the prognosis, surgeons have not always been agreed; for, while a large majority of the most experienced surgeons in all countries and all periods of the history of surgery have acknowledged their inability to restore most broken femurs to their original length, a few less distinguished, less observing, or less honest surgeons have from time to time claimed that they seldom or never fail to make these bones unite of the same length as before, if indeed they do not sometimes happen to make them a little longer."

"I have myself often met with this latter class of men; and I have also seen the results of their practice, both in this city and elsewhere; and it has never surprised me to find that so far from always making thighs of the same length as before, they almost constantly fall considerably short of my own standard of average results. In other words—to state a matter of fact very plainly—through ignorance, inadvertence, or intentionally, these men do not tell the truth."

From these quotations I think the reader must be satisfied that the inference drawn by others as well as by myself, that Dr. Hamilton believed in shortening after fractures, was justifiable. I am, however, delighted to know that I did not understand his writings correctly, and that he agrees with me that shortening after fractures is not an absolute necessity, for he now says: "If any one has ever laid down such a law, he is a proper subject of ridicule."

THE NEW DISCOVERIES IN HYDROPHOBIA.

PINE RIDGE PAPERS.

I.

Who would be a dog at this time, when hydrophobia is such an interesting topic to the community? Not that I am prejudiced against the animal, but no one cares to have his character damaged by the sly and malicious insinuation of people who never attend to their own business, and who persist in misinterpreting the motives of others. Raise the cry of mad dog, and

the chances for the poor beast are gone. But this is the dark side of the hydrophobic picture, and it is not my purpose to dwell upon it. The bright side embraces the discoveries that have recently been made in connection with the disease. I wish to make a few remarks upon these discoveries, because I have some new and original ideas which I wish to ventilate before some luckier person does it for me. I have read everything about hydrophobia that has been printed in the newspapers, and you need not know that I have had enough to do to keep posted. But if a man wants to be a specialist he must work. I am certain now that I have read enough about the subject to be entitled to write about it. I have tabulated all the newspaper articles under their respective heads, and can lay claim to some very general ideas upon the subject. Aside from this, I have collected nine hundred and fifty accounts of special cures, and six hundred and ninety-three suggested remedies, which are considered worthy of trial. You can then imagine that I have not been idle in my search for information. In all my extensive reading, however, nothing interested me so much as the discoveries which have been made in the pathology of the disease, and which have been published at such length in a recent issue of the *N. Y. Tribune*. We are informed that the marked abnormal change is a fatty degeneration of the outer layers of the nervous centres, and that the cells are very much enlarged. As you are aware, I am a believer in the microscope, for I have an instrument that can show anything, from a granule the ten-millionth of an inch in diameter up to the largest cell that was ever conceived. I believe I was one of the first in this country to demonstrate the existence of Löffler's syphilitic corpuscle, among the first to point out to a class of medical students all of Salisbury's infusoria, and I believe myself competent to see anything. I am aware a great many disbelieve in the microscope, but such observers do not know how to use it. You must understand focussing to a dot in the first place, and you must know what you want to find in the second place. For instance, if you are in search of a granule, and you know it ought to be in a particular part of the field, a long focus will bring it very satisfactorily into view; but if you know this granule ought to be an oil globule, shorten your focus and you can get your refraction. Any observer who can't make his granules refract is either no microscopist or else he has not enough imagination—both very grave deficiencies in these progressive times. We have been told of a new method of slicing nerve-tissue at short notice, and I have no doubt that this of itself will be a great stimulus to microscopic research in hydrophobia and all other kindred disease. In fact, we have it down to a point, and all that it is necessary for future observers to do is to confirm the grand discoveries already made. This, as I have before remarked, is an easy thing to do if you have the right sort of an instrument and know how to use it.

I believe I have said enough to introduce what I have to say upon the subject, and lay what humble claims I may have to originality before the profession. In the first place, I am enabled to say that I have (excuse the first person, but I use it for short) two hundred and twenty-one patients afflicted with hydrophobia now under observation, not including the one hundred and fifty respective dogs who have been known to have bitten these patients. If I should have the misfortune to lose any of these (which is very improbable under my new plan of treatment), I intend to make a fluid extract of the pharyngeal mucus, and a resinous extract of the nerve-centres. For the first extract I

* The Italics are mine.

shall propose the name of Kanine or Extract of *Bark*, and for the latter Hydrophobine, which is probably the real active principle which spends itself upon the brains of the great majority of patients afflicted. I intend to commence my observations (lacking at present the opportunities for post-mortems) upon some sausages, which Humbageon, of Paris, affirms contains twenty per cent. of an active principle, which he calls *Humidine*, and twenty per cent. of *Kattine*. By these means I expect to obtain this new substance, Kanine, in large quantities. I make these statements to guard against the possibility of being forestalled in my discoveries and in view of the great importance of the subject to me I would ask a place for this letter at once. In some future communication I may give the results of some special observations on this prevalent disease.

PINE RIDGE, ON THE HUDSON.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from July 5, 1874, to July 18, 1874.

WAR DEPARTMENT,
ADJUTANT-GENERAL'S OFFICE,
WASHINGTON, July 10, 1874.

SPECIAL ORDERS,
No. 149.

Extract.

* * * * *
12. The following Boards of Medical Officers are appointed for the examination of Assistant Surgeons for promotion, and of applicants for admission into the Medical Staff, U. S. Army:

At New York City.

Surgeon Joseph B. Brown.

" John Moore.

" J. H. Bill.

" B. E. Fryer.

Assistant Surgeon A. H. HOFF.

At San Francisco, California.

Surgeon Charles McCormick.

" C. C. Keeney.

" George E. Cooper.

Assistant Surgeon D. L. Huntington.

" Edwin Bentley.

The Boards will assemble August 4th, 1874.

The junior member of each Board will act as recorder.

* * * * *
By order of the Secretary of War.

THOMAS M. VINCENT,

Assistant Adjutant-General.

SIMONS, JAS., Surgeon & Med. Director.—Granted leave of absence for 30 days on account of sickness. S. O. 100, Department of the Gulf, June 29, 1874; and extended two months on Surgeon's certificate of disability by S. O. 155, A. G. O., July 17, 1874.

RANDOLPH, JNO. F., Surgeon.—Assigned to duty as Post Surgeon at Camp Robinson, Wy. Ty. S. O., 90, Department of the Platte, July 3, 1874.

WEBSTER, WARREN, Surgeon.—Relieved from duty in Department of California, and to report in person to the Surgeon-General at Washington, D. C. S. O. 154, A. G. O., July 16, 1874.

BYRNE, C. C., Surgeon.—Granted leave of absence for six months with permission to go beyond sea. S. O. 145, A. G. O., July 3, 1874.

BROWN, J. M., Assistant Surgeon.—Assigned to duty as Post Surgeon at Plattsburg Barracks, N. Y. S. O. 131, Mil. Div. of the Atlantic, July 8, 1874.

HUBBARD, V. B., Assistant Surgeon.—During temporary absence of Surgeon Simons, in addition to his other duties, to discharge those of Med. Director at these headquarters. S. O. 100, c. s., Department of the Gulf.

BROOKE, JNO., Assistant Surgeon.—When relieved by Assistant Surgeon Fitzgerald, to report at these headquarters for assignment. S. O. 86, Department of the Columbia, July 3, 1874.

KINSMAN, J. H., Assistant Surgeon.—Assigned to temporary duty at Fort Abercrombie, D. T. S. O. 136, Department of Dakota, June 29, 1874.

VICKERY, R. S., Assistant Surgeon.—Assigned to duty at Little Rock, Ark. S. O. 102, Department of the Gulf, July 6, 1874.

O'REILLY, R. M., Asst. Surgeon.—Assigned to duty as Post Surgeon at Fort D. A. Russell, Wy. Ty. S. O. 90, c. s., Department of the Platte.

LAUDERDALE, J. V., Assistant Surgeon.—To report in person to the Commanding General Department of the Missouri for assignment to duty. S. O. 144, c. s., A. G. O.

LORING, L. Y., Assistant Surgeon. To report in person to the Commanding General Department of Arizona for assignment to duty. S. O. 144, c. s., A. G. O.

FITZGERALD, J. V., Assistant Surgeon.—Assigned to duty at Sitka, Alaska Ty. S. O. 86, c. s., Department of the Columbia.

HALL, J. D., Assistant Surgeon.—Leave of absence extended 30 days. S. O. 147, A. G. O., July 7, 1874.

WOODRUFF, E., Assistant Surgeon.—Granted leave of absence for 30 days, with permission to apply for 90 days' extension. S. O. 153, A. G. O., July 15, 1874.

HARVEY, P. F., Assistant Surgeon.—To report in person to the Commanding General Mil. Div. of the Atlantic for assignment to duty. S. O. 144, c. s., A. G. O.

DICKSON, J. M., Assistant Surgeon.—Granted leave of absence for 2 months, with permission to apply for an extension of 2 months. S. O. 144, c. s., A. G. O.

Medical Items and News.

DR. JAMES McNAUGHTON, of Albany, died June 9, in Paris, of heart disease. He was born in Grampian Hills, Scotland, 1796; was admitted into the University of Edinburgh in 1812, and graduated in medicine from that institution in 1816. He then became a surgeon of a merchant ship, and while on a visit to some friends in Albany he was persuaded to commence practice in that city. Three years subsequently he was appointed Professor of Anatomy in the Medical College of Fairfield, which chair he filled for nineteen years. In 1840 he was appointed Prof. of the Theory and Practice of Medicine in the Albany Medical College, which position he held at the time of his death. For a long time he was considered to be the oldest medical teacher in the world. During his lifetime he delivered fifty-three courses of lectures, and during the whole period that he was engaged in teaching was not absent from his post more than a dozen times. At the time of his decease he was President of the Albany Medical College. He was universally respected, not only for his medical attainments but for his devotion to the interests of his calling.

Original Lectures.

A CLINICAL LECTURE ON INTERNAL HÆMORRHOIDS

DELIVERED AT CHARITY HOSPITAL.

By ERSKINE MASON, M.D.,

ADJUNCT PROF. OF SURGERY, UNIVERSITY MEDICAL COLLEGE.

TO-DAY, gentlemen, I show you some cases of internal piles, and it is for the relief of these that you will be more frequently consulted than for those that are external, and which we studied the other day. Very much that I have told you about external piles you will find equally applicable to those that are internal. For instance, you will find that a majority of these tumors are chiefly composed of varicose hæmorrhoidal veins. That the causes which produce one also give rise to the other. That very many of the symptoms are common to both; and the means employed in the treatment of one is often as applicable to that of the other. Notwithstanding all this, you will learn that they often differ from the external variety in very many respects. First, as to the locality of these growths. They are always found to arise above the sphincter, though often they are found to project below the anus, and if you are careless in your examination you may mistake them for the external variety. As you saw that the external tumors presented different appearances as to color, size, and consistency, so you will find to be the case with the class we are now studying.

These tumors, at times, are found to be arranged one above the other, as in rows, and if your examination be superficial, some may escape you; and the most certain way of avoiding this is always to have the patient take an enema of warm water, so as to force the piles down just before you operate, or else to resort to the over-distension of the sphincter, an operation which I shall presently show you in a case of fissure. The size that some of these hæmorrhoids attain to is often very great. Here you see, in this patient, a single tumor the size of a pigeon's egg; in other cases you will see several of these protruding through the bowel, and all equally large. At times they will be attached by broad bases to the side of the bowel, presenting a blue or purplish appearance. Again, they may project along the side of the bowel, like distinct columns; their surfaces are usually smooth and glistening, and this class are chiefly composed of veins and infiltrated areolar tissue, covered over with mucous membrane. At times, however, an artery of some size is found in these tumors. Another variety you will often observe projecting from the anus (and you see it well shown in this man, who also has a tight stricture of the urethra, which, no doubt, is the cause of his piles). It is a tumor not at all blue, but of a bright, florid appearance, soft to the feel, and always moist, and which, you will see, readily bleeds upon slight examination; and you notice that the blood which escapes is not at all venous in character, but of a bright arterial hue. Into such a tumor as this we have the capillaries entering largely. Higher up in the bowel, above what is termed the internal sphincter, you will meet at times tumors that are sessile, red like a strawberry, which readily bleed upon being touched, and which are composed chiefly of arteries. I might separate these growths into still other classes, but I think this will suffice for all practical purposes, and you will remember them better than if the division was more minute, and then I have now the opportunity

of illustrating just these varieties. There is, however, a condition of the bowel which is always spoken of under the term hæmorrhoid, though it consists of no tumor, but nevertheless gives rise at times to copious hæmorrhage, and is, I believe, always associated with some distinct hæmorrhoidal growth. You will observe at times, in examining the bowel with the speculum, little vascular spots of the mucous membrane, the slightest touch of which will cause an oozing of bright arterial blood. Whether the mucous membrane covering these vessels which give rise to the bleeding is simply changed in character, or whether it is broken, I have in several examinations been unable to determine. All these varieties you will often observe in the same patient, and some have regarded many of them as only changes occurring in the same original tumor, either from long continuance of the disease or as the result of some special form of treatment.

The cause of these internal growths is precisely that which we have seen give rise to the external variety, and therefore it is, you so often observe both classes of tumors in the same individual.

The symptoms that denote the existence of this class is in many respects also like those belonging to the external group. The first symptom which perhaps attracts the patient's attention will be loss of blood while at stool, and for this it is that he often seeks your advice. This woman, for example, will tell you that she frequently loses large quantities of blood in this way. The amount which escapes in this manner varies from a mere tinge to many ounces; nor does it come away only at the time just mentioned. While walking or riding patients are often subjected to this hæmorrhage, which is very distressing; and I have known it to be so profuse as to cause faintness in a man that was otherwise strong and hearty. The amount that patients will tell you that they sometimes lose is very remarkable. This hæmorrhage, when it recurs frequently, will soon debilitate the strongest person, and induce a long train of symptoms. It is from this symptom these tumors derive their name—hæmorrhoids. When they have increased in size they give rise to tenesmus, bearing-down pains, weight in the bowel, and pain in the back and down the thighs; every one of those symptoms this man has given you. At first these tumors only protrude while at stool, and then return within the bowel, or else are returned by the patients themselves. After a while, the sphincter becoming relaxed through the pressure, they are constantly protruded, or, as the patients tell you, their "piles are down." So many and so large are the tumors, as often seen while in this condition, that by their weight they have brought down some of the mucous membrane. Indeed, such conditions have been taken for prolapsus of the rectum. But be sure that you do not make that mistake, for prolapsus of the rectum is quite another thing. Only a short time ago a patient came to consult me for a prolapse of the bowel, and for which he was wearing an instrument "to keep the bowel in place." Upon examination, however, there was no sign of prolapsus, he was only suffering from hæmorrhoidal tumors, which at times came down and annoyed him. The instrument he was wearing only served to keep the tumors in a continual source of irritation.

At times these tumors, when they are protruded, become grasped by the sphincter; this causes the lower portion of them to swell, and their return for a time impossible, unless proper assistance is at hand, and as a result we may have a case of inflamed piles. So tightly are they constricted at times that sloughing of the parts has taken place, and the patient has become

cured through this accident. More frequently, however, it but leads to ulceration, and sometimes to abscesses in the tumors, and a train of very painful symptoms, in which the neighboring organs, such as the uterus and bladder, sympathize. From the presence of these tumors defecation becomes not only painful, but often very difficult, and we will also find that there is a mucous, perhaps a purulent, discharge from the anus; that troublesome symptom of which we have spoken in connection with external piles, itching, may be also present here, though the external growths be small. When these piles become inflamed, not only do we have local symptoms to combat, but we find also great constitutional disturbance, as high fever, furred tongue, frequent pulse, and great restlessness. This condition will often continue for several days before your patient becomes relieved.

When internal piles are neglected, and have continued for a length of time, you will find the general condition of the person becomes affected. They are apt to become dyspeptic, despondent, bowels more and more constipated, and from constant losses of blood they become pale and haggard. Indeed, we have seen persons that at times are completely incapacitated from attending to their business; and, strange to say, that many will continue to remain great sufferers, and will resort to all kinds of nostrums rather than submit to an operation, which alone holds out any prospect of relief.

Our treatment consists in hygienic, medical, and surgical means, as in the external variety, and the two former means are alike in both. The aperients that are the most valuable are the salines, in combination with sulphur, though I have lately seen a pill of taraxacum and aloes act very kindly. I know also is regarded by many as deleterious in cases of hemorrhoids. This fact has, however, been doubted by some, and Mr. Brodie in his surgical lectures states he has never seen the ill effects arise from this drug that is popularly ascribed to it. It may follow when large quantities of the drug is employed; but this will be found also true of many other cathartics. In the use of such medicines we never desire to produce violent cathartic action—merely to assist the bowels to regular action. Medical treatment will suffice but to palliate in the majority of these cases, or act as an adjuvant to the more radical means, when this affection has been of any long continuance. I know very well that there are hosts of persons suffering from internal piles who never resort to a surgical operation, and I may say are never even counselled to do so by their medical advisers, and yet for long intervals maintain themselves in comparative comfort, and free from very great annoyance. Yet, to accomplish this, great numbers are constantly watching themselves, and may be said to be constantly more or less under some sort of treatment, whereas a comparatively simple operation might suffice to give them more radical relief.

I take it that in those cases where patients are losing large quantities of blood, and in those where the growths are of long standing and constantly protrude, or where they cause great pain and become a troublesome impediment to defecation, or are in any way a serious source of annoyance, and are affecting the general health—all such, other things being equal, viz., there being no disease present that would contraindicate an operation—are suitable cases for surgical interference. You, of course, would not think of operating upon a woman who is in the condition of the woman I have just shown you, she being pregnant; nor on this man, who is suffering from a tight urethral stricture; and yet both these patients have and are

suffering from internal hemorrhoids. In these instances we do all that we can to palliate until after the exciting cause has been removed; then, if they are still the cause of trouble, your operation can be resorted to with every prospect of success. Should your patient be the subject of a displaced uterus, or of some vesical trouble, in these instances, as in every other, seek first the removal of the exciting cause before you resort to an operation.

The modes employed by surgeons for the removal of these tumors are nitric acid, actual cautery, ligature, and the *feraseur*; at least these are the modes adopted at the present day, though I believe the latter instrument is now very generally and very justly discarded in these affections. Some years ago these tumors we cut off with the scissors, and either left alone or else the wound touched with the hot iron, or the wound brought together by suture to promote speedy union. So serious and even fatal was the hemorrhage resulting from such a course as this in many cases, that this mode of dealing with these internal growths is no longer employed. We will now consider these different appliances in the order I mentioned them. I believe it was due chiefly to Dr. Houston, of Dublin, for first bringing favorably to the notice of the profession nitric acid in the treatment of this affection. Since that time it has been highly extolled by many writers, and again severely deprecated by others, as not only of no avail, but actually very harmful. I think we may find a reason for both the opposing views not only in the manner in which it has been used, but to the class of tumors to which it has been applied. At first, no doubt, it was applied, and may be yet by some, indiscriminately; and as a result, failure is bound often to occur—and the remedy receives the blame, not the operator. If you wish, therefore, to see its favorable action, you must select your cases and apply it in the proper manner. Its use, I think, should be confined solely to those vascular spots of mucous membrane which I have described as sometimes seen in connection with other tumors, and to the small, florid, sessile growths which so readily bleed upon the slightest touch. If you but confine its use to these cases, I feel sure you will meet with happy effects; while, if you apply it to the other tumors, you will often be disappointed. There is no objection to using this, at the same time you treat the larger growths by other means, as I have often done, and with the happiest result. The acid you use should be of the strongest kind, and the parts should be well brought down into view by the means I have described. Then dry the parts and touch them lightly with a piece of wood dipped in the acid, taking great care that no acid comes in contact with surrounding mucous membrane. You then oil the parts and return them; often one application will suffice, if the growth be extremely small, or you may have to repeat the operation after a little interval. The pain attendant upon this is often but slight, and of short duration as compared to other means; and with very nervous patients not so terrifying. The acid acts by the inflammation of the parts it produces, which closes the vessels, and, as a result, the tumor shrivels.

The next operation to which I call your attention is that by means of the actual cautery, and which I have frequently made use of in this hospital, and the application of which I shall now show you. The use of the actual cautery in these affections is a very old one; but in more recent years it was reintroduced by the Dublin surgeons. Its great advocates among English surgeons are Mr. Henry Lee, of St. George's Hospital, and Mr. Henry Smith, of King's College Hospital, and

the operation is now chiefly done with the aid of a clamp, suggested by the latter gentleman. It is the instrument I now hold in my hand. The claims that have been advanced for this operation were that it is freer from danger than the other operations; recovery was more rapid; that it is less painful, and, I think, it has also been said to be free from hemorrhage. I must tell you, however, that cases have been reported, where not only complications have happened, but death also has followed from pyæmia. With respect to pain, I have seen patients complain severely for some time after its use; and as to hemorrhage, I have seen that follow in several cases, and where I have taken great pains, to follow strictly the rules laid down for its use. Recovery, perhaps, may be more rapid than after the ligature, though my employment of it, perhaps, has not been frequent enough for me to speak authoritatively on this point. I regard it, however, very favorably in some cases; and not one to be treated with such scorn as a recent writer has seen fit to do. In our venerable ward we frequently have had women coming in suffering greatly from hemorrhoids, at the same time having chaneroids both of vulva and anus. Here the clamp and cautery I have almost always used, there being less danger of the resulting wound becoming inoculated than if the ligature or *écraseur* were employed. You apply the clamp and cautery thus: seizing a tumor with forceps or tenaculum. I drag it down, and grasp it around its base with a clamp and strongly compress it—the pressure may be maintained by means of this screw—then, with a pair of curved scissors, you clip off the pile a little distance from the clamp, so as to leave a stump over which an iron heated to a dull red heat is drawn. This is for the purpose of producing an eschar, and thus sealing the vessels; after which you slowly open the clamp to see if there be any hemorrhage. If bleeding occurs, another application of the iron is required. You must bear in mind that in the use of this means you should never try to hurry the operation by grasping more than one tumor at a time; if you do, you will be more liable to have hemorrhage.

I shall now show you the use of the ligature as applied to piles. This is used far more frequently than any other means, and is, I think, very justly regarded, almost universally, as not only the best, but as safe a mode of operating as we can employ. Mr. Allingham, in a recent work, has cited many hundred cases as having been operated upon in this way, both in private practice and in a hospital specially devoted to diseases of the rectum, in which the number of deaths following have been extremely few. Some have even gone as far as to assert that it may be used without the slightest risk of serious trouble. But I think I have often told you that no surgical operation, however slight, can be truly said to be absolutely free from danger in every case. The ligature strongly recommends itself both from the facility of its application, the great safety, and the radical relief which so frequently follows. You will hear of some who are said to tie off piles without pain. In your practice you will find few patients, I think, who will not suffer more or less for a short time after this operation; though in this respect you will find great differences in individuals. In the use of the ligature you do not wish to use a large one; if it does not give rise to more pain, it certainly is longer in coming away. A moderately fine, waxed, silk ligature, or what I like as well, is one of linen, such as I am about to use. I prefer this on account of its strength. You readily procure it at any of the sewing-machine stores. Various methods have been recommended for its application, and some with respect

to lessening pain. Bodenhamer, a writer on "Diseases of the Rectum," makes it a point never to draw down the tumor with the forceps, but simply applies the ligature around the tumor a little from its base, so as to avoid including the mucous membrane that lines the bowels. I have tried this, but have not found it so free from pain, as I was led to suppose might be the case when reading the description of his operation. In the ordinary operation you seize the tumor and drag it down; this gives you a clear view of the part you wish to ligate. You then surround the tumor with the ligature (and I do not think it necessary that the ligature should surround the pile *close* up to its attachment to the wall of the bowel). The ligature is now to be tied *tightly* with two knots. Cut off the ligature a little distance from the knot; and in some instances the tumor, a little beyond the ligature, is cut off, and the parts returned into the bowel. The great benefit, I think, you derive from not tying your ligature *close* up to the base of the tumor, and in not dragging them down too forcibly, is that by thus not including the coats of the intestine you thereby avoid a troublesome contraction of the bowels, which I have seen follow in a case where several tumors were thus ligated.

The method that Mr. Allingham has recently described as the one practised at St. Mark's Hospital, I have of late frequently performed, and regard it with great favor. It consists in separating the pile, with the scissors, from its attachments to the muscular and other tissues of the bowel beneath its mucous membrane. Your cut is carried up parallel to the wall of the bowel for a little distance—perhaps an inch or more—and the neck of the tumor, so to speak, is then ligated. In this way you tie little more than the vessels which form it; and there being less tissue for the ligature to separate, it comes away sooner. The vessels running parallel to your incision, you are not likely to wound them, and if you have any bleeding point, it is readily seen and should be tied at once. The wound you make being an incised one, readily heals. This operation I now proceed to show you. After this operation of the ligature your patient should be confined in bed for at least a week, and should not go about for some days further. The ligatures will usually come away from the fourth to the sixth day; and the bowels should be confined for the first three or four days. Should they not move before this, a saline may be given. I am in the habit not only of having the anus frequently bathed with warm water, but also with a small syringe, having the parts, so to speak, irrigated with tepid water containing opium and a little carbolic acid. It not only adds to the cleanliness, but subdues the pain your patient may suffer. Immediately after the operation a pad of picked lint over the anus, and held in position by a tight T-bandage, will also prove serviceable in subduing pain. You will find some patients able to go about much sooner than others; indeed, I have known them to walk about in a day or two after the operation; but this is wrong, they should remain quiet some days after the ligatures have come away, in order that the ulcer, which necessarily is present after the separation of the pile, should heal kindly. After all these operations you must remember the bladder, for not unfrequently will you be required to use the catheter for a day or so after the operation. The operation by means of the *écraseur*, I do not intend to show you. It is dangerous, as liable to give rise to stricture, and I do not think it should be resorted to when we have safer means at hand.

The accidents that have been known to follow operations upon hemorrhoids are tetanus, pyæmia, and hemorrhage. With respect to hemorrhage, when the ope

ration is done properly, I do not think it will often be serious. About the means employed to arrest bleeding after operations upon the bowel, I must speak to you of at another time. Tetanus and pyæmia are rare accidents.

Will hæmorrhoids ever return after an operation, will be a question you will often be asked. That they will in some instances, is true, especially if a patient neglects himself, and thus brings about the condition which originally induced his piles; whereas if he is careful, he may remain clear of them. Should they return, there is no impropriety in repeating the operation. There are some people who seem to be peculiarly predisposed to a varicose condition of their veins, and that, too, at a comparatively early period of life. In this class, I think you will find a disposition to the return of hæmorrhoidal difficulties under any treatment that may be used.

Original Communications.

THE PROBABLE ORIGIN OF SOME FORMS OF NERVOUS DEAFNESS.

By SWAN M. BURNETT, M.D.,

ENOXVILLE, TENN.

AN examination of the reports of hospitals, infirmaries, and dispensaries of several years back, will show that nervous deafness constitutes a large per cent. of the recorded cases of aural disease.

The great improvement in our methods of diagnosis of affections pertaining to the auditory apparatus has of late largely diminished this per cent., and we now find that a great number of those cases that would hitherto have been referred to disorder of the nervous perceptive organism are classed among affections of the conducting mechanism. And, furthermore, there is no doubt but that as our knowledge of aural pathology is extended, and our skill in diagnosis becomes more certain and accurate, this percentage will be still more largely reduced.

Such has been the case in the sister department of Ophthalmology, where amaurosis is now no longer what it was once facetiously defined to be, viz., "a condition where neither patient nor surgeon was able to see anything," and it is but reasonable to hope for such a happy day in Otology.

But until some instrument similar to the ophthalmoscope is invented, whereby we can ocularly examine during life into the condition of the auditory nerve and its expansion, our knowledge of its pathology must remain to a greater or less extent a matter of conjecture, while reasoning, inductive and deductive, must take the place largely of actual demonstration, and the term "nervous deafness" remain, as amaurosis did for so long a time, but a word to conceal our ignorance.

Thanks to the investigation of such men as Hughlings Jackson of London, we are able to trace a connection between some forms of nerve blindness and certain intracranial irregularities. Reasoning from analogy, it is but fair to infer that some such connection should exist between nervous deafness and troubles within the cranium; but, so far as we are able to inform ourselves, but little advance has been made in that direction.

The investigations of Menière, of Paris, have indeed given an impetus to study in that direction, but as yet little knowledge of a positive character has been

attained. Still these researches, and those of other men working in the same field, have taught us that we may hope for important results in the course of time.

Some cases of impaired hearing have recently fallen under my notice, whose previous history and present condition have caused me to reflect on the *probable connection between the occurrence of sick-headache or migraine in early life and the existence of a diminution of hearing power in more advanced years.*

How many persons have unimpaired hearing power at middle life? To answer this question definitely is not an easy matter, for the defect may be slight, and there is always a disposition on the part of those affected to conceal as far as possible any deficiency in this particular, and where only one ear is affected this is comparatively easy. It is the opinion of Troeltsch that "the majority of persons beyond fifty or sixty years no longer hear well." Impairment of hearing at this age and beyond, is commonly considered to be physiological, and no attempt is generally made to investigate the cause.

But, again reasoning from analogy, are we warranted in referring a failure in the faculty of audition to the influence of age simply, any more than we would be in considering a retinal or optic-nerve derangement a natural accompaniment of advancing years? Of course we do not refer to the loss of accommodative power, which is a demonstrated physiological change, and in accordance with the natural laws of structural development.

When, therefore, there is a nervous deafness before the age when the whole powers of the system are giving way, with no evidence of existing or previous disease of the conducting apparatus, but with a history of an antecedent cerebral trouble of whatever kind, are we not justified in inferring the existence of some connection between the two occurrences?

Our reasons for an affirmative answer to this question we propose to give in this article, and shall now relate the following cases in point:

CASE I.—P. K., aged 50, was from his eighteenth to his thirty-eighth year subject to very severe attacks of sick-headache, which commonly ran a very definite and regular course.

The first sensations would manifest themselves in the morning, generally about 10 o'clock. These premonitory symptoms consisted of a dimness of vision, to such an extent sometimes, that he was not able to recognize an individual ten feet distant; and a feeling of vertigo, occasionally so strong that to prevent falling he would be obliged to lie down.

Soon pain would set in, confined mostly to the temples, and gradually increase in intensity for some three or four hours. If nausea followed by vomiting took place at the end of this period, the pain would abate, and soon he would fall into a slumber, from which he would awake much relieved or entirely well. If vomiting did not occur, a drowsiness would supervene, merging gradually into sleep, followed by the same results.

No trouble referable to the auditory apparatus was noticed until about the twenty-fifth year. At that time, after a very severe attack, he noticed for the first time tinnitus aurium. Soon after, a deficiency of hearing power became apparent, beginning in the left ear, but in course of time involving the right. Subsequently to this he noticed that after an attack his hearing was much worse for several days.

His hearing power gradually diminished from year to year, until about two years ago, since which time there has been no perceptible difference.

On examination it was found that the watch, on the

left side, could only be heard on contact; on the right, at about one inch.

No abnormality was found in the conducting apparatus. Tuning-fork on the forehead not heard in either ear.

From him I learn some facts in his family history which bear directly upon the question under consideration.

His father suffered from sick-headache in early life, and at forty years of age began to lose his hearing power, which increased to the time of his death. No assignable cause for the deafness, so far as he knew.

The patient also had a brother who was affected in a manner very similar to himself, and who began to notice a diminution of hearing power at thirty-five. He is now about in the condition of our patient. Of the rest of the family, three brothers and one sister, none had headache and none suffered from impairment of hearing.

CASE II.—Mrs. M. K., aged 48, suffered from youth until some time beyond maturity with most violent attacks of sick-headache, similar in all essential particulars to the case above related. Ten years ago, about the time when the headache ceased, tinnitus aurium began, with impaired hearing power, which has increased until now; the watch is heard only on contact, in either ear.

Examination shows the membrana tympani to be healthy, and no signs of present or past inflammatory action.

Tuning-fork on glabella not heard.

CASE III.—L. E. M., *et* 50, had severe sick-headaches in early life, and has them yet occasionally, though not nearly so often as formerly. The history of each attack is essentially as follows: The pain begins in the morning when she first awakens, generally on one side, and by preference the right; commencing in the forehead, it progresses backwards to the occiput and down to the neck and shoulder of the affected side. It increases in severity for a length of time varying from twenty-four to thirty-six hours, when she finally vomits and becomes drowsy, then falls asleep and awakes free from pain.

For the last several years, during and for some time subsequent to the attacks, the hearing power has been very much diminished. This state of things would continue but for a few days, however, and she would return, as she thought, to her normal hearing standard. At the same time she would have a tinnitus aurium and vertigo; and more latterly, when she was not suffering from headache, a vertigo accompanied by tinnitus would come over her.

Within the last three or four years her friends have noticed that they had to speak louder to her than they formerly did, and for the last few months her hearing power has very rapidly diminished. *Status presentis*, R. W. 1 inch; L. W. 5 inches. Tuning-fork on glabella not heard in either ear, except on closure of the meatus, and then only faintly, and more in the left ear than in the right. Constant tinnitus. No abnormality found in the external or middle ear. Has never had any pain or discharge from the ears.

These are undoubtedly cases of so-called migraine. The history is clear and unmistakable, the symptoms pathognomonic. The question for us now to determine is, Is there any connection between the occurrence of migraine and the existence of the deafness which, so far as we are able to determine, is purely nervous?

If migraine is to be considered primarily a gastric disorder, an evidence of deranged digestion, then there will be little hope of establishing such a connection. But, if we look upon it as a neurosis, with at-

tendant gastric symptoms, the way is more clear to a satisfactory solution of the difficulty.

We have to thank Dr. F. E. Anstie, of London, for a positive classification of migraine among the nervous affections. Some, it is true, before him, had written upon the nervous character of some forms of migraine; but he is the first to take the ground that it belongs exclusively to the neuralgias, and to point out its connection with other neuroses, either antecedent or following. We have not space to reproduce his argument in full, as it was published in the London *Practitioner* for November and December, 1872, but the tenor of his observations goes to show that:

... "The personal (and usually the family) history of migrainous patients, taken together with the remarkable course which the disease runs, even in ordinary cases, and the important and suggestive group of occasional complications which are associated with it, almost compels us (*per eam exclusionis*) to look upon the medulla oblongata as the starting-point of the disease, and to believe that migrainous pain means atrophic molecular irritation in the trigeminal root, that migrainous vomiting means a similar process in the vagus root, and so on, for the whole widely varying group of possible phenomena of the disease."—(*Prac.*, Jan., 1873.)

Accepting this as the pathology of migraine (and it is certainly in all respects the most satisfactory of any yet offered), the connection we are seeking is not difficult to demonstrate.

But in order to do so satisfactorily, we must review somewhat carefully the anatomical questions involving the origin of the nerves in question, viz., the trigeminal and auditory.

The deep origin of both is in the medulla oblongata. According to Gray, "the deep origin of the larger or sensory root (of the fifth pair) may be traced between the transverse fibres of the pons varolii to the lateral tract of the medulla oblongata, immediately behind the olivary body. According to some anatomists it is connected with the gray nucleus at the back part of the medulla, between the fasciculi teretes and restiform columns."

According to Brunner (*Archiv. Oph. und Otol.*, vol. ii. No. 1, page 328), the origin of the acoustic nerve has been traced:

"1. Into fibres of the striae acusticae. The latter take their course around the restiform body along the floor of the fourth ventricle, to the median line, where they disappear. Their further course is not known. 2. Into fibres to the ganglion of the acoustic. 3. Into fibres running to the funiculus cuneatus et gracilis (sensory). 4. Into the floor of the restiform body (motory). 5. Into fibres to the accessory acoustic ganglion of Stilling. This is a small body situated beside the restiform body in the cerebellum. 6. The acoustic ganglion is connected, by means of the so-called acoustic cord, with the cortex of the insula Reilii near the fossa Sylvii. The acoustic cord constitutes a bundle of fibres which can be traced posteriorly to the acoustic ganglion in the medulla oblongata, where it becomes lost."

It will be seen from this, that though no very direct connection can be traced between the origin of the two nerves throughout their whole extent, still their ultimate origins ramify pretty generally throughout the medulla and contiguous parts, in such a manner that morbid causes acting on the one could very well be supposed to affect the other. These facts can be interpreted in such a manner as to throw much light both upon migraine and upon some forms of nervous deafness.

Suppose you have in the medulla an "atrophic molecular irritation" (a term indefinite enough, it is true, but it serves to give a "local habitation and a name" to some pathological condition there and then present) and affecting the origin of the trigeminus, what is to hinder that "atrophic molecular irritation" from invading the origin of some portion at least of the portio mollis of the seventh pair, or, if you choose to call it so, the centre of audition in the brain? The vertigo and disturbance of equilibrium generally present in these cases could, in like manner, be referred to a like irritation of the centre controlling equilibrium.

In all cases of migraine it is not likely that this "atrophic molecular irritation" would invade the cerebral centre of audition, and consequently we would not look in every case for nervous deafness as a sequela.

I give these cases and the opinions based thereon to the profession, in hope that some, whose opportunities for observation of such cases are more extended than my own, may examine into the truth of the position I have taken; and to stimulate investigation upon the subject: for, so far as I am aware, no such connection as I have tried to establish has been maintained by any writer on Otology.

JUNE 1st, 1874.

DYSPEPTIC SYMPTOMS DEPENDENT UPON TUMOR.

By E. M. HUNT, M.D.,

METTCHEEN, N. J.

Two cases of abdominal tumor have come under my observation the past year, which are worthy of some comment. Dr. C. McKnight Smith, of Perth Amboy, aged 70, a man of robust frame, of excellent general health, of no known hereditary taint, and of regular habits, commenced several months since to show some dyspeptic symptoms, accompanied with pallor and moderate loss of flesh, with occasional nausea. An examination of the urine showed oxaluria, and this persisted throughout his sickness. About two months after his first ailment a small tumor was detected in the left hypochondriac region. It seemed flat and nodulated, and to be growing slowly; but its attachments and character were of difficult diagnosis. The case was seen by Dr. Baldwin, of New Brunswick, Drs. Draper, Gouley, and Hunt, of New York, and by myself, in consultation with Dr. Clarke, of Perth Amboy. It was variously suggested that it might be enlargement of the left lobe of the liver, scirrhous, fecal impaction, or a glandular mesenteric enlargement. The tumor enlarged until it spread itself over the umbilical region, and could be felt in a flattened and nodulated form, as movable from side to side. There was at times some pain, easily controlled by opiates. After about two months the patient kept his room and his bed a good part of the time, but was still quite comfortable. For the last six weeks anæmia and increasing loss of flesh, slight œdema of the abdomen, and increased frequency and feebleness of pulse, showed accelerated progress of the disease. He died, however, a few days sooner than was anticipated, quite suddenly, while sitting up in bed, without any warning of rapid sinking. Post-mortem revealed a tumor, the basis of which was the entire omentum. The whole apron, from the stomach downward, had become thickened and nodulated with bunches like rounded buttons, of varying sizes, piled one upon another, so as to make in parts a thickness of four or five inches. They were all um-

bilicated and run together like a confluent variola, some as large as a two-cent piece, others small and distinct. Some of these smaller ones were scattered over the lower surface of the diaphragm and the lining membrane of the abdomen. One on the outside of the intestine had undergone a sloughing process, and involved the interior of the intestine, and was probably the immediate cause of death. The thickest part of the omental bunch was in the left hypochondriac region, but it spread variably over the whole extent of the omentum. Under the knife it cut with some solidity, like a firm sarcoma. This omental formation of tumor by aggregation of disk-shaped nodes was new to most of us, as the mass seemed definitely formed by the conjunction and piling together and upon each other of all these developed cells or hollowed rings. The question of cancerous disease is one often difficult of positive affirmation. Two excellent microscopists arrived at different conclusions in this regard.

Mr. I. P., a farmer aged 60, of spare form, of good health and habits, of no known hereditary taint, came under treatment one month before the death of Dr. Smith. He too complained of loss of appetite, and was showing some loss of flesh and anæmia, with jaundiced appearance of skin and constipation. Tonics and moderate cathartics and good diet had been prescribed, with such bathing, oiling, and friction of skin as would improve its function. A closer examination, however, revealed a tumor the size of a goose-egg just below the umbilicus, inclining to the left. It was harder than the other, a little more movable, but having attachments which seemed to be continuous above the margin of the left ribs. There was no vomiting at the time, but soon severe cough and free expectoration occurred, which in a few weeks yielded under free use of cod-liver oil and tonics. The tumor increased in size, and, after about three months of walking invalidity, the patient was confined to his bed. There was but little pain, but much loss of flesh and occasional vomiting. The tumor enlarged about to the size of a large cocoa-nut. Occasionally, but rarely, there would be an attack of vomiting. The close attachment extending under the ribs on the left side seemed to point to this as the starting-point of the abnormal growth. The stomach was suspected of being involved from the first, but I was not fully satisfied, until, by quick pressure, I was able to force eructation, and afterward, by giving the patient two or three swallows of milk, could, by succussion, get the motion of the fluid in the tumor. After three months of emaciation the patient died as a candle would go out, and from complete inanition. A post-mortem showed the stomach firmly attached to the left lobe of the liver throughout its entire lower boundary. The stomach itself was so involved outside and inside throughout its entire upper curvature, that its interior had lost all appearance of stomach, except that reaching from the cardiac to the pyloric orifice was a curve of natural appearance, of calibre not larger than the duodenum, and capable of containing not over an ounce and a half. All the rest was a mass of abnormal growth, creaking under the knife. A specimen could not be allowed for microscopical examination. The patient owed his prolongation of life and freedom from vomiting to the fact that this stomach tube, while it could do but little digestive work, could still convey food readily to the intestines. These cases are worthy of note, because the first, although anomalous, had such a marked character of its own, like a well-defined form of skin disease; and in the latter, which was in all probability cancerous, the diagnosis of local pathology was dependent upon a mode of examination

slightly different from usual. Besides, in the middle stage of this disease, the man made recovery from serious lung complication. His ability to digest oil, starch, and milk was enough for this. Both cases were typical and instructive to me, as they may be to others in respect to future diagnosis.

REPORT OF A SINGULAR CASE OF STABBING.

By A. T. HENLEY, M.D.,

MACON STATION, ALABAMA.

In June, 1870, I was called to see Wells Kelly, a mulatto, aged 24, who had been stabbed in the back with a knife. Upon examination I found the patient lying on his face, with the knife still deeply embedded in the wound, with only the handle projecting, and apparently suffering very little pain. The knife was an ordinary pocket one, of large size; and the blade measured three inches in length, by a little over a half inch in width, and was firmly fixed in the vertebral column at the sixth dorsal vertebra, with the cutting edge towards the left side; *i. e.*, the blade was in the left side of the body of the vertebra, with the edge outward. When I arrived the knife had been in the wound over an hour. I attempted to remove it, thinking it an easy matter; but, to my surprise, found that all the strength I could exert had no effect upon it, no matter in what direction the force was employed. After trying faithfully to remove it by traction, I made a crucial incision around the knife, and cut down to the bone, carefully dissecting back the flaps in such a way that the bone was clearly exposed, showing the blade to be embedded entirely in bone. I again tried every way that I could think of to pull it out, and again failed. I then called the strongest negro man on the place, and made him try his strength. He got over the patient, and I directed him to pull exactly in a line with the blade, while I put my knee over his hips, and at the same time required an assistant to hold his shoulders down; and notwithstanding he used strength enough to raise the patient entirely from the bed by the knife, yet it did not move at all. I tried every position for the patient I could imagine, and yet neither position nor strength seemed to affect it in any degree. I then sent for consultation, and instruments to chisel away a part of the bone. A physician soon arrived, and notwithstanding he tried his best, yet he failed. While waiting for the instruments I made one more effort, and, to my surprise, with scarcely any force, the knife suddenly came out. Perhaps, now, some one will suggest that it was caught between two of the vertebrae; yet we examined carefully to see if that could be the case, and could clearly make out the joints both above and below the knife; and besides, we could see it up to the hilt in the body of the bone, and nowhere else.

The wound was inflicted by a man standing directly in front of Kelly, with his right hand around his body under his (Kelly's) left arm. After the removal of the blade there was very little hemorrhage; and I immediately closed the wound and applied cold dressings, giving one-fourth of a grain of morphia. I continued the treatment for a few days, and had no bad results. There was no inflammation of any consequence, and no pneumonia or pleurisy. Sensation was somewhat impaired about the lumbar region for about two weeks, but there was no loss of motion. The patient made a good recovery, but died two years afterwards, in the penitentiary, of another trouble. The case is one so unusual that I have thought it might be of interest to the profession.

TWO CASES OF RUDIMENTARY UTERUS.

By SUSAN DIMOCK, M.D.,

RESIDENT PHYSICIAN TO THE NEW ENGLAND HOSPITAL FOR WOMEN AND CHILDREN.

Mrs. MARY W—, twenty years old, a tall, well-developed blonde, was sent to me by her family physician in autumn of 1872, to be operated upon, if advisable, for atresia vaginae. The patient had always been tolerably healthy as a girl, and had developed physically at the usual age; had, however, never menstruated, nor had the slightest molimina ever been felt. At the age of nineteen the patient married, remained well for six months, but was then seized with severe and frequent headaches, dizziness, want of appetite, and feeling of general debility. Under a tonic treatment these symptoms were alleviated, and when the patient consulted me three months later, she seemed well, with the exception of slight anæmia. Upon examination I found the external organs of generation normally developed, and the remains of the hymen existing as four or five caruncles. The vagina was one inch in length, and large enough to admit the end of the common bivalved speculum. Not the smallest opening was to be found in the vaginal walls. By introducing a catheter in the bladder and a finger in the rectum, the rudiment of the uterus was to be felt about an inch above the blind extremity of the vagina, measuring about one inch in length and one inch and a half in width at the fundus. The thickness at the fundus seemed little more than half an inch. The ovaries were not to be felt. Of course an operation here was out of the question, since, even were the difficulty of making an inch-long passage to the uterus overcome, the functions of menstruation and procreation would be impossible, the uterus being in so undeveloped a condition.

A few weeks after observing the above case, the following came under my care, which, independent of the anomaly in development, presents some points of interest:

Louisa B—, aged eight, a healthy little German Jewess, was brought to the N. E. Hospital for Women and Children, quite unable to stand or walk without screaming with pain. The parents stated that she had always been well until three days before, at which time, while playing with other children, she had tried how far she could stretch her feet apart. The next night she complained of great pain at the vulva, and the parents found a swelling there which they took for a prolapsed uterus. Indeed, upon a cursory examination this seemed to be the case, for protruding between the labia was a small tumor presenting the exact appearance of a congested cervix uteri. Upon etherization, however, this tumor was found to be a hypertrophied ring of mucous membrane around the orifice of the urethra. The hymen was found torn (from the strain at the time of injury?), the vagina of normal length and width, but presenting at its upper extremity a cul-de-sac without trace of uterus. With the catheter in the bladder and finger in the rectum a small thickened strand was to be felt above the vagina, barely larger than the united Fallopian tubes would be.*

The ring around the meatus having been very sensitive to the touch, I removed, drawing it out with dressing forceps, and cutting above with curved scissors.

*The uterus is formed not from the uro-genital sinus, but by the coalescence of Müller's ducts, the upper ends of which become the Fallopian tubes.—Weber, Walteyer, Frey, etc.

sors. The bleeding, which was for a moment profuse, was checked immediately by the actual cautery. The little patient felt very slight discomfort after the operation; during ten days she was placed in a warm sitz-bath to urinate, and at the end of two weeks, as she could walk without difficulty, and the wound had entirely healed, she was discharged.

Two cases of supposed occlusion of the vagina from defective development have lately been brought to me. Both proved to be the merely epithelial adhesion which is so frequent, and which gives way upon slight stretching with the probe or finger.

Progress of Medical Science.

TREATMENT OF ACNE ROSACEA.—In *The Practitioner* of July, Dr. W. B. Cheandle describes the difference between acne depending upon disease of the sebaceous glands and acne rosacea; showing that the latter is caused by relaxation of the vascular system of the diseased tissue. He believes that the proper method of treating the affection is to increase the tone, and produce contraction of the blood-vessels, and this, he thinks, can be accomplished by the use of the faradic current of electricity. Four cases are reported by him, all of which were more or less benefited. "In three of them the eruption had so far faded after treatment by this method for from two to three months, that the patients professed themselves sufficiently cured, and ceased to attend. The fourth case is still under observation. The patient has repeatedly appeared almost well, and has then ceased to attend for a time, returning with a relapse in the course of a few weeks, and always improving steadily on the application of the remedy." In these cases a current of medium intensity was applied for about ten minutes twice a week.

THE LIVER IN JAUNDICE.—Dr. J. Wickham Legg contributes some papers to the *British Med. Jour.*, in which he describes the changes in the liver which follow an obstruction to the flow of bile into the duodenum. These morbid appearances divide themselves into two heads: 1. The changes met with in the bile passages; 2. Those met with in the parenchyma of the liver itself. The first effect of an obstruction of the bile-ducts is a dilatation of the duct behind the obstruction; the gall-bladder, if the common duct be occluded, suffering first and becoming filled with dark viscid bile. If the gall-bladder be distended and the cystic duct become occluded by a gall-stone, for instance, the bile undergoes absorption, and its place is taken by a colorless fluid, which is either viscid or limpid, constituting the hydrops micæ fellie of the older writers. The extent of the general dilatation of the ducts, both within and without the substance of the liver, depends upon the degree of the obstruction, and the length of time it has lasted. In some cases the dilatation does not reach the interlobular ducts, and it is doubtful whether the capillary ducts ever become varicose. The left branches of the hepatic ducts have, in the cases Dr. Legg has examined, always been much more dilated than the right. The catarrh which is set up by the long-continued obstruction, sometimes goes on to suppuration of the duct, and a mixture of pus and mucus is found in the biliary canals. In another form multiple abscesses appear. In all cases of long-continued obstruction to the bile-ducts, the connective tissue grows, the overgrowth beginning a few hours after the obstruction. The chief change in the liver-cells

is atrophy, their contents seems to be chiefly fat, and a few pigment granules; the fat is rarely in large drops. Within a few days after complete obstruction to the gall-ducts, the liver ceases to secrete glycogen. The function of the secretion of the biliary acids is believed to be interfered with or abolished, but further evidence is required. The quantity of urea excreted by the kidneys has in several instances been quite normal. —*The Practitioner*.

AN EXPERIMENTAL OBSERVATION ON HAY FEVER.—*The Practitioner* for April has a letter from Prof. Binz, of Bonn, on this subject; and as the disease appears to be on the increase in this country, and is the cause, annually, of so much suffering, we reproduce the letter in full, hoping to receive the results of numerous experiments made with the remedy during the coming season:

"From what I have observed of recent English publications on the subject of hay fever, I am led to suppose that English authorities are inaccurately acquainted with the discovery by Professor Helmholtz, as far back as 1868, of the existence of uncommon low organisms in the nasal secretions in this complaint, and of the possibility of arresting their action by the local employment of quinine. I therefore purpose to republish the letter in which he originally announced these facts to myself, and to add some further observations on this topic. The letter is as follows: *

"I have suffered, as well as I can remember, since the year 1847, from the peculiar catarrh called by the English 'hay fever,' the speciality of which consists in its attacking its victims regularly in the hay season (myself between the 20th May and the end of June), that it ceases in the cooler weather, but on the other hand quickly reaches a great intensity if the patients expose themselves to heat and sunshine. An extraordinarily violent sneezing then sets in, and a strongly corrosive thin discharge, with which much epithelium is thrown off. This increases, after a few hours, to a painful inflammation of the mucous membrane, and of the outside of the nose, and excites fever with severe headache and great depression, if the patient cannot withdraw himself from the heat and sunshine. In a cool room, however, these symptoms vanish as quickly as they had come on, and there then only remains for a few days a lessened discharge and soreness, as if caused by the loss of epithelium. I remark, by the way, that in all my other years I had very little tendency to catarrh or catching cold, while the hay fever has never failed during the twenty-one years of which I have spoken, and has never attacked me earlier or later in the year than the times named. The condition is extremely troublesome, and increases, if one is obliged to be much exposed to the sun, to an excessively severe malady.

"The curious dependence of the disease on the season of the year, suggested to me the thought that organisms might be the origin of the mischief. In examining the secretions I regularly found, in the last five years, certain vibrio-like bodies in it, which at other times I could not observe in my nasal secretion.

"They are very small and can only be recognized with the immersion-lens of a very good Hartnack's microscope. It is characteristic of the common isolated single joints, that they contain four nuclei in a row, of which two pairs are more closely united. The length of the joints is 0.004 of a millimetre. Upon the warm objective stage they move with moderate activity, partly in mere vibration, partly in shooting backwards and forwards in the direction of their

* Cf. Virchow's Archiv., vol. xlvii., p. 100.

long axis; in lower temperatures they are very inactive. Occasionally one finds them arranged in rows upon each other or in branching series. Observed some days in the moist chamber, they vegetated again, and appeared somewhat larger and more conspicuous than immediately after their excretion. It is to be noted that only that kind of secretion contains them which is expelled by violent sneezing; that which drops slowly does not contain them at all. They stick tenaciously enough in the lower cavities and recesses of the nose.

"When I saw your first notice of the poisonous action of quinine upon infusoria, I determined at once to make an experiment with that substance, thinking that these vibronic bodies, even if they did not cause the whole illness, still could render it much more unpleasant through their movements and the decomposition caused by them. For that reason I made a neutral solution of sulphate of quinine, which did not contain much of the salt (1.800), but still was effective enough, and caused moderate irritation on the mucous membrane of the nose. I then lay flat on my back, keeping my head very low, and poured with a pipette about four cubic centimetres into both nostrils. Then I turned my head about, in order to let the liquid flow in all directions.

"The desired effect was obtained immediately, and remained for some hours; I could expose myself to the sun without fits of sneezing and the other disagreeable symptoms coming on. It was sufficient to repeat the treatment three times a day, even under the most unfavorable circumstances, in order to keep myself quite free.* There were then no such vibrios in the secretion. If I only go out in the evening, it suffices to inject the quinine once a day, just before going. After continuing this treatment for some days the symptoms disappear completely, but if I leave off they return till towards the end of June.

"My first experiments with quinine date from the summer of 1867; this year (1868), I began at once as soon as the first traces of the illness appeared, and I have thus been able to stop its development completely. I have hesitated as yet in publishing the matter, because I have found no other patient† on whom I could try the experiment. There is, it seems to me, no doubt, considering the extraordinary regularity in the recurrence and course of the illness, that quinine had here a most quick and decided effect. And this, again, makes my hypothesis very probable, that the vibrios, even if being no specific form but a very frequent one, are at least the cause of the rapid increase of the symptoms in warm air, as heat excites them to lively action.'

"I should be very glad if the above lines would induce medical men in England—the haunt of hay fever—to test the observation of Helmholtz. To most patients the application with the pipette may be too difficult or impossible; I have therefore already suggested the use of Weber's very simple but effective nose douche. Also it will be advisable to employ the solution of quinine *tepid*. It can, further, not be repeated often enough, that quinine is frequently adulterated, especially with cinchona, the action of which is much less to be depended upon.

"Dr. Frickhöfer, of Schwabach, has communicated to me a second case in which hay fever was cured by local application of quinine (cf. Virchow's Archiv.

[1870], vol. 51, p. 176). Professor Busch, of Bonn, authorizes me to say that he has succeeded in two cases of 'catarrhus astivus,' by the same method; a third patient was obliged to abstain from the use of quinine, as it produced an unbearable irritation of the sensible nerves of the nose. In the autumn of 1872 Helmholtz told me that his hay fever was quite cured, and that in the meantime two other patients had, by his advice, tried this method, and with the same success."

TREATMENT OF SERO-SANGUINEOUS CYSTS BY ELECTRICITY.—Dr. A. Amussat says: "We often meet with cysts on the anterior part of the neck, developed either in the thyroid gland, the ganglions, or the connective tissue.

"When these tumors are small they are merely unsightly; but as they increase in size they interfere with deglutition and respiration, they force the patient to carry the head either to one side or forward, and they usually cause a habitual congestion by their pressure upon the vessels of this region. Their contents vary, but they generally consist of serum either alone or mixed with blood, or of pure blood. Their inconvenience obliges the patient sooner or later to seek a cure, and they are usually treated by incision, excision, extirpation, injections of iodine, etc. Celsus recommended cauterization, and I treated a case successfully by this method in 1852.

"Four years ago, having been consulted for a sero-sanguineous cyst of the neck, I cured it by galvanocautery, as will be seen in the following observation:

"Oct. 8, 1869.—In consultation with Dr. Morpain, I saw M. S., aged 69 years, who had a tumor on the right side of the neck. I found a fluctuating and indolent tumor, extending from the inferior angle of the lower jaw to the sternum. The patient had first noticed it about eleven years before.

"Thinking that it was a sero-sanguineous cyst, I punctured it with an exploring trocar, and drew off about half a pint of chocolate-colored fluid. We then agreed to leave it until it should fill up again, when we would endeavor to cure it by galvanocautery.

"Dec. 3.—I punctured the tumor with an exploring trocar just above the sternal end of the clavicle, and directing the point obliquely upward and backwards I brought it out behind the angle of the lower jaw. I then withdrew the stylet, and passed a platinum wire through the canula, and securing the ends of the wire, I drew the canula back until its extremity was in the cyst, the contents of which I evacuated, after which I withdrew the canula. Then, connecting the wire with a battery, I thoroughly cauterized the cyst, bending the wire so as to reach every portion of the walls. The operation terminated, I applied poultices to the neck, at first cold, afterwards warm. The patient was not confined to his bed, and made no change in his diet.

"January 7, 1870.—I withdrew the wire, and dressed the orifices with simple cerate; by the end of April the orifices had completely cicatrized, and the patient was cured. I saw him six months afterwards, and could find no other trace of the tumor than the two small cicatrices.

"In 1860 Dr. Otterbourg requested me to examine a lady twenty-four years of age, with a tumor on the left side of the neck, which had been treated for several months with discutients without amelioration.

"Upon examination I found a cyst the size of a walnut, situated over the course of the carotid, the pulsations of which could be distinctly felt through it.

"Madame S. dated the development of the tumor back to a labor three years before.

* There is no foundation for the objection that syringing the nose could not cure the asthma which accompanies hay fever; for this asthma is only the reflex effect arising from the irritation of the nose.—B.

† Helmholtz, now Professor of Physics at the University of Berlin, is, although M.D., no medical practitioner.—B.

"Being quite a belle, she refused to allow any operation which would be likely to leave a visible cicatrix.

"My associate was of the opinion that we had better puncture the tumor, and after drawing off its contents, inject it with tincture of iodine, but the volume of the tumor, and more especially its situation over the artery, determined me to propose electrolysis, which was accepted.

"Every other day I introduced into the tumor two fine steel needles, which I connected with a small-sized Bunsen's pile during five minutes. When the patient was able to support this without inconvenience I used a larger pile, and by the third séance I employed one twenty-one centimetres in height. After a time, in order to hasten the reduction of the tumor, I applied tincture of iodine between each séance. After forty-five applications of electricity, Madame S. was so well satisfied with the result that she gave up the electricity, but continued the application of tincture of iodine. I heard from Dr. Otterbourg some time afterwards that she was completely cured.

"These two are the only cysts of the neck that I have treated by electricity. The first was cured by galvanocautery alone, the second by electrolysis in connection with tincture of iodine, which latter, after a while, sufficed alone to complete the cure; but as it had been employed before using electrolysis without any result, and as the size of the tumor was considerably diminished by the electricity before recommencing the use of iodine, I believe that a complete cure would have resulted from the use of electrolysis, if it had been kept up long enough.

"With regard to the first case, if I should have a similar case again, I would withdraw the platinum wire immediately after the operation, in order to abridge the duration of the treatment."

Reports of Hospitals.

BELLEVUE HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

SECOND SURGICAL DIVISION—DR. SHAW, HOUSE-SURGEON.

SILICATE OF LIME SPLINT.

This splint is obtained by using a saturated solution of chloride of lime and the silicate of soda. It is supposed that a chemical decomposition occurs between the two articles, which gives rise to silicate of lime. The apparatus is made in the following manner. First apply a bandage which has been soaked in the solution of lime and then squeezed very nearly dry. Next give the bandage applied a coating of silicate of soda. Then apply another bandage wet in the lime solution and follow it with a coating of the soda. Thus go on until the requisite number of bandages are applied. The splint when dry is much harder than the silicate of soda splint. It is much lighter than a plaster splint.

PENETRATING WOUND OF THE ABDOMEN.

A wound of this sort was just above the crest of the ilium upon the left side, and was inflicted with a knife. The patient was being kept fully under the influence of opium. Respirations were retained at twelve to fourteen per minute. In this manner the peritonitis was held in abeyance, and at this writing the patient is doing very well.

CUT THROAT.

The arytenoid cartilages were exposed in a case of cut throat. Like cut throats in general, he was willing to comply with any requirement which would facilitate recovery. The wound was healing by granulations.

SURGICAL DRESSING.

A case which we saw was one in which amputation had been performed. The dressing is a valuable one for all similar granulating surfaces.

R. Basilicon ointment..... $\frac{3}{4}$ i.

Balsam of Peru..... $\frac{3}{4}$ i.

M.

Apply, spread upon lint.

BURNS.

One case of burns was being treated by giving the parts a coating of mucilage of gum arabic and dusting it over with powdered lycopodium. This was reapplied as soon as any of the covering fell off.

Another case was being treated with a solution of nitrate of silver grs. xx. to the ounce of water. Much stronger solutions, as forty or sixty grs. to the ounce, are sometimes employed. The burn was dressed, but the wound had filled up with granulations to something more than a level. Apply the solution with a camel-hair brush, and leave the surface exposed to the influence of light and air. The solution is renewed whenever fissures occur in the coating thus formed. The application does not cause much pain.

WOUND IN THE PRECORDIAL REGION.

The wound was inflicted by a pistol ball. There were extensive pericardial and pleuritic effusions.

Treatment supporting and quieting.

Prognosis grave.

LACERATING WOUND INVOLVING THE KNEE-JOINT.

A boy had been run over by a street car. The tissues about the joint were extensively torn and the joint opened. The inflammatory action had been combated by means of rest, ice, leeches, etc., and recovery had been so far established that the knee was being strapped with adhesive plaster. It was doing exceedingly well.

ACUTE SYNOVITIS.

The synovitis involved the elbow-joint. The limb was in a jointed splint which could be regulated by means of a key so that any angle desired could be maintained. In this way perfect rest could be secured. The patient was also kept in bed. Rest, leeches, and ice were the chief elements in treatment.

THIRD MEDICAL DIVISION—DR. YOUNG, HOUSE-PHYSICIAN.

PNEUMO-HYDROTHORAX.

When the patient was admitted to the hospital she was in a typhoid condition, and had pneumonia affecting the lower lobe of the right lung. By dint of the free use of stimulants, quinine, good nourishment and nursing, she gradually improved. Eight days after admission the temperature fell and her general condition was very much improved. About one week after the disappearance of all her typhoid symptoms, the temperature suddenly became elevated 3° or 4° without any apparent cause. The next day it fell again, and then for four or five days an irregular temperature was present which could not be accounted for. About a week after this, evidences were

obtained of the presence of fluid in the right pleural cavity. The fluid gradually increased, and soon reached as high as the angle of the scapula. The introduction of an exploring needle determined that the fluid was pus. The aspirator was employed and forty-four ounces of pus removed. The general condition of the patient was very much improved. The morning following the use of the aspirator, there were evidences of lung expansion. About a week afterwards, succussion was obtained. The aspirator was used a second time, and sixty-four ounces of extremely fetid dark brown pus were removed. The patient was now doing badly.

A free incision was made through the chest-wall in the sixth intercostal space, and several ounces of fetid pus removed. Since that time, the cavity has been washed out daily with a weak solution of carbolic acid. Since the free incision was made, all her symptoms, both constitutional and local, have improved in a most remarkable manner. The noticeable features of the case are the recovery from the pneumonia; the pleurisy becoming the leading feature in her case while in a debilitated condition, consequently an empyema from the beginning; the marked benefit she received from the first aspiration; the marked retrogression as soon as air entered the pleural cavity; and the very marked improvement that followed the free incision. It was remarked by the visiting physician that, as soon as air enters the pleural cavity, causing the pus to become fetid, aspiration is unavailable, and the free incision should be resorted to at once.

PYO-NEPHROSIS AND ASPIRATION.

A case of this sort was interesting in one feature at least. The patient was a man aged 36 years. About one year and a half ago he first noticed a tumor in the left lumbar region which had steadily increased in size until admission to the hospital. He has never suffered from pain during its development. Bowels have, as a rule, been very regular. Has had no chills or elevation of temperature. There is an imperfect history of an attack of venal colic occurring several years ago. Has never had any special disturbance with the urine until about a year ago, when he first began to notice that it was somewhat turbid and of a whitish color.

Physical examination revealed the presence of a tumor of considerable size, flatness upon percussion extending from near the median line in front to the spinal column. There was a finger's-breadth of tympanic percussion between the upper border of the tumor and the lower border of the spleen. There was scarcely any doubt but that it was a tumor of some kind connected with the kidney. By exclusion the diagnosis was reduced to three possibilities. Pyonephrosis, hydro-nephrosis, and hydatids.

It was determined to make an explorative puncture for purposes of diagnosis. The needle of the aspirator was introduced at the point where the tumor seemed nearest to the surface, and $\frac{3}{4}$ xij. of pus were withdrawn.

It was remarked by the visiting physician that no hesitation need be made with regard to introducing the needle at any point that best suited the convenience of the operator, without special regard to peritonum or intestines. If a coil of intestine should be punctured the perforation would in all probability prove harmless. Removal of the kidney was suggested. Simple removal of the pus is not curative. One week later, no particular change in the condition of the patient.

THE DIFFICULTIES IN DIAGNOSIS OF ABDOMINAL DISEASE, WITH PAIN AND CRAMPS AS THE ONLY SYMPTOMS.

PATIENT admitted March 7th, and had been sick one week previous to his admission. Night watchman; moderate drinker.

On Saturday, one week before admission, he got his feet wet. Went to bed Saturday night and soon after was taken with "pain and cramps in his bowels." These lasted all night. Sunday morning he took a couple of drinks of brandy and Jamaica ginger which gave some relief, but not marked. Was about more or less during Sunday and Monday forenoon. Pains continued, but less severe. Monday afternoon was obliged to go to bed, and remained in bed until Wednesday; then sat up an hour or so; afterwards went to bed, and remained until Friday. During all this time he remained in bed on account of the pain. If he drank anything he would immediately vomit, and the material vomited was of a greenish color. Took physic on Monday and Tuesday, but bowels did not move afterwards during the time he was sick previous to admission. Physic worked very well. When the physic operated some fresh blood was passed, and the discharges were accompanied with some smarting and burning pain at the lower portion of the bowels. No hemorrhoids.

Two years ago he suffered from a similar attack, and was unable for three months after his discharge from the hospital to lift any weight, or bear percussion or pressure over the right side of the abdomen. The attack at that time lasted about eight weeks, during which he suffered more or less from pain in the bowels. Recovery was apparently complete, although convalescence was somewhat prolonged. Since that time he has been well until the present attack. Bowels are usually constipated, moving only with the assistance of medicine. Bowels were constipated at the time of the occurrence of the present attack. No history of lead-poisoning. Pulse 70. Temperature normal.

Physical Examination.—Abdomen a little full and muscles triflingly rigid. Slight tenderness upon pressure; more particularly upon the right side of the abdomen in the region of the cæcum. There is little more fullness upon the right side than upon the left. Percussion gives considerable pain upon right side. Has improved markedly since admission. The pain from which he has suffered has been colicky in character, rather than like the characteristic pain of peritonitis. There was no dullness upon percussion at any point. Such was the history. What was the diagnosis? What was the thing sought for?

Sympathy between the large intestines and stomach being more marked than between small intestines and stomach, would direct attention to the large intestine in search of an explanation for the vomiting. Was the trouble obstructive or inflammatory? If a localized peritonitis continuing for some time, could the patient be able to travel about? It was thought by one of the visiting physicians that he might. The pains were colicky. What was the cause of the colic? Perhaps some impaction of feces in the ascending colon, producing obstruction. Obstruction may also be due to some old peritoneal adhesions. Colic dependent upon constipation does not as a rule last a week at a time. Was it typhlitis, or was it perityphlitis? It was concluded that the case was one which required careful watching. In the present condition the essential feature in the treatment was rest, for with rest the patient was comparatively comfortable.

ANTHRAX.

In a vast majority of cases crucial incision and caustic applications are injurious. A very simple and efficient method of management is to take a broad piece of spongio-piline, cut a hole through it large enough to receive the apex of the tumor, apply it, and let the anthrax itself alone. This method of treatment is sufficiently simple to secure for itself some ridicule, "but try it," says one of the visiting surgeons, "and you will be surprised at results."

ABSCESS OF THE LIVER.

A case of abscess had opened externally. The patient had had another abscess of the liver, which had discharged into the colon. Under the treatment adopted, the case was progressing very favorably. The treatment was, first, to inject the sac with a solution consisting of equal parts of water and tincture of iodine. This was continued every two or three days for some time; but now the injection, having been gradually increased in strength, is composed of pure tincture of iodine. What the termination will be cannot be safely predicted, but the progress of the case is thus far very satisfactory. The abscess has diminished in size very markedly since the commencement of this plan of treatment.

PENETRATING WOUND OF THE CHEST.

A patient was stabbed with a knife; and had not expectorated blood. It is not proper, however, to infer from this that the lung has not been wounded. A number of days sometimes elapse before blood is coughed up. Ordinarily, patients with wounded lungs expectorate blood at once.

Absence of expectoration for forty-eight hours after the receipt of the wound is not evidence that the lung has escaped injury. Neither is the entire absence of expectoration absolute proof in that direction.

POTT'S FRACTURE.

In Pott's fracture, and also any fracture about the lower extremity of the tibia, the point of interest is whether the internal lateral ligament is torn open or not.

If the internal lateral ligament remains unruptured there will be no deformity with almost any plan of treatment; but if the internal lateral ligament is ruptured, with almost any form of treatment that can be devised there will be deformity. Ruptured ligaments are never completely restored. Patients with this condition of things are always informed at the commencement of treatment what they may expect.

WHAT WOULD BE A CORRECT DIAGNOSIS?

Patient æt. 18. Male. Irish. Previously healthy until March 15. "Taken with pain in the head while in church. Soon got very cold; got very hot afterwards." Chill lasted less than an hour. Fever continued until admission. Vomiting came on after the fever. Vomited occasionally, and that without taking anything into the stomach. Pain in the left side. Dry cough. Since admission, which was upon the 17th, cough has continued, and has been accompanied with some thick, yellowish expectoration. There has not been any characteristic expectoration of croupous pneumonia. No blood expectorated. When admitted he had a temperature of $106\frac{1}{2}^{\circ}$.

March 18. P. 120; R. 36; T. $104\frac{1}{2}$. Evening, P. 112; R. 38; T. $101\frac{1}{2}$; March 19. P. 116; R. 48; T. $104\frac{1}{2}$. Evening, P. 108; R. 28; T. $102\frac{1}{2}$; March 20. P. 116; R. 32; T. $103\frac{1}{2}$. From this time T. was $104\frac{1}{2}$, $105\frac{1}{2}$,

$102\frac{1}{2}$, and March 23, $104\frac{1}{2}$; March 24, morning, $98\frac{1}{2}$; P. 94; R. 32. Pulse, 24th, soft and easily compressed. Skin moist. Sordes upon teeth. Vomiting has continued to some extent since admission. Urine negative.

Physical Examination, March 24th.—Vocal fremitus somewhat more marked upon right than upon left side of chest. Percussion gives slight dullness over scapular region. Posteriorly, bronchial respiration over the scapula, and not heard at any other point. Large moist râles over middle portion of left lung.

Anteriorly, slight dullness over middle portion, left side. Râles as found behind, but less distinct.

There was no history of bronchitis existing early in the case.

Temperature has not followed the ordinary course of croupous pneumonia. "What's the matter?" The visiting physician was in some doubt. Meanwhile the boy had been receiving a liberal supply of quinine and stimulants; nourishment; application of cold compresses to the chest, and rapidly changed while his temperature was so high. The chances were very much in favor of his recovery.

ARREST OF BILIARY SECRETIONS AND NO DIAGNOSIS.

Male, 40 years of age. Sailor. Temperate. "Been sick 18 months, and has been yellow 18 months." Pain in the infra-mammary region upon the *left* side. Has not suffered from pain at any other point. No vomiting at any time. Urine, red; and passages from bowels clay-colored.

Physical Examination.—Body well nourished. Jaundice of a quite bright yellow color all over the body. Abdomen slightly more prominent above the umbilicus than normal. Veins upon the abdomen not enlarged. The liver was found to be uniformly enlarged, but the increase in size extended *upwards* and laterally only. No tenderness upon pressure over the region of the gall-duets. Nothing in the history of the case that would indicate that gall-stones had ever been passed. Poorly defined *specific* history. Spleen considerably enlarged. Has never lived in a malarial district, or had malarial fever in any form. No abdominal tumor could be detected. There was no effusion into either pleural cavity. What was the cause of the enlargement of the liver, and what was the cause of the jaundice? The case was not a plain one.

SUBACUTE PLEURISY, WITH ALMOST COMPLETE ABSENCE OF RATIONAL SYMPTOMS.

The patient was a young man 20 years of age, who had worked in a printing-office *ten* hours a day. Had been sick five weeks. Taken with a chill, and was obliged to go to bed. Suffered no pain. Had cough which gradually increased, and about one week after his attack he expectorated a yellowish-looking material. Never expectorated blood or rusty sputa. *Never had a pain in the side.* This was the entire history of the case so far as rational symptoms were concerned. Physical examination revealed the fact that one pleural cavity was *two-thirds filled with fluid*. The fluid was disappearing rapidly under treatment, without the use of the aspirator. He was receiving tonics and good food.

It was remarked that there are two conditions in connection with subacute pleurisy in which the effusion is not likely to be absorbed. First, when a large amount of plastic material is poured out. Second, whenever the cavity is distended. In these conditions the absorbents are not in a condition to carry off the products of inflammation. In such cases the aspirator is of service.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, August 15, 1874.

HOSPITAL APPOINTMENTS.

THE resolutions adopted at a recent meeting of the Commissioners of Charities and Correction, which we publish in another column, will be read with interest by every one who has given the subject of hospital appointments any consideration. It is well known that the abuses connected with the old system of appointing members of the medical board have been very great. The gaining of a position has been, in fact, so much more a question of college or political influence, that it has been the exception rather than the rule for any professional man to be successful on the basis of merit alone. How the proposed changes in the appointments in Bellevue Hospital are calculated to correct the evils of which the profession as a body has so long complained, remains to be seen.

After the first of September the medical board is to consist of but eight members, who shall have the power of nominating thirty-three professional men of good reputation and ability, from which number the Commissioners shall select eleven additional members. The new board of eight is so constituted as to give no particular medical college any advantage, there being two members from each, while the other two are not representatives of any school. It is the declared intention of the Commissioners to maintain the ratio of the respective representation of professors and non-professors as already made in the new board.

While it is true that a great deal of political pressure has been brought to bear upon the appointing power, school influences have after all carried the day. Bellevue Hospital is not only a great field for practice, but offers the best means for clinical instruction to be found on this side of the Atlantic. It was perfectly natural for each medical college, by what has been technically called honest rivalry, to strive after the greatest number of positions for their respective

clinical teachers. The struggle has always been a hard one, to adjust what each institution claimed to be its right; and very often, to preserve that harmony which is so proverbial among medical men who have only the interest of the profession at stake, many compromises had to be made which were hardly in keeping with the professional dignity of unselfish persons. The principle involved, of promoting the great cause of clinical teaching in our schools, was such a laudable one, that the profession at large at once signified its willingness to leave the whole matter in the hands of the professors, and few if any "outsiders" interfered in the struggle for position.

Keeping a virtuous eye upon this principle, and fighting manfully for its maintenance by the ordinary chances of luck and grace, one school gained the ascendancy, whereupon the others, not believing in the "survival of the fittest," became discontented, and in retaliation rather ignominiously dropped the standard of principles and fought for men. The school which had gained the vantage ground had, however, committed itself too strongly to the grand issues of the contest to yield, and has nobly maintained its position in spite of all those who envied the number of its students, or its many clinical advantages.

The profession all the time took such an abiding interest in the exercise of this laudable and generous rivalry for the cause of science and the progress of clinical teaching, that it merely looked upon the successful school as the humble instrument of such grand results. We are, in fact, free to interpret this sentiment of the profession as a triumphant vindication of the importance of clinical teaching in all medical schools.

The Commissioners have now, however, determined to alter the condition of things so far as to give all the colleges equal rights, and let us hope that the great cause of clinical teaching will not suffer thereby. As far as the student is concerned, the same amount of clinical teaching will be dispensed; the only trouble that can possibly arise will be the lack of power and opportunity for any one college which may offer the greatest facilities for clinical teaching in the hospital to perform that part of its contract. The student who has a fancy to receive clinical instruction only from his professors will be the real sufferer. But some one must suffer when radical reforms are initiated, and why cannot the student take his share with the rest? If any greater wrongs are intended, we must console ourselves by shifting the responsibility of the changes upon the powers that willed them.

The provision which necessitates a division in classes of different periods of service is a wise one, and will tend to keep up a healthy rotation in office, at the same time obviating the necessity of compelling useless and fossilised members to resign.

Whenever any vacancy shall occur in the board, it shall be the duty to advertise the fact in the different

medical journals, so that all who may desire to become applicants may do so. We have repeatedly advised this measure as the one which would give the best possible chance for an honorable competition for a position. Heretofore every vacancy has been filled before its existence was generally known. Now every one will have an opportunity of putting in his respective claims in time to take the ordinary chances.

The rule that the service of each member of the medical board shall be continuous throughout the year will have a tendency to divide the labor equally, but will doubtless cause some inconvenience to those of our college teachers who only care to attend to their wards when the students are in town.

As a whole, the proposed changes are reasonably good ones, and the show of justice in making the appointments, leaving the nominations to the profession as represented in the new board, etc., entitles the new plan to our best wishes for its success.

CASES OF POISONING.

THE recent cases of poisoning in East 32d street, although stripped of the sensationalism which at first hung upon the possibility of poison in pickles, nevertheless carry with them a very suggestive and timely lesson. Two female servants and a male companion partake of pickles from a jar which had been left open, are all seized with the same symptoms of poisoning, and all die rather suddenly. On investigation by the coroner's jury it is found that real cause of death was the plentiful and accidental admixture of Paris green in the jar aforesaid, the pigment having been strewn upon the shelves of the closet for the purpose of destroying the cockroaches which infested the apartment. When we consider how frequently this particular article is used for this purpose, it is a wonder that a similar accident has not happened before. Those who use it for vermin hardly ever consider the possibility of being victimized themselves. Strychnine, arsenic, Paris green, and many other deadly poisons are used about our cupboards with a recklessness that is truly appalling, especially when we consider the many chances of having the poison season every article of food upon our table.

MR. ERICHSEN.—The *Phila. Med. Times* says that a letter has been received in that city which announces an expected visit of Mr. Erichsen to this country. He leaves England on the 30th of July, and after spending a few weeks in Canada, where he has friends and connections, will come to the United States. The *Med. Times* promises him, with good reason, a hearty reception by his professional brethren in this country.

PROF. JAMES P. WHITE, OF BUFFALO, N. Y.—At a stated meeting of the New York Academy of Medicine, Prof. James P. White, of Buffalo University, was unanimously elected an Honorary Fellow.

Reviews and Notices of Books.

THE PHYSICIAN'S DOSE AND SYMPTOM BOOK. By JOS. H. WYTHES, A.M., M.D. Eleventh edition, revised. Philadelphia: Lindsay & Blakiston.

THIS *vade-mecum* contains much useful information for the student and practitioner of medicine. The arrangement of its contents is such that if one desires to refresh the memory relative to doses of remedies and pharmaceutical preparations, he can do so satisfactorily without being obliged to consult more elaborate works. It is a sort of therapeutical remembrancer. Its value, however, might be very much enhanced if the author would carefully revise and correct the chapters containing an index of diseases and treatment, and also the chapter upon symptomatology. The measures recommended for adoption under the head of treatment are in many cases more antiquated than is necessary. The treatment of uræmia, apoplexy, uterine diseases, chronic nephritis, whooping-cough, and pneumonia, might be revised with profit.

If, under the head of symptomatology, the author believes that sibilant and sonorous râles are produced by "modified calibre of air-cells," of course he should stand to it; but if he knows the generally accepted opinion is opposed to the idea that they are produced in that manner, and it is that opinion which he wishes to present, those lines should undergo another revision. In the twelfth edition, revised, corrections will be looked for, which will add much to the value and appearance of this estimable little book.

LECTURES ON THE CLINICAL USES OF ELECTRICITY. By J. RUSSELL REYNOLDS, M.D., F.R.S. Second edition. Philadelphia: Lindsay & Blakiston.

THE acknowledged value of this little book has not been depreciated by the appearance of the second edition. The identity of the work is retained. The revision consists chiefly in the addition of such practical conclusions as have been arrived at by the author since the first edition was issued. The book itself is sufficiently elementary to be adapted to students' use, and sufficiently theoretical and practical to meet the wants of the average practitioner. It was not the design of the author to give an exhaustive treatise upon the subject of electricity as connected with medicine, and he has succeeded in retaining his writings within the bounds prescribed for them at the outset. At the beginning a salutary warning is given, both to students and practitioners; namely, do not over-estimate the power of electricity in the diagnosis and treatment of disease.

It is well known that, to a very great extent at least, the use of electricity in the treatment of disease is empirical. Recitation of attenuated theories are therefore uninteresting to one who simply wishes a guide for its use. This book is a very good guide, in the application of electricity for diagnostic and therapeutic purposes, for those who are, either from lack of disposition or from lack of opportunity, ignorant regarding the method of its action or the theories relating thereto.

MANUAL OF TOXICOLOGY. By JOHN J. REESE, M.D. Published by J. B. Lippincott & Co. Philadelphia. 1874.

THIS is certainly a useful and practical book; its various chapters are systematically arranged, and the subject-matter generally well handled. The style is clear, and well adapted to instruct the student, and the

physician as well. It is a good book for reference in all matters where poison is to be demonstrated in medico-legal cases, and contains many useful and important hints and directions for this purpose. Some chapters are fuller and more exhaustively treated than others. Thus Chapter VI., on Compound Poisoning and Antagonism of Poisons, is quite imperfect; many antagonistic poisons are not mentioned at all. In the following chapters a résumé is given of information on the subject of poisoning already published before in some of the standard works on medical jurisprudence. The administration and action of toxic agents forms the better part of the book; but we regret it is not complete. We miss a description of many of these toxic agents, such as thallium, barium, iridium, argentinum, rubidium, and others. He does not tell us anything of the action of irrespirable gases upon the human system, and the mode of detecting the action of such gases after death.

Dr. Reese ought to have boldly ventured out of the old trodden paths, and might have given to the world the results of spectral analytical research, which would have been a real desideratum. To ignore the diagnostic importance of spectral analytical examination, was, in our opinion, a great mistake, and we regret that he has thrown away a golden opportunity. This regret is so much more sincere, because we think the book has otherwise undeniable merits, and might have been made a standard work by furnishing to his readers the rich material accumulated and still unpublished upon this subject.

ON THE QUESTION OF THE TRANSMISSION OF SYPHILITIC CONTAGION IN THE RITE OF CIRCUMCISION. By R. W. TAYLOR, M.D., etc. New York: D. Appleton & Co. 1873.

This work embodies the facts ascertained, and the conclusions arrived at, in the author's investigation of four cases in which the Jewish rite of circumcision was followed by diseased manifestations very closely resembling, to say the least, those of syphilis.

The investigation was undertaken by Dr. Taylor at the request of the Board of Health, and we may here remark that sanitary boards would do well to adopt more generally, as was done in this instance, the course of committing inquiries of a special and unusual nature to those most competent to conduct them, even if they do not happen to occupy official positions.

Four Jewish children, previously healthy, were, after circumcision, attacked with ulcerations of the penis, followed by lesions of the skin and the lymphatic ganglia, and ending, in three of the four cases, in death from gradual exhaustion. Curiously enough, the surviving child was the only one of the four considered by Dr. Taylor as bearing satisfactory evidence of syphilis. In this child the circumcision wound healed kindly; but, at the end of two months, ulceration of the scar occurred, preceded by induration of the inguinal glands. It was considered probable, also, that the characteristic induration, which was observed to involve three-fourths of the whole line of incision, originated prior to the ulceration. Nine months after the circumcision the child was found to be in good general condition, but presenting a well-marked papular syphilide over the trunk, arms, and thighs, in the stage of decline. In each groin there was a sinus communicating with inflamed ganglia. The posterior cervical glands were enlarged. The condition of the epitrochlear glands was not ascertained. Three months later the papules had nearly disappeared, leaving small, slightly pigmented, desquamating spots, and had been replaced by a more pronounced rash on nearly the same

sites. The child's general health continued good. Reasoning by analogy from the course of development of the initial lesion in children, in other portions of the body, Dr. Taylor concluded that in this case the syphilitic process, either by erosion, ulceration, or induration, developed itself within a fortnight after contagion.

In the three other children, ulceration of the circumcision scar occurred early, in one case destroying nearly the whole penis, and in the two others, followed by suppuration in the groins and elsewhere. In one of the cases eczema of the penis afterwards occurred, and in another, a syphilitic eruption was said to have shown itself, but details were not ascertained in regard to it.

Unable to look upon these three cases as syphilitic, Dr. Taylor passes in review the suggestions that they might have been due to chancroidal or diphtheritic contagion, which he considers not to be warranted by the facts, but rather inclines to attribute them, not to mere uncleanness, but to a local tissue change, allied to the disease called *nomma*, and due indirectly to uncleanness.

The circumcisor was an aged Jew, who, while not a physician, or even a professed peritomist, appears to have often officiated on like occasions. It does not appear that in these cases he sucked the wound, as is often done among the lower class of Jews, but it seems probable that he squirted a styptic fluid upon it from his mouth, a practice little less hazardous. The old man submitted readily to the most searching examination of his person, and answered questions with perfect frankness and apparent truthfulness. Dr. Taylor found no evidence of his being syphilitic, particularly no lesions in his mouth. His instruments appeared cleanly and in good order; and he stated that it was not his custom to circumcise more than one child at a sitting, except in case of twins.

There was no evidence of syphilis having been subsequently engrafted on the first child, either by the libidinous conduct of a syphilitic female or by the application of soiled dressings or caustic.

Dr. Taylor considers that the trouble in these cases was due to the circumcision, notwithstanding the unusual duration of the period of incubation of the chancre in the first child; and while admitting the generally negative character of the conclusions arrived at, justly expresses his satisfaction at being able to make such an important addition to the scanty casuistics of inoculated infantile syphilis originating on the genitals.

Dr. Taylor sums up as follows:

1. That in the Jewish rite of circumcision there is a possibility of the occurrence of syphilis.
2. That the contagion is most likely to be communicated in the act of sucking the wound, the mouth containing a styptic liquid, and that, perhaps, it may occur by means of instruments soiled by syphilitic blood.
3. That the chances of such contagion are rendered greater by the performance of the operation by irresponsible, non-professional persons.
4. That the operation of sucking should be wholly abolished; and that, if a styptic solution of any kind is used, it should be poured from a vessel on the wound, rather than squirted upon it from the mouth of the operator.
5. That in no instance should two or more children be thus operated on consecutively without a thorough cleansing of the instruments and utensils used after each operation, and that in every instance the greatest care should be taken in cleansing the instruments.

6. That the performance of the rite should be absolutely confined to responsible and educated persons—either a physician alone being selected, or a physician assisting an officiating rabbi, or a circumciser of recognized merit.

7. That, under these circumstances, accidents of any kind are reduced to a minimum.

THE MEDICAL REGISTER OF NEW YORK, NEW JERSEY, AND CONNECTICUT, FOR THE YEAR COMMENCING JUNE 1, 1874. Published under the Supervision of the New York Historical Society. ALFRED E. M. PURDY, M.D., Editor. New York: W. Wood & Co. 1874. 12mo, pp. 402.

EACH year, as this annual makes its way to our table, we congratulate ourselves on its continued success. The present volume (xii.) is equal in all respects to its predecessors. This is saying all we can for its excellence; in fact we are, after a careful perusal of its contents, unable to offer any suggestions to improve its present indispensability. It contains everything necessary to make it a complete medical directory of the profession of New York and vicinity.

EMERGENCIES, AND HOW TO TREAT THEM. The Etiology, Pathology, and Treatment of the Accidents, Diseases, and Cases of Poisoning which demand prompt Action. Designed for students and practitioners. By JOSEPH W. HOWE, M.D., Clin. Prof. Surg. Med. Dept. Univ. of New York. Second Edition. New York: D. Appleton & Co., 1874.

THE second edition of this work is, as far as we can see, a reprint of the former edition, and needs no other notice than that which we have given it on a previous occasion. We need only to reiterate our former opinion that it is a useful, instructive work. We are glad to notice the fact that the demand for a second edition, so soon after the first, bears out this opinion.

ELECTRO-THERAPEUTICS; A CONDENSED MANUAL OF MEDICAL ELECTRICITY. By D. F. LINCOLN, M.D. Pp. 186. Philadelphia: H. C. Lea. 1874.

WE have had so many small books upon Medical Electricity of late, that when we opened the little volume from Dr. Lincoln we expected to find something new; but we were disappointed. The title "Electro-Therapeutics," which by the way is plagiarized from that of the work of Dr. A. McL. Hamilton, of this city, prefaces one of the best compilations for general use, and shows a familiarity on the part of Dr. Lincoln with the European authors.

While fully aware of the good points of the book, we must differ from the author in some of his statements, and excuse them upon the ground of undue haste. On page 68 we are told that "tenderness of the sympathetic nerve is to be noticed as a symptom." The author lays great stress upon galvanization of the brain, although its feasibility is denied by Cyon, Mason, and other writers. It is needless to refer to their arguments, except to add that Dr. Lincoln and the adherents of this theory probably forget that an electric current is always carried by the best conductors, and the bones of the cranium, as well as all other bony tissues, being exceedingly bad conductors, it is but logical to suppose that the pericranial fascia will conduct the current, and that none will pass through the brain. On page 121 he advances the somewhat fanciful statement that "a galvanic current passed through the spinal cord refreshes some persons like a stimulating bath."

The chapter on physiology is good, and the section upon therapeutics, though somewhat confused in its arrangement, shows hard work.

The illustrations, confined to the exhibition of a great many different kinds of batteries and apparatus, are clear and well drawn.

Reports of Societies.

NEW YORK MEDICAL LIBRARY AND JOURNAL ASSOCIATION.

DR. J. C. PETERS, President, in the Chair.

EXSECTION OF THE HIP-JOINT.

DR. LEWIS A. SAYRE read a paper before this Association on Exsection of the Hip-joint. The following is a synopsis of his remarks:

The operation for exsection of the hip-joint was proposed by Mr. Anthony White, in the year 1769. It was first performed by Mr. Charles White, in the year 1821. In my first paper upon "Exsection of the Hip-joint," I stated that the operation was first performed in 1818. Dr. Hodges has stated, in a work written subsequent to the reading of that paper, that the operation was first performed in the year 1822. If, however, you will refer to Reese's edition of Cooper's Surgery, with supplementary index, for 1845, pp. 49 and 50, you will find a letter from Anthony White, written in April, 1821, giving a complete history of his case and the operation. The letter concludes as follows: "In April, 1821, we met, and the boy being placed upon a table of convenient height, I proceeded to divide the integuments covering the bone, carrying the incision from an inch above the head directly along the middle line of the bone, about two inches below the greater trochanter; this was completed at one incision down to the surface of the bone." Three or four cases had been reported previous to that date, in which the head of the bone (exfoliation having taken place) had been removed after dilating the fistulous openings which led to it; but that was not, properly speaking, an "exsection of the hip-joint," and should not be regarded as such. The operation was subsequently performed in the years 1829, '32, '33, '45, and '47, by various surgeons in England and France. In the year 1852 the operation was performed in this country by Bigelow, of Boston, but was unsuccessful.

I performed my first operation for exsection of the hip-joint March 29th, 1854. It was the first time the operation had been performed successfully in this country.

The little patient was the daughter of an engineer, and was at the time of the operation in the most extreme condition of emaciation and suffering. All hope of her recovery had been abandoned, unless there was some help for her in this direction.

Somewhat more than a year before the operation was performed, the case had fallen under my observation. I then called what was regarded as the most eminent surgical counsel in this city, and although at that time I was desirous of performing the operation, counsel decided that the operation was improper, and accordingly it was discontinued and deferred.

The father of the child was very anxious that something should be done, and I gave him my ideas upon the subject, somewhat as follows: I had asked him the question, knowing that he was an engineer, if his cellar was filled with decaying potatoes and bilge-water, how he would proceed to remove them? Would he cut a drain direct to the offensive accumulation and remove it at once; or would he cut a drain running around three or four squares, down to the City Hall and up

on the east side to his cellar, and in that manner secure only a partial and slow discharge of the offensive accumulation? His reply was that he would cut a drain direct from his cellar to the East River, in order to give direct and rapid escape to the foul material within.

At the end of little more than a year, as already stated, the father came and said that he wanted me to perform the operation. He said "that decaying-potato and impure-water business had been upon his mind ever since I had first suggested it to him." He also said that it was evident his daughter would soon die unless relief from some source could be obtained. The operation therefore was performed, as the *dernier ressort* for saving the girl's life. The result of that operation, gentlemen, you now have before you. The girl recovered, has grown into womanhood, and now enjoys the most perfect health.

So much for the first case. The results obtained in operations since that time I will mention further on.

I will now direct your attention to the nature of the disease and the indications for the performance of the operation.

With regard to the nature of the disease, I am fully convinced that in an immense majority of instances it is of traumatic origin. At one time I spoke upon this point with some hesitation. It was held by the profession in general, and I had been taught to regard the disease, as being essentially one of a constitutional character; and that it occurred in a great majority of cases, if not always, in persons who were of a sturmiest habit.

After several years of careful investigation, I have arrived at the conclusion that attributing this form of disease exclusively to a constitutional origin is erroneous teaching.

The very fact that so many of those patients who, perhaps, have been sick for years, finally recover under nature's operation, and are daily seen about the streets, is of itself sufficient evidence to disprove the doctrine of exclusive constitutional origin. I am fully convinced, as already stated, that in a vast majority of instances the disease has a traumatic origin.

The child receives a strain, a blow, a concussion, some injury which causes pressure upon the blood-vessels of the head of the femur or acetabulum, etc., etc.

It is something of that order which excites inflammatory action that goes on to the production of effects which we see developed during the progress of the disease. It seems to me it is just here that there has been this fatal error with regard to the propriety of the operation; namely, the almost universal belief that the disease is essentially constitutional in its nature. This belief has formed a sort of Chinese wall, which has prevented a correct understanding and appreciation of the nature of the difficulty, and the proper treatment to be adopted for its relief. Taking this view of the question, the treatment of these cases by adopting constitutional measures *alone*, administering remedies for the purpose of rectifying a local injury, is in my opinion entirely wrong, and the results obtained by that form of treatment prove it to be so.

The position, therefore, which I assume is this: if the disease is recognized early, it can be by appropriate treatment, such as extension and counter-extension, properly applied and continued, perhaps assisted by some form of moderate counter-irritation, perhaps by the application of leeches, be brought to a favorable termination without any operation at all.

It is proper at this point to say that those forms of counter-irritation which are sometimes resorted to for the purpose of keeping up a continuous discharge,

such as setons, etc., I do not approve of. The actual cautery is a most excellent and serviceable form of counter-irritation, and the form which I usually employ unless there are some special objections to its use.

When, however, the disease has so far advanced that the case falls under any of the indications which are to be enumerated, then it is that I regard the operation not only as justifiable, but I regard it as the duty of the surgeon to perform it if possible.

Before adopting any plan of treatment, however, it is essential to arrive at a correct diagnosis. For this end, proper position of the patient is absolutely necessary during the examination.

The proper position is upon the back, upon a hard table, with the spinous processes touching the table. Placed in this position, if the pelvis, trunk, and extremities are in a normal relation to each other, two lines, one drawn from the centre of the sternum to the centre of the symphysis pubis, and the other drawn from the anterior superior spinous process of one ilium to that of the other, will cross each other at right angles, and the extremities can be brought into a position of parallelism with each other, and the popliteal spaces will touch the table.

In the first stage of the disease, the limb is slightly abducted, slightly flexed, the foot is rotated outwards, and the toes are slightly everted.

In the second stage, the same symptoms are present, except that they are considerably increased. There is increased flexion, abduction, eversion of the toes, and rotation of the foot outwards. These symptoms are present after suppuration or extensive effusion has occurred within the joint, and are due to the fact that the pressure upon the inside of the capsule has caused it to unfold itself, as it were, compelling the limb to assume this peculiar position to accommodate the increased amount of fluid within the joint. This is the most painful period of the disease, and continues so until rupture of the capsule occurs.

When rupture of the capsule takes place, the real deformity incident to the third stage of the disease begins to be developed. In this stage the limb is abducted, the foot is rotated inwards, the toes are inverted, and the limb becomes shorter.

It is generally taught that luxation occurs in this stage; but I have seen only a single instance among all the cases upon which I have operated, in which luxation has been present. The head of the bone is *diminished* in size by the process of absorption, and the acetabulum is *increased* in size, which permits of considerable displacement. It is also true that when the acetabulum becomes very much absorbed, the capsule and the periosteum become displaced, and the head of the bone is invested with its capsule in a new position upon the ilium.

These changes may take place through the process of absorption, but as a rule there is no proper luxation.

When the disease has passed into the third stage, the case must be cured, if cured at all, either by the operation of excision, or by nature's method.

If nature is left to cure the case without assistance, excessive suppuration must occur, and frequently patients die from the exhaustion incident to it.

The deformity which remains when nature effects a cure, is one with which all are familiar.

This brings us to the consideration of the indications for the performance of the operation.

1. If there is denuded bone present, the operation is justifiable.

2. If the discharge is excessive, and is increasing, the operation is justifiable.

If the discharge is diminishing, and the patient is improving in health, the case may perhaps be left to get well by nature's method.

3. If there is danger of perforation of the ilium, the operation is justifiable. This point can be settled by rectal examination. A spongy feel or sense of fluctuation can be detected as the finger passes over the plane of the ischium if perforation is threatened. In such cases it is better to operate than to run the risk of having perforation occur.

This brings us to the operation itself, which is to be performed as follows: Anesthetize, and place the patient upon the well side. Carry the point of a strong knife home to the bone at a point midway between the anterior superior spinous process of the ilium and the top of the trochanter major. Holding the knife firmly upon the bone, carry it through the tissues in a slightly curved direction, to a point midway between the centre of the trochanter and its posterior border, and then continue the incision from two to three inches farther down upon the thigh, curving it slightly forward. Cut through the periosteum freely. Make a second incision through the periosteum at right angles with the first, extending as far around the bone as can be conveniently reached, at a point nearly opposite the lesser trochanter. Introduce the elevator, and peel up the periosteum, until it is reflected, to the digital fossa, at which point it will be necessary to cut the muscular attachments. Continue the reflection of the periosteum until the bone can be turned out sufficiently far to permit the introduction of a narrow saw (a saw is always to be used), and then remove the bone below the trochanter major. More of the bone must be removed if found diseased below this point. It is better to remove the trochanter major even though it be not diseased, because, if left, it will obstruct free discharge of pus. If the disease has been of long standing, and nature has formed a large amount of involucrum, it may be necessary to first saw the bone off before it can be turned out.

It has happened to me in two cases that another difficulty has been met with regard to turning the bone out before sawing it off. The acetabulum in these cases had been perforated, and a portion of the femur had become engaged in the opening. Fixed in this manner, the acetabulum offered so much resistance that, in both instances, the femur was fractured by the force used for luxating the bone.

All dead bone is next to be carefully removed from the acetabulum, taking great care not to injure the internal periosteum.

Wash out the wound, pour it full of Pernian balsam, tampon with oakum in such a manner as to permit a perfectly free discharge from the bottom of the acetabulum, apply one or two sutures, and then dress the child in the *wire-cuirass*, which is a modification of Brower's wire breeches. Never tampon the wound with cotton, for I feel certain that one of my cases was killed by accidentally having it used.

The application of an India-rubber bed to the cuirass adds very much to the comfort of the patient. The well limb is to be dressed first, and made a solid column upon which to make counter-extension for the diseased limb.

Place the anus of the child in proper relation with the opening in the cuirass. Extend the well limb and fasten the foot to the foot-piece by means of a roller bandage. Place a moderate splint, such as a folded newspaper or piece of soft pasteboard, over the knee to prevent flexion. Carefully secure the whole with the remainder of the roller bandage, which is to pass over the entire limb and perineum. Apply the

bandage with great care, in order to avoid wrinkles and undue pressure. The requisite amount of extension is made by means of the thumb-screws attached to the foot-piece.

The foot of the diseased limb is to be fastened to the foot-piece by means of broad strips of adhesive plaster, which extend along the sides of the leg and reach *above* the knee, in order that traction shall *not* be made upon the lateral ligament of the knee-joint, but upon the thigh. The plaster is secured to the limb by means of a roller bandage applied in such manner that all wrinkles in the plaster shall be avoided. Extension to the diseased limb must be *gradually* applied.

The tissues about the wound should be firmly supported with a bandage for the purpose of preventing infiltration of pus. The first dressing of the wound may be made at the end of forty-eight hours. Subsequently the dressing may be repeated according to the amount of discharge, etc. In the subsequent dressings it is important to keep the periosteum well stuffed with oakum in order to permit the deposit of sufficient bony material to finally bear the weight of the body. The well limb must be undressed at least once a week, free motion restored to the joints by passive movements, and then replaced in the cuirass.

If the wire-cuirass cannot be easily obtained, a long Haggerdon's splint may be employed, with the modification of adding a foot-board.

It is possible to treat a case upon a firm bed, making extension by means of a weight and pulley. This, however, necessitates continued confinement of the patient, which is undesirable, if it can be avoided.

The children are kept in the wire-cuirass, as a general rule, about six weeks.

At the end of this time the short splint which I have devised is applied, and the child permitted to go about with the assistance of a crutch.

If the thigh is so short that this splint cannot be advantageously applied, Taylor's long splint may be employed, or a modification of that splint which you will see in position upon one patient here to-night.

The modification which I have introduced is securing an abduction movement and rotation outwards at the same time, by means of screws adjusted to the joint in the instrument opposite the hip-joint.

Several cases were then presented.

CASE I.—At the time of the operation there was extensive abscess on the left hip, disease of the opposite knee-joint; acetabulum was perforated; a probe could be carried through and emerge at the root of the penis. Recovery with motion perfect, and three-quarters of an inch shortening. The wound closed in about nine months after the operation.

CASE II.—Little child operated upon a few weeks previous, and was dressed in the wire-cuirass.

CASE III.—Little girl wearing an instrument which is a modification of Taylor's long splint. The case was one of fibrous anchylosis. Since the use of the instrument abduction had been obtained sufficient to more than bring the limbs parallel; rotation could be obtained, and flexion and extension to some extent.

CASE IV.—Extensive waxy degeneration of liver and kidneys. Operation performed for temporary relief. Very great improvement had been realized.

Two cases of cure by nature's method were presented, to afford opportunity for comparison.

One most remarkable case was presented which well illustrated the value of one item of after-treatment. The more care and attention the patient receives after the operation, the better will be the results obtained.

The movements of this young man were so perfect

that it was impossible to determine by those alone which hip had been operated upon. In all the cases presented motion at the hip-joint was perfect; the patients were able to sit down with perfect ease, and to abduct the limbs far enough to ride on horseback.

The whole number of cases presented was thirteen.

Since my first operation I have operated forty-four times, of which I have complete histories. An analysis of these cases is given below. The results which have been obtained have been obtained upon cases taken indiscriminately. The percentage of mortality is so small, I am compelled to believe that the operation is not only *justifiable*, but, if the cases could be selected and the operation performed at the most proper time, there is much better prospect of obtaining good results.

I am aware that the operation is disapproved of by many surgeons. In some institutions in this city it is absolutely prohibited. At the same time, however, in one of these institutions the operation for necrosis of the upper extremity of the femur is performed, and during the operation the head of the femur is removed. Still, they do not admit of the feasibility of the operation of exsection. That is what I call "whipping—him around a stump."

Analysis of 44 cases of exsection of the hip-joint.
Males 28, Females 16.

The acetabulum was perforated in 30 cases.

The disease could be traced to traumatic causes in 36 cases.

TABLE.

Age of Patient.	No. of Cases.	Died before wound healed.	Recovered.
Under 5 years.	8	1	7
Between 5 and 10 yrs.	19	2	17
" 10 and 15 yrs.	13	5	8
" 15 and 20 yrs.	2	2	
" 20 and 30 yrs.	1	1	
" 30 and 50 yrs.	1		1
Total.	44	11	33

Of the thirty-three cases which recovered, all are now living except two.

One of those died of marasmus and cholera-infantum six months after the wound had healed, and two years and 70 days after the operation.

The other died of phthisis two years after the operation. The wound had been healed more than a year.

The following is a record:

Of the 11 cases which died before the wound healed—under 5 years of age: one died of dysentery two weeks after the operation.

Between 5 and 10 years: one died of exhaustion in two weeks, and one died of exhaustion on the 24th day after the operation.

Between 10 and 15 years: one died of exhaustion on the 8th day; one died from tetanus on the 15th day; one died on the 14th day of double pneumonia; one died at the end of 9 months, of exhaustion, six inches of the shaft of the femur having been removed at a second operation; and one died at the end of 17 months, of dysentery. In this case, at the time of death there was limited motion, and only a very slight discharge from two sinuses at the back of the thigh.

Between 15 and 20 years: one died on the 40th day after the operation, of sunstroke. Wound nearly healed. One died at the end of three weeks, of amyloid degeneration of the kidneys.

Between 20 and 30 years: one died at the end of 11 months, from fatty degeneration of the liver and kidneys. Wound nearly healed. Three inches of new bone had formed.

The cases now under observation, upon which the operation has been performed, are certain to recover, with a single exception.

In the case in which a second operation was performed and six inches of the femur removed, my present opinion is, that amputation at the hip-joint would have been much the more favorable operation.*

The paper being open to discussion, Dr. C. FAYETTE TAYLOR remarked as follows:

The *abduction* modification of my long splint, which Dr. Sayre claims, I have employed for the past ten years. I first recorded it in THE MEDICAL RECORD, in September, 1867. I have what is called an *abduction attachment*, which is applied to the long splint, but only in those cases in which it is necessary.

The screw for producing rotation I do not claim.

With regard to the nature of this disease, I fully agree with Dr. Sayre that it is essentially traumatic. I have found that, in private practice, 75 per cent. of the cases can be traced directly to injury. In dispensary practice, about 53 per cent. have a fair history of injury. Of course, in strumous cases, a slighter injury will produce the same effect that a more severe one will in a healthy constitution; but that it is a traumatic disease essentially, and that there are but few cases which originate without traumatic causes, I am fully convinced.

I have never performed the operation of exsection of the hip-joint, but I do not hesitate to say that the procedure is often justifiable. I am of the opinion, however, that cases do not occur so often which require the operation as might be supposed.

The amount of amelioration which can be given to a case of hip-joint disease is very great. I have been looking for a case for some time upon which to perform the operation, but out of 167 cases, 41 of which were private patients, I have not met a case which seemed to justify the procedure. None of those cases terminated fatally; consequently it may be fairly assumed that we did not neglect our duty.

Dr. Shaffer, who has also been desirous of obtaining a case proper for operation, has had under his observation cases sufficient in number to increase my own number to 200. Among all these cases there was one in which the operation for exsection seemed justifiable. The operation was performed, and the patient did very well. It was in only one-half of one per cent., then, of the cases which fell under our observation where the operation was thought to be proper. As the other cases did well, there would hardly be a question as to whether the operation should have been performed. While I do not doubt that there are cases where the operation would save life, it is much better to cure without the operation.

Dr. YALE remarked with regard to Dr. Taylor's suggestion concerning the relative frequency with which the operation should be performed, that it should be borne in mind that the frequency is in inverse proportion to the early treatment. In those cases where treatment can be adopted at the outset or the early stage

* Since the reading of the paper, the forty-third case, the one referred to above, has died at the end of the eleventh week after the operation. The specimen was presented at the New York Pathological Society, April 8th, 1874. The patient was 10 years of age. The acetabulum had become covered with new material, and four inches of dead bone at the upper extremity of the femur had been surrounded by a heavy involucre, which had been rounded off at its upper extremity so as to fit the acetabulum in the most perfect manner.

of the disease, it can be cured without an operation. But there are very many cases which are treated for other diseases, until the time when such early treatment will be of service has been expended; until abscesses are developed, and the true nature of the disease has been determined. In such cases as these, which have been neglected in their early stages, and gone on to the formation of abscesses and destruction of the bones, etc., the problem is, Shall we cut short the disease by means of an operation, or shall we permit them to die? Shall we diminish the deformity and give them useful limbs, or shall we permit the work to be accomplished by nature, if indeed she proves herself able, and have remaining a very great deformity, and a very much less useful limb? The first inclination of the surgeon may be to say that the patient will die anyhow, and he therefore feels like permitting him to die peaceably. My experience and observation, however, have taught me that it is not altogether untrue that the *worst* cases do the best, and it is in this class of bad cases that an immense amount of benefit can be derived by an operation. It is in that large number of cases which by want of money have been deprived of the benefits of proper surgical attention, and thus the disease has been permitted to go on to its most advanced stages; or, what is much more common, the natural discouragement which the parents have because the disease is not cured at once, hence fail to carry out the treatment necessary to give any benefit in the early stage, consequently neglect treatment altogether until irreparable damage is done—it is in such cases as these that the operation is pre-eminently beneficial. I believe that the so-called "American plan of treatment" is better than all others for securing good results in this class of cases. Most of us may live to see the time when these crooked cases will have disappeared from among us, because of the benefits which may be afforded by early treatment. It has probably been Dr. Taylor's fortune to meet with that class of cases in which operation was contra-indicated; but I am of the opinion that, in the field of observation in which I have been engaged, I have seen at least from 25 to 50 cases in which the operation would have been justifiable.

DR. POST being called upon, remarked that when the lion roared it was becoming for the other beasts of the field to remain silent. There was, in his mind, however, no question but that in properly selected cases the operation is a justifiable one; and not only that, but that it is the duty of the surgeon to perform it. In many cases the operation is necessary to save life. Where better results can be secured by the operation than by permitting the case to be cured by nature, even though life would be preserved without it, the operation is justifiable. In the cases where nature is successful in removing the dead bone, the tendency to deformity is so great that in very many instances the limb is almost useless. In all the cases in which he had performed the operation, the results obtained had been very satisfactory. He then referred to the history of several cases, and in the course of his remarks alluded to the actual cautery as a very serviceable means to be employed in the treatment of hip-joint disease.

DR. SAYRE remarked that he wished to be understood as saying that with proper treatment of the disease at the beginning, we shall never be compelled to resort to the operation of excision. With the improved methods of treatment which we now have, the operation may become obsolete. It is in cases where the disease is progressing, even under the best treatment, showing no symptoms of improvement, that the operation is especially beneficial, and is justifiable.

Correspondence.

NEW DISCOVERIES IN HYDROPHOBIA.

PINE RIDGE PAPERS.

II.

SINCE I last wrote I have had an opportunity of performing an autopsy upon one of the dogs under observation. The patient was a Scotch terrier of an erratic temperament, and, except for the slight eccentricity of nipping any one who might be passing him in the dark, he had a quiet disposition. My attention was first directed to the possibility of his having hydrophobia, by the fact that one day on entering my stable I caught him chewing a portion of the leg of my pants with evident relish. Withdrawing my leg he still persisted in his hold, pulled and shook his head as if with a determination to tear out that portion of the fabric for a vicarious meal. During all this performance there was a marked twitching of the tail and a peculiar expression to the eye, half significant and half determined, which reminded me of one of the pathognomonic symptoms of emotional insanity. As the animal had not yet inserted his teeth into my skin, I felt composed, and had an abundance of opportunity to study the symptoms with the requisite care to make a correct diagnosis. During the whole time that his jaws were clenched, the spasmodic action of the tail continued at regular intervals, proving that the disease is a purely nervous affection. If we accept such a view, and are able to make out the nervous connection between the muscles of the jaw and those of the tail, I think we can very satisfactorily explain the reason why the tail is drawn so tightly between the legs when the masseter muscles are relaxed in the last stages of the disease. I only throw out this suggestion because, in all my reading upon the subject, I have never met with a similar observation; hence, I am glad of this opportunity to place it on record. Inserting the bulb of the thermometer into the left ear, the animal bent his body laterally in the opposite direction, and for a moment seemed to have a tonic spasm, clearly proving that the power of reflex action still remained.

Having thoroughly satisfied myself that the animal had hydrophobia, I caused my attendant to pass a collar around the dog's neck and fasten thereto a chain. The collar was of leather, one inch and five-eighths wide by $\frac{1}{2}$ of an inch in thickness, and provided with a large stout buckle. The chain was the ordinary one "sold in our shops." During the operation of ligating the neck, and in order to prevent my attendant from being bitten, I engaged the dog's attention by a to and fro motion of my leg, thus increasing his hold. This I have found, by an experience in one hundred and fifty-two similar cases, to be very effectual, provided the animal's teeth have not already entered the flesh.

After being conducted to the kennel and secured, the attendant had a narrow escape. While in the stooping posture, pouring some water from a pail into a smaller vessel, the dog leaped and snapped at his buttocks, and just missed the skin. By a timely jump, no other injury than a loss of a portion of the pants was suffered. Immediately on being released the attendant gave the dog a smart kick in the perineum, when the animal uttered a short yelp, retired to the corner, and had an abundant evacuation from the

bowels, at the same time urinating freely. This may have only been a coincidence, but I refer to the circumstance to show that the sphincters were in good condition, and that the posterior extremities were not paralyzed.

I may state, in passing, that this animal was kept under constant observation, as are all my other dog patients, night and day, each watcher being relieved every two hours. The enclosure is abundantly shaded by trees, each kennel is supplied with a curled-hair mattress, a urinal, earth-closet, and a special drain for subsoil moisture. Besides this, each patient is regularly supplied with ice-water, by direction of the Society for the Prevention of Cruelty to Animals. I mention these facts to show the facilities I have for treating these cases.

Well, to make a long story short, the patient met a violent death by attempting to climb over his kennel, with a short chain, and falling on the wrong side.

Before proceeding further, I may state that the portions of pants that were lacerated by the dog's teeth were carefully cut out for purposes of analysis. I shall confine myself to a description of that portion removed from my own person. Examined with the naked eye, there were six distinct perforations by the animal's teeth, and one tear an inch long, slightly smeared with saliva. No blood visible. Examined under the microscope, the damp portions of the cloth were found to consist of a glairy mucus with a mixture of salivary corpuscles, which were mostly congregated around the perforations. Besides this, there were numerous granules, spindle-shaped cells, fibres, oil globules (high refraction power with a short focus), the whole mixed in a confused stroma of woollen fibre. Except for the oil globules and granules, the microscopic examination was negative. The fabric being treated with dilute acetic acid, gave rise to effervescence, due to the accidental presence of some white-wash. A drop of concentrated sulphuric acid gave rise to a momentarily brilliant red stain, followed by a marked and immediate loss of substance. Except for the character of the stain, the same may be said for nitric acid tried in a similar manner. Examined again under the microscope with a high power, oil globules and granules still existed in great quantity, with broken-down woollen tissue. With the view of obtaining some extractive matter, the fabric was then digested in a retort heated to redness. The cloth quickly curled upon itself, became crisp, and gave forth a characteristic odor of burnt wool. Nothing but ashes left in the retort. (This I intend to send to a young medical student, a friend of mine, who is taking a practical course in a laboratory.)

Now we shall proceed to the most interesting part of the autopsy. Cadaveric rigidity marked. Froth oozing from the mouth; abdomen tympanitic; eyes congested; mark of cord around the neck; marked turgidity of vessels of the hemispheres and effusion in the arachnoid. Aside from the ordinary lesions of suffocation, I noticed a punctate injection in the left optic thalamus, an embolus in the middle meningeal artery, a thrombosis of the left lateral sinus, and a small clot quietly undergoing fatty degeneration in the left lateral ventricle. At the point where the spinal cord was separated at the autopsy, there was a marked laceration. The corpus striatum was intact.

The larynx was filled with mucus, which I intend to analyze and report upon. The brain of the animal was at once placed on ice, to prepare it for microscopic examination.

PINE RIDGE, ON THE HUDSON.

New Instruments.

FOR THE ARREST OF EPISTAXIS.

By SALVATORE CARO, M.D.,

NEW YORK.

If the epistaxis prove obstinate, endangering the life of the patient, it is always proper to resort to mechanical means for its arrest, by plugging the nose posteriorly with Zurnoff's sound or Bellocque's canula, and anteriorly with sponges, bits of linen, or patent lint. The india-rubber bag is the last and best instrument for this purpose. My preference is for anterior plugging, for the following reasons:

I. The alarm created by the paraphernalia and difficulty of drawing the plug into the posterior nose is generally very great.

II. The inflammation caused by the pressure upon the delicate parts, and the consequent profuse suppuration and poisoning of the system by the absorption of putrid matter.

III. The uncertainty of arresting the hemorrhage by the unequal pressure, and the increasing danger of its renewal by tearing the newly formed membrane; and

IV. The blood having its free exit intercepted, finds its way into the cranial cavity, and may cause tetanic convulsions and death by pressure upon the encephalic mass.

The india-rubber bag to which I have reference is the one shown and described in the diagram.

Dr. Luigi Malavasi, of Modena, in 1843, gave us the first knowledge of this instrument, and in 1871 Dr. Küchenmeister, of Dresden, perfected it. But the last change which I have made is, I think, an improvement upon the latter. This consists simply in the change of tubing from elastic to non-elastic. By this alteration a firmer traction can be made upon the bag, and more easily adjusted, and by the help of an elastic bougie

a. Natural size of the bag.
b. Line of the inflated bag.
c. Insertion of the non-elastic tube.
d. Silk thread to tie the tube after inflation.
e. Natural size and length of the non-elastic tubing.

can be readily passed from the anterior to the posterior fossa, and when *in situ* can be inflated with iced water or air. The tube is tied with strong silk, and by gently pulling the tubing the bag will adjust itself upon the bleeding parts and arrest the hemorrhage. If the epistaxis should continue, the bag, without removal, can be collapsed and afterwards reinflated so as to form a stronger pressure.

If offensive suppuration should cause distress, by

collapsing the bag the nose can be washed with any detergent, and the danger of the absorption of deleterious matter removed. My first experience in its use was in April, 1873, in the cases of two boys, both suffering from severe epistaxis, one caused by a fall down stairs, the other by a blow whilst playing ball. Local remedies and external pressure proving unsuccessful, the india-rubber bag immediately arrested the hemorrhage, without giving the slightest inconvenience, as testified by the boys.

A NEW HYPODERMIC SYRINGE.

By GEO. R. FOWLER, M.D.,

BROOKLYN, N. Y.

EVERY physician who uses a hypodermic syringe has experienced the many inconveniences attending the use of the old pattern. When not often used, the leather packing upon the piston becomes dry, and some time is consumed, in perhaps an emergency, in getting the syringe to work. The points frequently become occluded, and the wires used to prevent this, when the syringe is not in use, often become fastened tightly in the point, breaking off when attempts are made to disengage them, thus adding to the physician's annoyance. As now made by the instrument-makers, they are put up in leather-covered cases, which, under the influence of moisture from the perspiration when carried in the pocket, soon wear out and fall to pieces.

Then there is the inconvenience of carrying the solution in the old way. The cork of the vial contained in the case frequently becomes loosened, and the solution of morphia, which of course is the one most frequently employed, evaporates, and the crystals are deposited about the cork, gluing it so effectually to the glass as to leave no alternative but to break the bottle in order to get at the contents.

Some time ago I conceived the idea of doing away with the case and vial, and attaching a reservoir to the end of the syringe, to which latter a point was permanently fixed. The accompanying cuts represent the instrument.

Fig. 1, at "a," shows the syringe, with an aluminum point permanently fixed; "b," the reservoir made of hard rubber, containing the solution, and having the lower end (as shown by the milled edge) removable, so that the reservoir may be filled without detach-

ing the syringe; "c," the case, also of hard rubber, for the syringe. The whole instrument when complete, as represented at Fig. 2, is compact, and occupies

but little more space than the ordinary hard rubber thermometer case.

To use the syringe, the case "c" (Fig. 1) is unscrewed and removed, and the solution drawn into the barrel to the desired amount, *without detaching the reservoir*. Then unscrew the reservoir, and the instrument is ready for use.

The leather packing is constantly kept moist and ready for use by a small portion of the solution passing to it through the point by capillary attraction. The point being of aluminum will never corrode, however acid the solution employed.

The morphia solution which I have been in the habit of employing for the past two years possesses the advantage of keeping, when properly made, unchanged for an indefinite length of time. The following is the formula:

- B. Morph. sulph. gr. xvi.
Aque dest. ebullient, . . . 3 vi.
Acidi sul. dil. ℥ ii.
Misce ad dale,
Acidi carbol. gr. v.
Glycerine pure. ii.

Again boil and filter carefully.

The above solution may be carried in the reservoir of this syringe any length of time without change.

A word as to the method employed by most physicians in giving a hypodermic injection. It is done by pinching up a fold of skin and thrusting the point of the syringe into this. This, I think, is very objectionable. By it all anatomical relations of the skin to the superficial veins are destroyed, and the danger of injecting into one of these increased. This accident has happened to me on two different occasions, and I never wish to witness such terrible suffering again. Both of these recovered, but the accident suggested to me the following method: instead of pinching up a fold of skin, draw the skin tightly over the subjacent cellular tissue at the point at which the injection is to be given. Then hold the syringe at right angles to the long axis of the limb or part, and press the whole length of the point firmly against the surface of the skin. This forms a furrow, one terminus of which is at the sharpened point of the syringe. The instrument is now thrust quickly forward, when it will be found to have entered the subcutaneous cellular tissue by the absence of resistance. This I have found to be the most certain, safe, and painless method of introducing the point.

AN IMPROMPTU ASPIRATOR.

By ANDREW H. SMITH, M.D.,

OF NEW YORK.

As the aspirator in general use is always expensive, and often not at hand, a substitute which may be arranged from the material at the command of almost every practitioner, will often be found useful.

Take a common pint bottle, fit it with a good firm cork, pierce the cork with a rat-tail file, and fit into it a piece of glass tube about three inches long, leaving about an inch projecting above the cork.

A hollow needle of appropriate size, attached to a piece of rubber tubing about two feet in length, completes the apparatus. In using it put a teaspoonful or

two of ether into the bottle, fit the cork in tightly, and set the bottle into hot water. Thrust the needle into the cavity to be emptied, and when all the ether in the bottle is vaporized remove it from the hot water and slip the free end of the rubber tube over the tube in the cork. As the ether condenses a vacuum is formed, and the aspiration is effected as completely as by the most perfect instrument constructed for the purpose. The effect will be a little more prompt if cold water be poured over the bottle. The thinner the glass, the less will be the risk of the bottle being cracked by the heat.

By adapting the needle directly to a cork and this to a small slender test-tube we have a very convenient pneumatic exploring needle. A drop or two of ether is in this case sufficient, the surplus vapor passing off through the needle before the puncture is made. The tube serves as a handle when the instrument is used, and at other times, by reversing the cork, as a case for the needle.

110 EAST THIRTY-EIGHTH ST.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from July 19, 1874, to August 4, 1874.

BROWN, J. R., Surgeon.—Relieved from duty as Medical Director of this Department, having been appointed President of the Army Medical Examining Board, to meet in New York City on August 4, 1874. G. O. 7, Department of the Platte, July 23, 1874.

PAGE, CHARLES, Surgeon.—To act as Medical Director of this Department until the arrival of the medical officer ordered to that duty. G. O. 7, c.s., Department of the Platte.

RANDOLPH, JNO. F., Surgeon.—Granted leave of absence for 30 days. S. O. 104, Department of the Platte, July 29, 1874.

WRIGHT, J. P., Surgeon.—Assigned to duty at Fort Hays, Kansas. S. O. 117, Department of the Missouri, July 30, 1874.

GRAY, C. C., Surgeon.—When relieved by Assistant Surgeon Middleton, to proceed to Fort Duncan, Texas, for duty at that post. S. O. 116, Department of Texas, July 28, 1874.

JANEWAY, J. H., Assistant Surgeon.—When relieved by Surgeon Wright, to proceed to Fort Wallace, Kansas, for duty at that post. S. O. 117, c.s., Department of the Missouri.

WATERS, W. E., Assistant Surgeon.—To proceed without delay to Fort Dodge, Kansas, and report in person to Colonel N. A. Miles, 5th Infantry, for duty. S. O. 116, Department of the Missouri, July 29, 1874.

PHILLIPS, H. J., Assistant Surgeon.—Relieved from duty in Department of the Columbia, to proceed to New York City, and on arrival report by letter to the Surgeon-General. S. O. 159, c.s., A. G. O.

MIDDLETON, P., Assistant Surgeon.—Assigned to duty at Fort Clark, Texas. S. O. 116, c.s., Department of Texas.

CRONKHITE, H. M., Assistant Surgeon.—Granted leave of absence for 60 days, to take effect no later than Sept. 1, 1874, providing he furnishes a suitable substitute during his absence. S. O. 35, Military Division of the South, July 23, 1874.

WOODRUFF, E., Assistant Surgeon.—Leave of absence extended three months. S. O. 168, A. G. O., August 3, 1874.

HARVEY, P. F., Assistant Surgeon.—Assigned to temporary duty at Fort Preble, Me., as Post Surgeon. S. O. 140, Military Division of the Atlantic, July 18, 1874.

CHERDONNIER, A. V., Medical Storekeeper.—To report in person to the Surgeon-General. S. O. 160, A. G. O., July 24, 1874.

Medical Items and News.

DEATH OF DR. MURRAY GAYLORD MILLIKEN.—It becomes the sad duty of a former associate to announce the death of Dr. Murray Gaylord Milliken, at his home, Hamilton, Ohio, July 14th, 1874.

He was graduated at the Bellevue Hospital Medical College in the spring of 1870. During his collegiate course he was distinguished among his fellows by his acquirements, and entering the Bellevue Hospital in the month of March of this same year, his examination was in keeping with his previous reputation. In the hospital Dr. Milliken was most enthusiastic and assiduous. The records of his cases were most faithfully kept, and his powers of observation enabled him to collect enduring clinical evidence; and in the earnest midnight consultations of the house-staff, no opinion carried greater weight than his.

It was while in the performance of his duties that he contracted relapsing fever, from the prostrating effects of which he never fully recovered. Leaving the hospital in poor health, he strove to begin his professional career in this city, and although success attended his efforts his strength was not commensurate with the ambition which impelled him, and last winter he was obliged to succumb. Returning from the city to his old home he gradually sank and died of Bright's disease.

A young wife and a large circle of affectionate friends mourn the loss of one who was destined to become pre-eminent in our profession, and to them we tender our heartfelt sympathy.—T. A. MCB.

BELLEVUE HOSPITAL.—At a recent meeting of the Commissioners of Charities and Correction, the following resolutions were adopted:—

"Resolved, That the Medical Board of Bellevue Hospital shall on the 1st of September be organized in the manner following, and thereafter the present Board, as at present constituted, shall cease to exist:

"First: On the 1st of September the following named physicians and surgeons shall constitute the Medical Board of Bellevue Hospital: Dr. Austin Flint, Bellevue College; Dr. Alonzo Clark, Twenty-third Street College; Dr. Alfred L. Loomis, University College; Dr. Wm. B. Eager, no school; Dr. James R. Wood, Bellevue College; Dr. Henry B. Sands, University College (College of Physicians and Surgeons); Dr. Stephen Smith, New York University; Dr. Ernst Krackowizer, no school.

"Second: The members of the Medical Board will, as soon as may be after September, nominate to the Commissioners of Charities and Correction such physicians and surgeons as members of the Medical Board of Bellevue Hospital as will enable the Commissioners to appoint from the persons so nominated ten members in addition to those above named, so that the Medical Board shall consist of eighteen members.

"Third: When the Medical Board shall have been constituted of eighteen members, they shall be divided by the Commissioners into three classes. The term of the first class shall be for three years; of the second class, for five years, and of the third class, for seven

years. The members of each class shall be eligible for reappointment, and all appointments to fill vacancies shall be for seven years.

"Fourth: When a vacancy shall occur in the Medical Board, it shall be the duty of the Board to give public notice through one or more of the medical journals published in the city of New York of such vacancy, and to invite the application of such members of the profession resident in the city of New York as may desire to be candidates for appointment.

"Fifth: All applications for appointment shall be considered by the Medical Board, and the names of the candidates who, in the opinion of the Board, are highest in the order of merit for professional ability, attainment and personal character, shall be transmitted to the Commissioners, who will appoint one of the candidates named to the vacancy.

"Sixth: The Medical Board will assign the service to its several members, but such service shall be continuous throughout the year.

"Seventh: The rules and regulations of the Hospital not inconsistent with the foregoing will be continued in force.

"Eighth: That a pavilion hospital be immediately erected after January 1, 1875, on Blackwell's Island, for a Maternity Hospital to be administered by a separate Medical Board, organized in like manner to the Bellevue Medical Board."

On the 28th ult., the resolutions were adopted with an amendment authorizing the eight members to nominate, by September next, a number of physicians and surgeons from whom the Commissioners are to choose eleven additional members of the Board, making nineteen members in all.

The clause relative to the Maternity Hospital was also adopted.

BOARD OF PHARMACY OF THE CITY AND COUNTY OF NEW YORK.—Within the past fiscal year the Board held 3 stated, 1 adjourned, 2 special, and 6 examination meetings, the last comprising eighteen days, as follows: 1873.—August, 3 days; 6 candidates examined; 4 passed; 2 failed. October, 3 days; 8 candidates examined; 4 passed; 4 failed. December, 3 days; 20 candidates examined; 10 passed; 10 failed.

1874.—February, 3 days; 28 candidates examined; 24 passed; 4 failed. April, 3 days; 23 candidates examined; 17 passed; 6 failed. June, 3 days; 19 candidates examined; 12 passed; 7 failed.

Total, 104 examined; 71 passed; 33 failed.

82 of the 104 examinations were first; 11 were second; 2 were third examinations; and one a fourth one. 19 of the candidates were proprietors and 85 assistants. 3 proprietors and 22 assistants failed. 8 of the rejected, 1 proprietor and 7 assistants, did not reappear. 15 of the candidates were non-residents.

The total number examined since the organization of the Board is 279; and the total of the rejected 63.

Nationality of the candidates who appeared for first examination during the last year.

Proprietors.—U. S., 7; Germany, 4; England, 1; Ireland, 4. Total, 16.

Assistants.—U. S., 38; Germany, 9; England, 6; Ireland, 2; Canada, 2; Russia, 3; Scotland, 1; France, 1; Poland, 1; Norway, 1; Cuba, 1; Costa Rica, 1. Total, 66.

The registrations within the last fiscal year are 62 proprietors and 101 assistants. Total of registered proprietors 517, and registered assistants 546. Grand total registered 1,063.

Nationality of registered proprietors.—U. S., 24;

Germany, 19; England, 4; Ireland, 9; Canada, 3; Austria, 1; Russia, 1; Cuba, 1. Total, 62.

Credentials.—From Board of Pharmacy, 26; from Pharmaceutical Colleges in U. S., 2; from Medical Colleges in U. S., 14; from Commissioners of Pharmacy (old Board), 13; Foreign Examining Boards, 6; German University, 1. Total, 62.

Nationality of registered assistants.—U. S., 37; Germany, 32; England, 8; Scotland, 2; Ireland, 5; Canada, 3; France, 4; Russia and Poland, 3; Austria, 2; Sweden, 2; Norway, 1; Cuba, 1; Costa Rica, 1. Total, 101.

Credentials.—From Board of Pharmacy, 48; from Pharmacy Colleges in U. S., 17; from Medical Colleges in U. S., 4; from Commis. of Pharmacy (old Board), 4; from Foreign Examining Boards, 23; from German Universities, 3; from French Schools of Pharmacy, 2. Total, 101.

The receipts are as follows:

From 82 first examinations at \$5, \$410; from 62 registered proprietors at \$2, \$124; from 101 registered assistants at \$1, \$101. Total, \$635.

The expenditures are:

Salary to secretary, \$200; books, postage, printing and stationery, \$136.73; legal adviser, \$25; clerical service, \$25; advertising, \$6; sundries, \$11.03. Total, \$403.76. Surplus, \$231.24.

Members of the Board of Pharmacy:—William Neergaard, M.D., *President*; Theobald Frohwein, *Secretary*; Paul Balluff; Benj. E. Hays, M.D.; W. De F. Day, M.D.

THEOBALD FROHWEIN, *Secretary*.

The *Medical Press and Circular* of June 10th comes to us with the following passage marked with a red pencil.

"THE 'CLINIC' AND THE 'MEDICAL PRESS AND CIRCULAR.'—About a month since we quoted from our American contemporary notes from an article which we headed *Obstacles à l'Amérique* as a specimen of descriptive talk-talk of a not very high or professional style. Whereupon the *Clinic*, of May 23d, favors us with the following paragraph, which has fairly taken away our breath: 'The sneering allusions of this American-hating journal are easily accounted for by the well-known fact that nothing so pleases most Englishmen as derision of this country.' Having recovered from the shock, we humbly beg our contemporary's pardon for having quoted from its columns anything which might offend American susceptibilities; but the fact is, whenever we read any 'sneering allusions' at American surgery, education, or schools, they are invariably in the columns of our contemporary, the *Clinic*.

"Our readers will bear us out that our quotations in this direction have been taken and acknowledged from this source. But we must beg our contemporary to disabuse the minds of its readers that nothing so pleases Englishmen as derision of America. We give this an emphatic denial. Medicine, like science, has no particular country; its disciples and true enunciators are found in all parts of the civilized world; and we may add (which our contemporary may take as soft-sap) that from our exchanges in a dozen languages we quote independently of name or country articles which are to our minds the most interesting, for perhaps the majority of which we are indebted to American journals. When political papers indulge in such language we attribute it to motives which are easily understood, but when a medical journal so far forgets its position as to assert that most Englishmen hate America, we are ashamed of it, as will doubtless all right-minded and right-thinking *confrères* be on the other side of the Atlantic."

Medical Department of Life Insurance.

LIGHT WEIGHTS AS LIFE INSURANCE RISKS.*

BY DR. A. HUNTINGTON,

OF NEW YORK CITY.

WHENEVER we wish to judge of a person's weight, or, as we say, *guess* at it, almost the first thing we do is to measure him with the eye, fixing his height, and of course along with this his general build or contour. But the one point that affords us most aid in forming our opinion is the number of feet and inches of his height, thus showing that we all have, as a result of ordinary observation, a certain idea of a standard or relation that should exist between a man's height and his weight. Now, connecting this with our subject, we observe that the object of all medical examinations in life insurance is to enable the company, through its examiner, to form a reasonable and approximate estimate—for of course it cannot be accurately determined—of the prospective longevity of the applicant.

In forming his opinion it is necessary for the examiner to consider many things aside from the mere physical examination of the applicant; but while the evidence derived from other sources may exert a powerful influence over his decision, yet that presented to his own educated senses by a careful physical exploration of his subject, is, after all, that upon which he most depends; and, as a result of some considerable experience, I am led to the belief that there is no one thing more important and worthy of consideration than the relation between height and weight.

I propose in this article briefly to consider the *significance* of this relation, or rather the *want* of relation, and more particularly as shown in those whose weight is *below* the proper standard rather than *above* it, for I am well persuaded that mistakes are oftener made in writing upon *light* weights than *over* weights. Waiving, however, all argument on the comparative safety of over and under weights, I shall speak only of the latter, and of the significance of a lack of weight as compared to a given height.

Observation among large numbers of people has pretty well established the fact that there is a standard or average co-relation existing between the height and weight of healthy adults. For instance, a man standing five feet seven or eight inches high should weigh about 145 lbs., and should such a person present himself for inspection, other things being equal, he would be set down as a good risk, and the result would, in a majority of instances, prove the judgment correct. Should, however, another individual of the same stature be found to weigh only 110, 115, or 120 pounds, the question naturally arises, Why this difference? and having in our mind the standard of weight that should coexist with a given height, we at once seek for some reason to explain this want of conformity to the rule.

A small variation is of course easily accounted for by the hundred constantly occurring things that are at work hindering the formation of tissues, or stripping off and destroying those already formed; and so we say there is a certain amount of variation in weight that is perfectly compatible with the maintenance of ordinary good health. It is not to these small and reasonable variations that we wish to call attention, but only to those that are sufficiently great to attract the particular notice of the examiner. The ordinary

causes of variation, such as mental trouble or excitement, prolonged muscular exertion, profuse perspiration, any slight and temporary derangement of digestion, etc., etc., are easily recognized by any careful observer, and so long as they do not affect us beyond reasonable limits, we pay no attention to them, considering them as the natural changes in our ever-changing bodies. But when there is something which goes beyond the ordinary and reduces the weight of a person far below the standard, then it is that this fact becomes a more significant and important one. The examiner may notice the fact, and yet it very often happens that he will not succeed in finding a satisfactory explanation of this failure of the powers of nutrition to bring the weight of the body up to the proper standard, and it is just here that I think we should be the more careful.

We know there is a reason, though we fail to discover it. We know there is a cause within interfering with digestion and assimilation, or in some way consuming and wasting the tissues as fast as, or faster than they can be produced. Whichever it be, we should be suspicious just in proportion to the extent of the shortcoming in weight. Our suspicions may be removed by evidence explanatory, and if so, well; but without a satisfactory explanation we will do wisely to use extreme caution in recommending light weights.

Many diseases in their incipency are very difficult if not altogether impossible of detection, and are yet all the while at work, persistently and silently, interfering with the nice balance that should exist in the system, and this may be the case often for a long time before any indubitable proofs of their presence exhibit themselves to the eye and ear. Most prominent among such insidious diseases, alas! is the one which the mortuary statistics of all life companies prove to be their bitterest enemy. I allude, of course, to consumption.

If it be true, then, that even among selected risks this disease is so often met with, and it be also true that this interference with the tissue-making process is often the earliest and only observable prelude to a more direct assault, it certainly is a point well worthy of the keenest scrutiny whenever present. Sometimes it is true that a party evidently afflicted with tubercular trouble will grow fat as we commonly say, and that, too, often before a final breakdown; but these are simply exceptional cases, and do not affect the position we maintain. As a rule, it may be safely laid down, that *want of weight*, plainly indicating the presence of the wasting or interfering process—one or both—is one of the most common and persistent features in consumptive people. Investigation has also revealed the fact that, of those insured who have died of consumption in several of our oldest and largest American companies, by far the greater part consisted of light weights at the time of insuring, thus clearly showing that the "picket guard" of the enemy was in view at the time insurance was procured, and also that the examiner in those cases failed to recognize him. Do we not all make like mistakes every day?

I believe many a loss to our companies could be saved if more importance were attached to this part of the record than is usually given to it. In an article so short as this must necessarily be I have not space to consider this subject in connection with other diseases, but simply to take up this one in which it is most prominent.

Of course I am well aware that light weights may sometimes be very good risks, but I am also well persuaded that they are too frequently passed and accepted when they are not good risks, and if this article should be the means of awakening thought in the mind of any examiner, tending to make him more

* A portion of this article was published in the *Insurance Times*, in 1871.

careful in the acceptance of light weights, it will not have been written in vain.

Without attempting, then, to establish any rule for guidance in these cases, I would simply suggest the propriety of rejecting cases of marked light weight where hereditary disease is revealed or suspected in the family; where the case is an exception to a family characteristic, even if hereditary disease is not marked (for many eminent minds, both in this country and in Europe, are becoming convinced that the proportion of non-hereditary cases of consumption is far larger than has heretofore been believed); where the habits are now or have been dissipated; where there has been chronic diarrhoea; where lightness of weight remains for an unreasonable time after any grave disease; and finally, where it exists to any *considerable extent*, even without apparent cause, and though the party seem to be well.

I am opposed to arbitrary rules in general, but I know of none that I think would be followed with better results than one applying to light weights, and when I say light weights of course I mean that degree of departure from the standard which does not come within a reasonable and allowable variation. Any man, as before stated, may vary somewhat from the standard; but when he is found to fall considerably short of it he should be at least postponed, and if within a fair time he fail to come up approximately to his gauge, it will be best to reject him, for I honestly believe that in eight cases out of ten he will, to say the least, fall short of his expectancy.

In conclusion, then, I believe that examiners too often fail to recognize the significance of light weight, and especially in those cases where there is no hereditary taint traceable in the applicant's family history. We are too apt, I think, to say to ourselves, "The record is a clear one, and though we cannot explain this light weight, yet we shall be justified in overlooking it on account of the *clear record* and *absence* of physical signs of disease," still entertaining the idea that all consumption is hereditary, when the real fact is that much of it is not. We should certainly attach much greater significance to light weight when the family history does reveal hereditary disease, but we should not be in too much of a hurry to ignore it in those cases where hereditary taint is absent. In the majority of cases it means something, and I think if any man will take the trouble to investigate the history of insured light weights, he will be satisfied that they are not healthy to insurance companies.

Every risk should be considered by itself, and all the arguments tending to satisfactorily explain away the lightness of weight should, of course, be allowed its proper influence. I am satisfied, however, that we will be justified in laying down the proposition that, *as a rule, light weights are not good insurance risks*, and then leave it to be hereafter determined how far and in what respects that assertion is correct.

DISEASES CAUSED BY THE INHALATION OF DUST.

By DR. GOTTLIEB MERKEL,

OF NÜRNBERG, GERMANY.

Translated by Dr. HORATIO BRIDGE, of New York City.

THE idea, that through the inhalation of impure air, especially that which contains dust in greater or less amount, diseases of the respiratory organs may be induced, is so old, so universally established, that, indeed, scarcely anything more in general can be said

concerning the same. Every text-book and treatise on pathology expresses this idea in its connection with the etiology of lung diseases, and no one has as yet seriously undertaken to maintain the contrary, or to doubt the fact. Meantime there are so many injurious influences which affect the respiratory organs, that this single noxious influence of the inhalation of dust, generally speaking, attracts but little attention, because the breathing in of air mixed with dust, as it occurs in every-day life, is only a transitory circumstance, and is wont to be considered only an exciting cause among persons otherwise predisposed to diseases of the organs of respiration (*e.g.*, through inheritance, unfavorable objective influences, improper diet and dwellings, irregular habits of life, defective development of the thorax, etc.).

This etiological consideration assumes a much more important aspect—1, when it can be proved that it is capable of producing forms of disease peculiar to itself; and 2, when large numbers of persons become diseased, who are compelled to breathe an atmosphere rendered impure by dust.

The first attempt to establish proof that special forms of disease follow the inhalation of dust was made, to the best of our knowledge, by the Italian, Ramazzini, in his work, "De Morbis Artificum Diatriba, Ultrajecti, 1703," for he was the first who called attention to wide-spread diseases prevailing from such causes among laborers and skilled workmen, whose employment was connected with the formation of dust.

From this time on there appear in all works upon diseases incident to the trades, and in board of health publications, opinions concerning the injuriousness of occupations which are characterized by the presence of dust.

Naturally the subject may be considered under two heads. On the one hand we have those forms of disease which may be induced by the inhalation of any kind of dust; and, on the other, the real "pneumonokonioses" (Zenker), which owe their existence to special kinds of dust. This division is then, I hold, the only possible one, and in the following pages I shall strictly observe the same, and only when treating of certain "pneumonokonioses" shall I incidentally enumerate the occupations of artisans and factory workmen which are capable of causing such forms of disease.

I must at this point at once remark, that the types of disease, even of the real "pneumonokonioses," are unfortunately not so well defined as one might believe and expect, and it is precisely on this account a difficult task to present a clinical picture of all the diseases here under consideration; it is all the more difficult, too, from the fact that it is scarcely possible for any one physician to have had the opportunity to observe all kinds of dust inhalation.

Although my opportunities for observation have been quite extensive, I must before proceeding farther confess, that in the majority of cases coming under my notice I have not made the diagnosis until the autopsy was performed; moreover, I cannot conceal the fact, that, the longer I have busied myself with the subject, the more decidedly has the conviction forced itself upon me, that in very many cases diseases of the respiratory organs, otherwise considered as idiopathic, have for their prime cause the inhalation of dust, and that the time will come when the diagnosis can be more positively made during life. In making this statement I do not at present take into consideration those cases of disease which affect large bodies of workmen, and which are ob-

served and easily recognized by physicians officially attached to mining and manufacturing companies, as they occur among miners, or needle and steelware polishers; I confine myself rather to those cases of chronic lung disease, as they are observed in private and hospital practice in all places, especially, however, in large manufacturing cities. I may add, also, that I do not write this little contribution as a monograph upon diseases caused by inhalation of dust, but rather as a statement of the views of a practical physician for the use of practical physicians, in order to call their attention to the meaning and importance of these forms of disease, and to offer them a ready guide to diagnosis and general prophylaxis.

Whoever wishes to enter into a more special study of the subject must consult that meritorious work written by Hirt (*Die Krankheiten der Arbeiter*. 1. Abtheilung, 1. Theil: Die Staubinhalationskrankheiten und die von ihnen besonders heimgesuchten Gewerbe- und Fabrikbetriebe. Breslau, 1871), from which I have for the most part taken statistical statements and many valuable ideas relating to the employments of artisans and factory workmen, with which I have had no opportunity to become personally acquainted. I would add, that I have in this work laid the chief stress upon the description of the "pneumonokonioses," properly so called, and have added all the rest, especially that in the appendix to the second part, for the sake of completeness.

I.

DISEASES WHICH MAY BE INDUCED, OR RENDERED WORSE BY THE INHALATION OF ANY KIND OF DUST.

1. *Catarrh of the Respiratory Organs.*—Whoever for the first time enters an atmosphere filled with dust, complains at once of dryness of the fauces, throat and lungs, as the first disagreeable symptom, and it would be superfluous to say another word in the endeavor to prove, that whoever must remain for a considerable time constantly in such an atmosphere is liable to contract a catarrhal inflammation, through mechanical irritation, in the parts above-named. The first troublesome sensations will appear at once, as stated, before material pathological changes can have occurred. The dryness in the throat is indicated at once by the effort of coughing to get rid of a disagreeable foreign substance, and this takes place before catarrh has declared itself; for there exist at this time not only real dryness of the mucous membrane, and clinging, tenacious mucus, but also an innumerable number of fine foreign particles, which the short and troublesome cough is designed to remove, but which, nevertheless, partly on account of their minute size and sharp edges (as sand, coal-, iron-, clay-dust), and partly on account of their propensity to attach themselves by suction to the moist mucous membrane (*e. g.* wood or cotton dust), cling firmly to it and withstand the action of the cough and of local muscular contraction. A long walk in our city, in a dry winter season, when a strong east wind whirls about the fine dust of the Keuper sandstone with which our streets are paved, is sufficient to excite these troublesome sensations; still more a prolonged stay in some factory, as, for instance, in a lead-pencil factory, in the room where the cedar-wood is cut and shaped, or in a tobacco-conist's workshop, where tobacco is being sifted. In a favorable case this irritation disappears, the foreign particles are expectorated, and no unpleasant consequence remains. Still (to choose a rather trivial example), the day after one has spent an evening in a small drinking saloon, in which there has been much

smoking, the grayish, black, tenacious sputa, and the particles of coal easily found in the same, are the only reminder of the noxious agent, which six or eight hours previously had attacked our organs of respiration.

In most such cases, then, it is quite sufficient to cease breathing the injurious atmosphere to avoid all bad consequences; those, however, who are especially disposed to lung diseases, do not so lightly escape, but acquire a real catarrhal inflammation, and suffer with the same for a long time, after the sputa no longer show a trace of the inhaled dust.

The irritation produced by the foreign substance results in a congested condition of the mucous membrane, with its consequent hypersecretion, in which we recognize the clinical picture of catarrh; and—upon this I lay especial emphasis—there is not the slightest difference between a simple catarrh and that induced by the inhalation of dust, when the exposure has been of slight duration. Such catarrhs arise, indeed, among all workmen without exception, whose employment is associated with the development of dust. These workmen, however, do not come under clinical observation, simply for the reason that they consider the catarrh an unavoidable evil, which each one, in accordance with a common experience, has to incur, and which in most cases passes off without inducing further evil results. The mucous membrane becomes accustomed to this mal-treatment after a time, and an occasional cough does not cause much annoyance. On the other hand, however, there are some who do not escape so easily. The catarrh, which occurred at first, does not subside; it is kept up by the continued action of the dust; it becomes chronic, and now perhaps after fever and other marked signs of departure from the normal physiological condition have declared themselves, the patient resorts to a physician, or enters an hospital.

The description of chronic catarrh is too well known to allow of the repetition of its symptoms here, even if I were so disposed. It should, however, be stated, that at the present time no distinguishing sign is known, which would pass as a means of differential diagnosis between simple chronic catarrh and that arising from dust inhalation. The sputa, indeed, do not at present aid us. I have repeatedly noticed, that workers in ultramarine, not suffering with disease of the respiratory organs, but consulting me on account of other diseases, have coughed up particles of ultramarine enclosed in cells, even a fortnight after they had left their work. This clinging of dust to the lining membrane of the bronchiæ does not continue, according to my observations, more than a fortnight.

If, then, the expectoration of such dust-particles continues still longer (after the work has been completely given up), this is a sign that other pathological conditions have supervened. But more in regard to this farther on. It may be said concerning the anatomical changes in these catarrhal affections, that one scarcely ever has the opportunity to observe them in the human being. And this opportunity is only then given when some workman, exposed to the inhalation of dust, and suffering with a consequent catarrh, dies in the first few weeks of his employment from some other disease. I was never so fortunate as to meet with such a case. The researches of Knauff give, at least in some degree, information on this point (*"Das Pigment der Respirationsorgane," Virchow's Arch., Bd. xxxix., 2, 3 S. 442, ff.*).

He placed animals for a longer or shorter time in an atmosphere thickly filled with coal-dust, and observed that the ciliary epithelium of the bronchial mucous

membrane became changed into chalice-like epithelium, filled with fat and myeline granules, and became detached from the mucous membrane. To this process Knauff ascribes chiefly the formation of the mucus, the secretion of the mucous glands themselves being comparatively insignificant. The desquamated degenerated epithelium, which assumed at one time the form of a Roman drinking-glass, whose base had been broken off, at another that of tumefied round cells, took up, he said, within themselves the minute foreign particles, which had been deposited on the mucous membrane. The same was true, however, of the alveolar epithelium. So the explanation was most simple, why, so soon after the first inhalation, dust-particles appeared enclosed in the cells. Knauff saw cells containing ultramarine, indeed, after the inspiration of pulverized ultramarine had been continued only ten minutes.

Knauff's assertion, however, that for weeks and months dust-particles occur in the sputa, enclosed in cells, without more serious pathological changes in cases of simple inhalation of dust, does not agree, as has been already stated, with my own researches. Here, in this connection, let me communicate an interesting observation which I made upon my own person. Although I noticed, after a short stay in a very dusty factory (whither I had gone to study the method of conducting the work, and the development of dust caused by the same), that the dust-molecules, from the very first demonstrable in the sputa, were after a short time no longer to be found, or at the latest on the following day, still, in the following case, the history was quite different:

I visited, while suffering with an intense catarrh of the nose, larynx and trachea, a factory (in my own town) in which gas-burners were polished with soapstone (magnesia and silica). I remained for about half an hour in the room in which the soap-stones were sawed out and turned into proper form, enveloped in a thick cloud of dust. Immediately after I left the room, the sputa contained free dust-particles in large amount, and a little later they were found enclosed in the cells. I found the last well-marked soapstone molecule three days after the inhalation. It was undoubtedly owing to the existing catarrh in this case that the dust remained so long in the bronchial tubes.

The chronic catarrhs of such origin disappear, when the workmen have absented themselves some time from their work, with such suitable régime and medication as one finds in every book on theory and practice. I have noticed that the workmen, after recovery from such chronic catarrhs, continued quite well, although they resumed their dusty employment, and followed it up for a long time. Of course the doubt always remained in these cases, whether the chronic catarrh was the result alone of dust inhalation, or whether other causes, either singly or associated with others, did not induce the disease.

II.

EMPHYSEMA OF THE LUNGS.

When we speak of emphysema of the lungs in connection with disease caused by dust inhalation, we of course do not take into consideration those vicarious emphysemas, which develop in cases of degeneration and destruction of greater or less portions of the lung tissue. These are simple conditions consequent on forms of disease, which shall be spoken of farther on, and which stand in no immediate relation to the original injurious influence exerted by the inhalation of dust.

We have next to notice that emphysema which is the result of simple or chronic catarrh, and that which would be considered as arising from the direct action of the inhalation of dust upon the lung parenchyma.

We can readily understand how an emphysema may result from a catarrh, if we bear in mind that, during the violent efforts of coughing, which are frequent in the course of this affection, the compressed air is forced upwards through the lower bronchus into the obliquely descending upper bronchus, and thence—under a sort of centrifugal pressure, caused by the obstruction which it encounters at the narrowed glottis—passes into and distends to their utmost the already full alveoli and the thorax. If this expansive force should meet with an obstruction, in the form, for example, of secretion within the bronchioles, there would then be no difficulty in accounting for the origin of emphysema, and especially so, in view of the fact that the dilatation of the upper portions of the lung, during the course of a chronic bronchial catarrh, through the compression of air by violent coughing, has been repeatedly proven.

Whether now the particles of inhaled dust which cling to the walls of the bronchioles, and so clog their apertures, can act the same part as an obstructing bronchial secretion, as Hirt is inclined to assume, remains as yet uncertain. It is indeed possible; still, in repeated microscopical examinations of fresh, of hardened, and of dried pneumonokoniotic lungs, I have never found such an obstruction due to foreign particles. Knauff, too, speaks nowhere of such a filling up of the alveoli or bronchioles with coal molecules.

Another question is this, whether a true emphysema can occur directly through the deposition of certain kinds of dust in the lung parenchyma, causing disease of the tissue. The observation of Zenker (atrophic conditions in the lungs of two tobacco workmen) has started this question, which seems to receive support, though indeed of no great strength, from a case observed by me (to be spoken of farther on). At all events, this question yet remains open, and still further observations and examinations must be added to those already made before a final decision can be given. At present the fact remains for us a fixed one, that the inhalation of dust leads to emphysema of the lungs, especially in that it gives rise to acute and chronic catarrhs. The classification of Hirt, according to which emphysema arises most often from mineral, then from vegetable, and finally from animal dust, seems to be based (diminishing in the order mentioned) upon the more varying powers of these different substances to produce catarrh than upon some specific influence exerted upon the lungs and their tissues.

We must reckon ourselves also among the sceptics when we consider the origin of bronchial asthma from the inspiration of certain kinds of dust (especially dust of the *ipeacuanha* root). In this case, irritation of the pharynx and mucous membrane may be the cause, and not the inhalation itself. Hirt is perfectly right in denying the propriety of treating hay-asthma under this head, for in this case a catarrh is indeed present, which is, in all probability, caused by parasites.

The consideration of the crystals, spoken of by Leyden, cannot be introduced here, for these may be present, according to my own and Zenker's observations, without a trace of asthma.

The treatment of emphysema in accordance with our views of its mode of origin differs in nowise from the treatment of this disease generally adopted. Here also the avoidance of an atmosphere filled with dust is of chief importance.

(To be continued.)

found to be greater than in those companies which hold insurances on a proportionately larger number of old lives.

Section 8 of this paper gives a statement of the mortality from small-pox among these 19 companies. The figures will be found in Table I. An average mortality from small-pox of nearly ten per cent. appears to us unusually heavy. In a recently published analysis of 1,000 deaths, which occurred in the experience of a life insurance company in this city, it was stated that 9 out of the 1,000 died from small-pox, or a little less than 1 per cent.

In section 9 it is shown that the mortality from consumption among the 19 companies is absolutely as well as relatively greater for the male than for the female sex. Among 1,000 insured males, 3.69 died from consumption; while among 1,000 insured females only 2.78 died from the same disease.

Section 10 discusses the question of age in connection with the deaths from consumption. The 925 deaths from consumption, which occurred among 18 of the companies already referred to, were distributed among the different ages, as follows:—

TABLE II.—CONSUMPTION.

Ages	20 and under.	21-25	26-30	31-35	36-40	41-45	46-50	51-55	56-60	61-65	66 & over.

Comparing the mortality rates for the different seasons, Dr. Oldendorff finds (Table III.) that during the spring of the year the mortality from consumption, as well as from all other causes, is greatest. Next comes winter, then summer, and finally autumn. This, we believe, coincides with the experience of our own life insurance companies; at all events, our mortality is almost always heavier during the months of March, April, and May, than at any other season of the year.

Finally, comparing the total consumptive mortality of the German life insurance companies with the average mortality from the same disease in the German population at large, Dr. Oldendorff comes to the conclusion that the mortality from phthisis among the so-called selected lives, at least between the ages of 20 and 30, is abnormally high. For instance, in the city of Frankfort-on-the-Main the mortality from consumption in 1872, for the ages 20-30, was 37.2 per cent. of the mortality for all causes; while, according to the experience of the life insurance companies, it was, for the same ages, 41.4 per cent.; or, out of every 1,000 persons living in Frankfort, between the ages of 20 and 30, there were 2.8 deaths from consumption, while the life companies experienced 3.5 deaths out of 1,000 persons of the same ages. And, furthermore, we must remember that the 989 deaths from consumption repre-

sented the *minimum* mortality experienced by the companies from this one source.

From section 18 we learn that the companies rejected, on an average, 14.7 per cent. of all the applications made to them for insurance; the smallest proportion being 6.4 per cent. (Swiss Annuity Institution), while the largest was 19.8 per cent. (The Prussian Life Ins. Co.).

In the last section of this exhaustive work Dr. Oldendorff discusses the scientific value of carefully-studied life insurance mortality reports, and urges upon the companies to make this hereafter a permanent custom among them.

THE MEANS OF AMELIORATING AND RETARDING THE EFFECTS OF AGE.*

By JOHN GARDNER, M.D.,

OF LONDON.

THE first item of advice we would offer to persons who have passed the meridian of life is, if possible, to secure for themselves mental tranquillity. The secular business of life, if it has been mainly employed, as it is with most of us, in obtaining the means of living

* From Gardner's "Longevity."

and provision for ourselves and families, ought to be over as soon as enough has been acquired to satisfy reasonable wants and desires, to secure contentment and quiet so far as worldly possessions can give them. If with an adequate fortune some object of ambition has been pursued, with age should come a calm retrospect and estimate of its worth. It is happy for a man who reaches this goal at the age of fifty, or earlier. At sixty, or as soon after as possible, our desires should be adjusted to our attainments and means, by modifying the former rather than attempting to better the latter by hazardous or even by legitimate enterprises. At least, all mental anxiety or disquietude should be carefully avoided. In this country, indeed, there are very many persons who never have any grounds for an anxious thought. Born to fortune and exempt from ambition, they are, nevertheless, subjected to the common lot of humanity, beset by troubles of another kind, some real, some imaginary. It is not the idle and listless who, in any marked measure, enjoy the blessing of longevity. Wholesome occupation and moderate means are most favorable to long life, which, as we have before remarked, attaches to the clergy, and to the female sex pre-eminently.

This fact teaches us the next lesson, namely, that *sobriety* is most congenial to health and life. Experience fails to support the pretensions of the zealous preachers of total abstinence from fermented liquors. A judicious use of wine, the quantity and quality being duly regarded, is certainly beneficial in advanced life. No rule can be given with any approach to accuracy as to the kind and amount of wine which is desirable. So much depends upon previous habits. I, for my own part, as a physician, greatly prefer to prescribe the wine, and define the quantity, for an aged patient who has been in early and middle age extremely temperate. If wine or other stimulant has been indulged in excessively, it is rare, on careful investigation, to find a person at or beyond the age of sixty-three entirely free from some damage in one or more organs. Still such damage, if not considerable, admits of reparation, when there is a resolute will to abstain, or regulate the amount of stimulants by the real needs of the constitution.

As to food, common sense should suffice for every one to observe the effects of any course, or article of diet, and to avoid any which is felt to be injurious. Generally, aged persons require a diet containing most nutrition in the least bulk. Hence, animal substances should preponderate. Generally, they will have a preference for mutton, poultry, game, and often for gelatinous food, rather than beef, pork, lamb, or veal. And this preference is in accordance with physiology. Farinaceous substances, although not excluded from the role of diet, should be adopted sparingly; exceptions depending upon special conditions, such as morbid leanness, disorders of the kidneys, etc., which will be spoken of below. We often witness grave errors committed from want of correct information. For instance, arrowroot, or some form of starch, beef-tea, so-called concentrated foods, etc., are taken for the muscular debility common in the aged. Under such a diet the weakness continues, and increases often to a fatal end. In the general defect of nutrition some one organ droops in function, and becomes disorganized, to the danger or loss of life.

As with the use of wine and stimulants, the diet of aged persons must be regulated by giving due consideration to their former habits, present mode of living, pecuniary means, and the like; but one rule may be suggested, namely, to divide the amount of

food taken into three or four meals, rather than one large one (dinner usually), in the day. A sense of fullness or oppression after eating should never be disregarded.

As the system in advanced life is more amenable to certain morbid influences from without than in early life, it is advisable for elderly people to be more watchful against them.

A wholesome dwelling, well drained, free from damp, its interior unaffected by changes of temperature without, and admitting free ventilation when artificially warmed, are certain conditions of prolonged life. Nothing is so fatal to old people as cold, and this is intensified by the addition of moisture. Therefore, when possible, a residence should be selected in an elevated position, on a sandy or gravelly soil, where fogs are rare, and where exercise, walking or riding, can be taken in fine weather without getting chilled or wetted. Night air, in our climate, ought never to be encountered. The evenings, if not the entire day, should be spent in rooms moderately heated—not too hot—and well ventilated. About 60° F. is the temperature most congenial. The bedroom especially should be kept at this heat both night and day. A glass-house for walking exercise during the cold of the winter is a great comfort. Exposure to cold with wraps about the throat and heavy clothing, should be decidedly avoided. Some people think it effeminate to have a fire in their bedroom in cold weather; this is a great mistake. Both for warmth and ventilation no means have yet been devised equally advantageous with an open fire and chimney; and by the use of certain species of coal, which burn slowly without requiring to be stirred, a tolerably equal temperature can be maintained through the night. When there is no fire the chimney should be kept open for the ventilation. Disturbed sleep and headaches in the morning are common consequences of the use of a closed register stove.

Of suitable clothing, varying with the seasons, it is unnecessary to speak.

Hot baths demand also great care. I have often known, and more frequently heard of, cases where they have proved fatal. When there are symptoms of head trouble, pains, dizziness, etc., suddenly depriving the brain of blood, immersion in hot water causes the blood to flow to other parts of the body, and induces cerebral collapse, and either immediate death, or fatal paralysis, or stupor (coma). For cleanliness, and to preserve a healthy state of the skin, I recommend all old people to employ hot water with soap and flannel or sponge (the flannel is best), using a moderate degree of friction. A foot-bath of hot water, with the addition of a tablespoonful of flour of mustard, is very useful when there is fullness of the vessels of the head, continued sleeplessness, or obstinately cold extremities.

A modified kind of shampooing—consisting of friction over the skin and kneading of the deeper textures, muscles, and joints—is a very useful proceeding to remove the stiffness and immobility and the sense of fatigue after slight exertion, often experienced. This process will often remove the pains in the loins besetting elderly people, as well as impart elasticity to the limbs and agility to their movements.

A tranquil mind, well-selected and arranged diet, moderation in the use of wine and other stimulants, exercise short of fatigue in favorable states of the weather, confinement to a warm house in cold or wet weather, well-warmed and ventilated sleeping apartments, clothing adapted to the seasons, maintenance of the animal heat of the body, particularly of the lower extremities, careful avoidance of external influences

tending to produce disease, malaria, and the like; judicious bathing, to secure a healthy skin—these are the principal points claiming the attention of aged persons, even when enjoying the best health.

To these must be added immediate recourse to the physician when any overt disorder or suffering is experienced.

My purpose is not to teach elderly people to treat themselves when ill, but to deal with infirmities besetting them, which are generally borne without an effort to obtain relief, being regarded as either too insignificant or as inevitable and irremediable evils. In some instances, such conditions or changes in the system as would be sure to bring, in a longer or shorter time, disorders and fatal disease if neglected are shown to be amenable to simple and easily-employed measures.

The question may now be asked, whether there is any probability, or even possibility, of the discovery of a physical agent capable of completely arresting the changes in the system constituting ageing, or preserving the integrity of the body and all its parts with the vigor of youth and middle age up to the extreme limit of life.

This question is by no means an idle one. If, a few years since, it had been asked whether it were possible for any thing or process so entirely to suppress feeling that the limbs could be amputated without pain, such a question might well have been deemed visionary, and treated with contempt. But the use of anesthetics has now been practised so long that their effects cease to excite our wonder, although they are really most wonderful. Not one or two agents with this property, but many, are now known.

Scientific ideas run long in grooves. When a new line is struck and followed, most unexpected discoveries are made. Inferences from analogy are easy or obvious; yet they are often most prolific in results. Inoculation of small-pox led to the discovery of vaccination. When the nature and properties of such agents as the ethers, chloroform, chloral, and its hydrate, are considered, together with their history and the manner in which they became known, we are greatly encouraged to hope for the discovery, at no distant period, of an agent which shall effectually stay the changes in the system incident to age,—in short, arrest the progress of what we call decay. Whether the mineral, vegetable, or animal kingdom will furnish it, we cannot foretell. Our knowledge of the action of vegetable products on the human constitution, extensive as it is, is yet only of a minute proportion of the whole. Vegetable substances exert a wide and various healing influence. Opium, foxglove, colchicum, belladonna, tobacco, tea, etc., etc., are to a certain extent known. Thousands are partially recognized; but who shall say what future experiment may bring to light?

It is, however, rather to a comparatively new class of bodies we look as the most probable source of the great desideratum. The chemistry of ternary and quaternary compounds, formerly designated organic chemistry, presents us with what is practically an illimitable number. To this class of substances belong the most energetic and manageable anesthetics; and either by enlightened inquiry, or as the result of some accident, it is almost certain some of them will be found to exert a powerful action on the living system. Already, out of the line of anesthesia, or narcotism, we have one of these artificially prepared substances, which promises to be a remedy for that habit of body termed the gouty diathesis—a condition so very frequently issuing in overt and fatal disease.

By the combined aid of physiology and chemistry we are approaching very closely to an exact knowl-

edge of every kind of material (proximate elements) forming the human body—their exact constitution, composition, and mode of formation. Some of them can be made artificially in the laboratory—a certain proof of science being on the right track. We may, therefore, look with confidence to these sciences to investigate completely the changes induced by diseases which are most frequently results of the intrusion of foreign substances with the air, water, or food into the processes of formation, sustenance, or decomposition of the natural compounds. The changes in ageing are consequently not beyond our reach; and it is probable that a rational and scientific basis will be laid ere long for completely arresting them.

Whilst great energy and vast sums of money are expended on experiments in mechanics, electricity, etc., the means of arresting disease and prolonging life are left to hap-hazard individual efforts, seldom or never rewarded.

Jenner's case is singular. Philanthropy is in complete subjection to fashion and precedent. Still I feel assured if the public could be brought to apprehend the prospect of success by investigations instituted with the object of discovering the means of prolonging human life, pecuniary aid would be forthcoming. It is only by well-concerted efforts, and having definite ends in view, that our present science can be made available for the purpose. Its processes are very costly, both in time and money, but in a country where wealth so abounds, the latter ought not to be the obstacle. There are men, too, quite capable and qualified, but they are necessarily engaged in other pursuits, whilst most erroneous ideas on the subject generally prevail. At some future time the indifference and neglect of the present will excite remark and wonder.

In the meantime we must proceed in another direction, guided simply by experience and such analogies as may be found and accumulated by observation. Much has already been done, but very few have the full benefit of the knowledge already obtained.

A healthy and vigorous state of every part and every organ is essential to the health and well-being of the whole system. And as ageing—or what is the same to our means of observation—begins sometimes locally, and sometimes over the system generally, we first look for the local degeneracy, and, finding none to call for special remedies, we address ourselves to the entire system. We have many and most valuable agents capable of invigorating and imparting tone to the whole. And these, judiciously selected and combined, and administered with a full knowledge and control over the diet, regimen, and habits of a patient, will greatly ameliorate the effects, if not retard the advance, of ageing. He must have had little experience who has not seen this influence exerted by well-selected remedies.

Miscellaneous.

THE CHAMBER OF LIFE INSURANCE.—The report of the Committee on Medical Examinations and Examiners, of which Mr. Bewley, of the *Universal*, is chairman, was read. It was able and thoughtful, its chief feature being the recommendation that the companies unite in each prominent locality upon the most competent examiner, and employ him exclusively. Action upon this report was deferred until the next meeting in October, for which meeting it is set down as first in the order of regular business, the companies meantime being requested to give it a careful consideration.—*The Chronicle*.

Original Lectures.

CLINICAL LECTURE ON FIBROUS ANCHYLOSIS, CHRONIC SYNOVITIS, ETC.

By LEWIS A. SAYRE, M.D.,

PROF. OF ORTHOPÆDIC SURGERY IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK CITY.

Phonographically reported for THE MEDICAL RECORD.

GENTLEMEN: The first case that I bring before you to-day is this girl, who has been suffering for some time from fibrous anchylosis at the hip-joint.

This form of anchylosis in many cases very closely assimilates bony anchylosis. It is important, therefore, that you should be able to distinguish one from the other with great certainty, for the management of the two conditions is conducted upon entirely different plans.

In those cases which most closely assimilate bony anchylosis—for it is in such that differential diagnosis is most difficult—if movements are made at the joint, and any motion whatever is secured during the manipulation necessary to a thorough examination of the case, it will be followed by more or less of pain within twenty-four hours. This is a distinguishing feature of cases of *fibrous anchylosis*.

For when bony anchylosis is present, no movements at the joint can be made, consequently pain will not be produced at the point of anchylosis. This rule you will find to be reliable. The subsequent occurrence of pain in and about the joint, even if there be no apparent motion, will justify you in resorting to measures calculated to give to it gradual restoration of motion.

In the case of this little girl, it was exceedingly difficult to determine whether any motion whatever was remaining at the hip-joint, so firmly flexed and adducted was her limb. But the day following the manipulation considerable pain was present, and other evidences of inflammatory action were quite well developed. The limb was placed at perfect rest by placing the child in bed. By the rest in bed and continued application of cold to the inflamed parts by means of icebags, an extension in the line of deformity gradually changed towards the normal. All inflammatory action was subdued within a few days, and then she was placed upon this instrument, which had been specially devised to meet the indications in her case. The instrument consists of a pelvic belt, with perineal bands; a long bar with a foot-piece and adjustment for extension; a knee-cap and a movable joint opposite the hip for flexion, extension, and abduction. At the movable joint arrangement is made so that, by means of screws, abduction and rotation of the limb outwards can be effected at the same time. It is, in short, a modification of Taylor's long splint, the modification consisting in the use of screws for obtaining abduction and rotation. It has now been one month since the instrument was applied, and the change which has been produced during that time is very marked. The limb has been abducted to such an extent that it is now nearly parallel with the opposite limb. This can be ascertained only by placing the pelvis in a fixed position. Rotation has been almost perfectly restored, and flexion and extension have been restored to considerable extent. Abduction and adduction are quite free, and the limb is upon the highway to complete recovery.

The case well illustrates what extraordinary results

can be obtained in the way of overcoming muscular rigidity by the application of a constant unremitting force. Under circumstances favoring the application of constant unremitting elastic force, equally as favorable results can be obtained by paralyzing muscular power, thus overcoming deformities produced by it.

CASE II. *Chronic Synovitis*.—This patient, as you see, is a man of medium size, exceedingly muscular, and forty years of age.

Some seven or eight years ago, while wrestling, his foot caught against the edge of a board in the floor, which was slightly elevated above the others, and the quadriceps muscle being placed in a condition of powerful tension, luxated the patella upon the right knee inwards, and he fell. While attempting to raise himself, the muscle restored the patella to its proper position. For a few days he was unable to walk, but in a short time recovery, as was supposed, was complete.

About two years after the occurrence of this accident chronic inflammatory action was set up on the opposite knee, and soon affected both knees; they gradually increased in size, and now, as you see, they are immense. One measures eighteen, and the other seventeen and a half, inches in circumference, and the calves of the legs are very much diminished in size.

For the last two years this condition has remained about stationary. The effusion is now so abundant that the patella of each knee is lifted from its articulation, and as pressure is made upon it, it can be made to strike the bones below with an audible *click*.

By transmitted light a lake of fluid can be seen below the ligamentum patellæ, with a large collection of semi-gelatinous material at its upper surface, presenting a very beautiful pathological appearance. These knees have received an almost endless variety of external applications, and his general system has received a great amount of medication, but all have failed to produce any change, and we now find them as they have remained for a number of years.

The effusion in this case has become so great as to preclude all possibility of its removal by absorption, simply because the excessive tension that has been made upon the absorbents has paralyzed their action in such a manner that absorption cannot take place.

The condition is analogous to that occasionally seen in ascites, when the pressure is so great from accumulated fluid that the absorbents will not respond to the influence of internal remedies. In that case, the removal of only a small portion of the fluid will in many cases reduce the tension sufficient to permit the subsequent removal of the remainder by the renewed action of the absorbents. This case, however, has been of so long standing that it is not probable that the removal of a portion of the fluid would be of any benefit, even though followed by the most constant and powerful compression.

In most cases, particularly in the sub-acute and earlier chronic stages, decided benefit can be obtained by pressure applied to the joints. This can be conveniently and effectually done by means of compressed sponge. Cover the joint which is the seat of the synovitis with compressed sponge, and retain it in position by means of a roller bandage. The sponge is then wet with warm water, which causes it to gradually expand and thus produce an equal amount of pressure over all the parts covered; and it can be kept up as long as may be desirable. The sponge can be applied once or twice a day, according to the necessities in the case. Changing it every twenty-four hours is usually sufficient.

The question now arises, What is the best thing that

can be done for the relief of the present condition of this case?

A free incision will permit the fluid to escape, but the risk of exciting an uncontrollable inflammatory action would hardly warrant such a procedure.

What I propose to do in this case is to remove the fluid by means of the *aspirator*. This, also, is not altogether a safe operation, for inflammatory action may follow its performance; but, under the circumstances, it is the best operation that can be resorted to. In such a case as this, a certain amount of risk must be taken, no matter what operative interference may be adopted.

In all probability, simple aspiration will fail to give any permanent relief, for the reason that the case has been of so long duration. It is also altogether probable that the synovial membrane has become changed in its anatomical structure to such an extent, that permanent benefit will only follow the adoption of some more active measure.

There is a chance, however, that the simple operation of aspiration, followed by elastic pressure, such as obtained by the use of compressed sponge and a roller bandage, may accomplish a cure.

If simple aspiration does not succeed, the fluid will then be removed by means of the ordinary trocar; and when removed, the cavity will be injected with Lugol's solution of iodine. This principle of treatment is precisely the same as that which governs us in the treatment of the tunica vaginalis in cases of hydrocele; namely, to excite a new action in the old and changed membrane, by means of an irritating agent; and for this purpose the solution of iodine indicated is much the safest agent to be employed.

In either case the patient will be placed in bed immediately after the operation, the knees will be firmly bandaged, locked in a perfectly immovable apparatus, elevated above the level of the body, and perfect rest maintained. In addition, icebags will be constantly employed if necessary. The object is to retain the inflammatory action *just within* the point of danger. In this manner we may reasonably expect to bring about complete recovery.

CASE III. Cancer of Lower Lip.—These growths, seen not infrequently upon the lower lip, are usually regarded as cancerous in nature. Some of them are not. Some of them bear so close a resemblance to the ordinary epithelioma of the lip, that they cannot be distinguished from each other by the naked eye. They are usually the result of constant and long-continued irritation.

Fortunately there is one plan of treatment best adapted to them all. Remove them with the knife, and that makes an end of them.

There are some steps in the operation which are necessary to be observed if you would make a nice operation, and one which will prove satisfactory to your patient. The ordinary operation is to remove the diseased mass, by making a V-shaped incision, large enough to embrace the whole of it.

Serious hemorrhage can be avoided during the operation by having an assistant make pressure upon the facial arteries as they pass over the ramus of the lower jaw. The wound can be closed by means of sutures, or pins with the figure-of-8 suture. I commonly employ the pins. These are to be passed through the lips of the wound, and then its edges are brought together in such a manner as to avoid leaving any notch in the free margin of the lip. The attachments of the cheek may be loosened with the knife if necessary, in order to give more opportunity for perfect adjustment. Two pins are usually sufficient. After

the pins have been adjusted and the sutures twisted about them, do not neglect to place a piece of adhesive plaster beneath the point of the pins to prevent irritation and excoriation. Next, long narrow strips of adhesive plaster are to be adjusted in a manner to give support to the pins in holding the lips of the wound in coaptation. These strips, passing above and below each pin, should be carried far back upon the sides of the face and neck. Carefully adjust the edges of the wound a second time, as the plaster is carried over them. The pins are to be removed within 48 hours at most after the operation. To do this without disturbing the wound, seize the pin at the head with a pair of pincers, and carefully turn it round once or twice before making the least traction. With this precaution the pins can be withdrawn without disturbing the threads or plasters, which together with the crust, are left remaining, and should not be removed for some time. Unless the pins are removed before ulceration and suppuration have been established about them, scars will be left at the points of insertion and exit; but with this precaution scar can be avoided.

CASE IV. Ingrowing Toe-nail.—Here, gentlemen, is a case which belongs to the every-day practice in surgery. It is important, therefore, that you should understand how to manage successfully such little cases. Almost any one can cut off a limb, but it is not every professed surgeon even who successfully manages these painful cases of ingrowing toe-nail. It is quite fashionable, especially in cities, to recommend these people to go to some *specialist*, who "knows all about corns, toe-nails, etc.;" and one of these cases is scarcely ever met here but what has been more or less treated by that class of men. Narrow-soled shoes and boots are the great prolific sources of this difficulty. A great many people imagine—and we are sorry to be obliged to say that the greater proportion of this class is made up of ladies—that a narrow foot and high instep are elements of beauty. The result, however, of these efforts to distort the foot is, the toe-nails cut their way into the tissues, and the tissues become hypertrophied. The appearance very commonly presented is a large mass of fungous granulations rising up from the side of the nail, as you can see very well illustrated in this case.

The toe cannot be cured until this redundancy of flesh is gotten rid of. Sometimes it becomes necessary to employ the knife in the removal of this superfluous growth. Nitric acid is a very good application, and nitrate of silver is another.

Immense relief can be afforded by applying a few threads of cotton beneath the cutting-edge of the nail, in such a manner as to protect the excessively tender tissues from the irritation produced by being crowded in contact with it. When the cotton is properly applied, pressure upon the ball of the toe will give no pain. The proper instrument with which to apply it is a narrow thin knife-blade without cutting-edge. With this instrument draw a few threads of cotton down between the nail and the mass of granulations, and so on until they are carried beneath the cutting-edge of the nail. This operation will give some pain during its performance, but the relief which will be afforded by it will be most marked. After the application of the cotton, pencil the fungous granulations over freely with nitrate of silver, or with whatever may be used for the purpose of destroying them. Repeat the application as often as the destroyed tissues separate, until the exuberant growth is all destroyed.

CASE V. Fracture of the Forearm, Phlegmonous Erysipelas, and Inflammation of Wrist-joint.—The next case I present to you, gentlemen, is one of consider-

able interest. This man first suffered from a fracture of the forearm. Phlegmonous erysipelas attacked the limb a short time after the accident; and you will here notice the many openings which have been made for the free escape of pus, numbering, as the house-surgeon says, thirteen. The wrist-joint has also become involved in the inflammatory process. The case was one set down for amputation, but I resolved to make an effort to save the limb.

The difficulty involving the wrist-joint was the chief obstacle to be overcome. The thing desired was to place the joint perfectly at rest, and at the same time remove all pressure from the articular surfaces. How was this to be done? Take a piece of sole-leather, long enough to reach from the digital extremity of the palm of the hand to near the flexure of the elbow, and wide enough to half or two-thirds surround the arm. Dip it in cold water, and make it thoroughly flexible. Cover it with a piece of adhesive plaster, plaster side out, long enough to go completely around it lengthwise, and lock. Now, having covered each opening with a piece of oakum, apply the leather-lined plaster to the palm of the hand, mould it, and secure it with a roller bandage as far as the wrist. Having arrived at that point, grasp the hand already covered, while an assistant grasps the arm near the elbow; then making extension and counter-extension, until the patient tells you that all pain is relieved, bring the remainder of the leather-lined plaster against the forearm, and secure it with a continuation of the bandage. In this manner all pressure is removed from the articular surfaces, pain is relieved, and an apparatus is afforded which retains everything at perfect rest. It is almost impossible to devise any means for meeting the indications in this case which is simpler than this. The leather is much better adapted to such uses than a board, for the reason that it can be more perfectly moulded to all the inequalities of the limb. The plaster lining holds it securely in position, in such a manner as to prevent slipping. Since the application of this splint the cedematous condition of the limb has passed away, and the question of amputation is no longer present for consideration.

DERANGED MENSTRUATION

FROM IMPERFECT DEVELOPMENT OF THE REPRODUCTIVE ORGANS AND DISEASES OF THE GENERAL SYSTEM.

By PROF. ALEX. J. C. SKENE, M.D.,

LONG ISLAND COLLEGE HOSPITAL, NEW YORK.

GENTLEMEN:—In girlhood the reproductive organs simply exist. They perform no function, and rarely suffer from any disease. It is not until the individual is matured that the attention of the vital forces is directed to these organs. Until then the young girl knows nothing, or should not know anything, of the nature or functions of this portion of her organization. But just as soon as she has attained to something like complete formation as regards size and shape, the pelvic organs undergo what has been already described as secondary development, and their functional activity begins. This occurs in accordance with the universal law which is observed throughout the whole vegetable and animal world. As soon as the plant or animal has attained its growth, the function of reproducing its kind comes into play.

In those glandular-looking bodies, the ovaries, an ovule is matured, and finds its way into the upper end of the reproductive canal. At the same time the vital forces direct special attention to these organs. This is manifested by greater excitability of the nerves, and an increased supply of blood to the part. The uterus stands prepared with accommodations and plastic material to build this ovule up into a human being. If impregnation occurs, then utero-gestation goes on and the function of reproduction is completed at parturition. If impregnation does not occur, then the blood sent to the uterus is recalled for. There is no new growth in the part to utilize the increased supply of material. In this engorged condition of the uterus, with no demand to relieve it, the smaller blood-vessels of the mucous membrane rupture, and hemorrhage occurs. Then we say that the patient menstruates, has her catamenia; or she may tell the doctor that she has her courses, periods, periodicals, sickness, turns, or feels poorly.

You will find in your books long chapters on the nature, cause, and character of this menstrual flow. Some call it a simple hemorrhage, and others claim that it is more of the nature of a secretion. Judging from the outward appearance of the menstrual fluid, we may safely call it blood slightly diluted with the normal secretions of the mucous membrane of the uterus and vagina. We might suppose, however, that the blood which is prepared and sent to the uterus for the purpose of nourishing the embryo, would differ in some of its constituents from ordinary blood. If so, then the menstrual fluid would contain elements peculiar to itself. The supposition grows more probable when we remember that, if the catamenia fail to appear from causes other than pregnancy, the general health suffers. The retention of the menses has a poisonous effect, some would say. All this, however, is only speculation; and it is far more important for us practical men to understand the laws which govern menstruation, and the nature and cause of its disorders.

We are told that very extensive observations show that menstruation begins at all ages, from twelve to eighteen; and that while in most cases it returns every four weeks, and lasts five or six days, still, within the bound of health, there are great variations from these rules. The truth is that there is a great difference among healthy females, but each person is generally guided by definite habits in the performance of this function. We must not seek for laws which will govern all persons in menstruating, but rather take those rules which apply to each individual. Most of you will remember facts better than figures. The following rules ought to be borne in mind, because they are useful in practice:

1. Menstruation should occur at puberty, *i.e.*, when the individual is physically mature, no matter what the age may be.
2. It should recur at regular intervals, say about every three or four weeks.
3. The flow should continue a definite length of time, at least varying but little.
4. The quantity should be about the same each time.
5. It should be uniformly fluid in character and sanguineous in color.

While we find great variation among individuals, each person ought to be regular as to recurrence, duration, quantity, and character of menstruation.

Keep these facts in mind; they will aid you in diagnosis, both in functional and organic uterine diseases.

There are certain conditions necessary to the performance of healthy menstruation. These are:

1. Maturity of the individual.
2. A normal development of the reproductive organs.
3. These organs must have a sufficient supply of healthy blood.
4. The nervous system presiding over the action of these organs must afford a normal influence.

If any of these requisites be partially or wholly wanting, then menstruation must be materially affected. There are so many ways in which this process may be directly or indirectly affected, that it would be impossible to even name them all. It will suffice for practical purposes to consider the more common causes of deranged menstruation. These may be grouped under two heads:

- I. Undeveloped or malformed reproductive organs, and lesions of these organs.
- II. Affections of the general system.

Under the first head, we find these organs immature—they remain through life in a rudimentary condition. And one or more of the organs may be entirely absent; the uterus or ovaries may be wanting. Again, the form and size of these organs may be normal, but the uterus or vagina may be occluded.

Under the second head may be briefly classed all diseases which decidedly impair the general health; such as the more important organic affections, and all serious blood diseases.

Turning to the first group of conditions causing defective menstruation, we find a necessity for a subdivision:

1. When from defective organs there is no effort made to menstruate. When the uterus or ovaries are absent or imperfectly developed, the external manifestations of maturity or womanhood do not appear. She either remains to all appearance a girl, or becomes masculine in character. The same may be said of cases where all the organs are present, but they remain in a rudimentary form.

2. When all the conditions necessary to menstruation are present, and the flow does not occur. In this class all the signs of the existence of the generative organs appear; the patient has all the symptoms of menstruating, except the flow. While the hemorrhage occurs, it fails to escape, owing to occlusion either of the uterus or vagina.

The point of interest which you ought to remember in this connection is the distinction between deficiency of the generative organs, and obstruction at some point in the reproductive canal.

Regarding the first of these, or imperfect development, they are rare to begin with, and in most of them our duty ends when we have made a correct diagnosis. When any of the organs are wanting, we cannot cause their formation; hence treatment is useless, and must be left out of the question. When the organs are present in a rudimentary state, we are advised to employ treatment, in the hope of inducing the completion of development. Thus we can stimulate the uterus by the introduction of the sound and sponge tents, the local use of electricity, cupping, blistering, etc. But these will all fail, in some cases at least, and the reason why will be explained by the history of this specimen of ovaries, uterus, and vagina. You see at a glance that they are all rudimentary, like those found in girlhood, though they were taken from the pelvis of a lady 32 years old.

The history of the case is this: Dr. Andrew Atterson kindly invited me to be present at the *post-mortem* of a lady, a member of a family he had long attended.

The doctor told me that he had known this lady from her youth up. She was known to have female external organs of generation, but had never menstruated. Indeed, when the period came for her to be transformed from a girl into a mature woman, she became quite masculine in appearance. In place of her mammary glands becoming developed, they remained rudimentary, exactly as in the male subject. Her beard grew black and heavy; her forehead got bald; and though she dressed like a lady, she walked like a man. She was attacked with apoplexy, and a physician near by, who was called in to see her, concluded at once that she belonged to the masculine gender. She never rallied from the attack, but died in a short time. *Post-mortem*, we found all the reproductive organs present, but only in the rudimentary form, as you here see them. A careful examination of the ovaries explains why the organs remained in this imperfect state of development. The ovaries are deficient in their essential element, the graafian follicles. These follicles develop the ovules, as you know, and the maturation of the ovule is the starting-point in the secondary development of all the other organs. They give the first impulse. The very first link in the chain is wanting in this case. The graafian follicles and vesicles, which are absent here, are the all-important elements; the other organs are all secondary to them. Practically, then, this subject was without ovaries.

In cases coming under the second subdivision, or obstructive condition, we are called upon to employ active treatment; and in general we may relieve such patients promptly and permanently. When puberty has come, and the patient has had all the subjective symptoms of menstruation, these being followed by excessive fullness, weight, pain, and distress in the pelvis, we may suspect obstruction. A physical examination will give the evidence of an accumulation in the pelvis; and if we still have doubt as to its nature, the use of the exploring needle will complete the diagnosis. The treatment, as will be readily understood, consists in removing the obstruction, wherever it may be; and when the accumulated fluid has escaped, to keep the part from closing again.

When great distention has occurred, either of the uterus or vagina, from the accumulation of menstrual fluid, there is generally marked disturbance, and occasionally severe inflammation of the pelvic organs. This is not always relieved when a free exit is established. On the contrary, the opening made to permit the fluid to escape occasionally sets up inflammation, and free suppuration follows, and at times even septicæmia or pyæmia. But fortunately such cases are rare.

Far more common, and hence more interesting to us, are those forms of menstrual disorder due to diseases of the general system. It may be stated as a general rule, that any important constitutional affection which reduces the strength a long way below par, will affect menstruation. This is most certainly the case when the general depression continues for a long time. Without attempting to name all the diseases which may cause either arrest or derangement of menstruation, I will simply mention phthisis pulmonalis. In the advanced stages of this disease, the menses generally stop altogether. The uterine function ceases under these circumstances, simply because the system is unable to sustain it. It is a conservative, economical tendency on the part of nature to drop this function of the uterus, because it is not immediately essential to the life of the individual. Now what occurs in phthisis may take place in any of the low forms of long-continued disease. In acute diseases, such as

pneumonia or typhoid fever, the menses may be interrupted for a period or two, but usually reappear when the constitutional disease subsides. On the other hand, in the degenerative diseases, such as organic affections of the heart, liver, lungs, or kidneys, the menses often become irregular and scanty, and finally stop altogether during the remainder of the invalid's life.

The diagnosis in such cases is, as a rule, easily made. By the time the uterine function is disturbed, the constitutional disease is so far advanced as to be recognized at a glance by any one at all skilled in diagnosis.

The treatment of menstrual derangements under these circumstances may be disposed of in a word or two. Remembering that it is a wise provision on the part of nature to drop the uterine function, because unable to sustain it, we see at once that it would be unwise on our part to try to restore menstruation. This we must keep in mind, because our patients are often very anxious about the absence of the menses, and urge us to give emmenagogues to restore them. We must protect such patients as far as possible from themselves.

The next class of menstrual disorders for our consideration are where the uterine function appears too early or too late; in other words, premature and retarded menstruation. The rule given is, that the menses should appear at puberty; hence if they come before or a long time after, there is something wrong.

Premature menstruation is an unfortunate occurrence, and one that is not uncommon. We cannot make a correct diagnosis by getting the age of the patient. We must judge of her capability to menstruate by her maturity of body. We know that until the individual is mature menstruation should not occur. There are many little girls, however, who begin to menstruate before they are properly developed. The causes of this premature effort of the reproductive function are various. I am inclined to think that bad air, poor food, and hard work may tend to cause premature menstruation occasionally. If I am right in this opinion, the fact may be explained on the general principle observed in nature, that all organic existences, be they plants or animals, placed under unfavorable conditions of life, make stronger efforts to reproduce their kind than those more favorably situated. They appear to feel that there is a danger of losing their hold on existence, hence they make extreme efforts to procreate, and are unusually prolific. According to this view of the matter, poorly-cared-for girls, like stunted plants, run to seed. Another, and perhaps the most important cause of premature menstruation, is deranged innervation. The attention of the individual being abnormally directed to the reproductive organs, they are called into functional activity before the proper time. Among this class you will occasionally find those who are so unfortunate as to have acquired the habit of masturbation. Among the rich—or I ought to say among those who are so poor that they have nothing but money—you will find young girls who do nothing but eat heartily, sleep, and slightly amuse themselves by reading questionable sensation novels. This high feeding and indolence, with unhealthy mental excitement, occasionally beget premature menstruation.

Regarding the management of such cases, I may briefly say, that when menstruation has begun, though prematurely, we use no efforts to stop it. We are limited in our treatment to simply trying to build up the general system of the patient. If overworked and

underfed, improve these conditions. If the abnormal conditions are in the brain and nervous system, then these require attention. The mind of the individual should be called away from the reproductive organs, and directed to healthy exercise.

Regarding the next section of this class—retarded menstruation—very little need be said after what has been stated regarding its premature appearance. Impaired general health from debility occasionally postpones menstruation. On the other hand, great, strong, healthy-looking girls sometimes go on to eighteen or nineteen without any appearance of the catamenia. What is popularly known as "good living," and lazy, indolent habits, produce a sluggish condition of all the functions; and menstruation under these circumstances may be occasionally retarded.

In the one class of cases we try to build up the general health, and in the other we try to excite greater activity of all the functions. When there are regular periodical symptoms of menstruation, a well-marked *molimen*, without the flow, emmenagogues may be given. I shall reserve what I have to say regarding those remedies which tend to produce menstruation till another part of my lecture.

The next form of derangement to be considered is what is known as amenorrhœa. This term, if taken in its literal sense, would not convey the meaning which we attach to it in medicine. We not only apply it to complete suppression of the menses, but we also use it when the flow is scanty. We include under the head of amenorrhœa all those cases where the function of menstruation has been established, but has stopped or is scanty. The causes of these derangements are very numerous, and cannot easily be remembered in detail; but we can readily recall the fact that all exhausting diseases, acute or chronic, generally affect menstruation. In acute diseases, such as typhoid fever or pneumonia, as already mentioned, the menses may be suppressed for one or two periods, and be scanty during convalescence, but when the general health is restored the uterine function resumes its normal activity. The organic chronic diseases which derange menstruation have already been noticed, phthisis pulmonalis being the chief. The rule is, that when the constitution breaks down under any severe disease, the uterine function is held in abeyance. As exceptions to this rule, I may state that in cardiac and hepatic disease we sometimes see menorrhagia, or unnaturally free menstruation. In practice, however, amenorrhœa is most frequently seen resulting from debility without organic disease.

Anæmia, or poverty of the blood, and derangement of the nervous system, are the most common causes of amenorrhœa. We stated at the outset that perfect innervation was one of the necessities to healthy menstruation, and we may as well dispose of that part of our subject before taking up anæmia and its effects on the uterine function.

Whatever greatly disturbs the nervous system tends to produce amenorrhœa. Shock from fear, profound sorrow, over-mental taxation in any form, the fatigue and anxiety of a long journey, will cause suppression of the menses. Menorrhagia may occur under the same influences, but the opposite condition, amenorrhœa, is the more common result of such disturbances. A sea voyage will often produce amenorrhœa, and I presume it does so by affecting the nervous system. We see much of this form of menstrual suppression in this city, where so many emigrants land every year. Strong, healthy young girls, who menstruate quite regularly at home, fail to do so when they get here. This suppression of the menses is most likely to occur if the period

cross on when they are at sea. If they can only get across in the interval between, they are more likely to escape. Knowing this fact, we should always advise our patients to cross the ocean between their menstrual periods, if they possibly can. While, as we have seen, strong mental emotions are liable to interrupt the uterine function, it is interesting to notice how the relation of cause and effect may be changed in such cases. A shock to the nervous system, about the catamenial period, will prevent its appearance; but when the mind has been quieted, the menses ought to return at the following term, and doubtless do so in most instances. There are cases, however, when the suppression of the menses so depresses the mind of the individual as to keep up the amenorrhœa.

The treatment of such cases may be given in a very few words. All sources of mental anxiety or irritation should be removed, and the patient cheered and encouraged. Good wholesome society should be secured as far as possible.

Amenorrhœa from a deficient supply of good healthy blood—in other words, deranged menstruation from anemia—is the condition most frequently met in practice. The causes which produce anemia are numerous, but they may be classed under two heads: first, an insufficient supply of proper food; and second, an excessive demand upon the powers of the system. Direct loss of blood, hemorrhage from any cause, might also be mentioned; but the anemia which is produced in this way generally disappears soon, if the other conditions of health are normal. Hence hemorrhage, unless often repeated, is very seldom the remote cause of amenorrhœa.

The symptoms of amenorrhœa, and the condition of the system accompanying it, are generally well marked. The menstrual flow is either suppressed altogether, or is very scanty and light-colored. In some cases the menses return at irregular intervals, say every six weeks or two months. In others a leucorrhœal discharge replaces the normal fluid. The patient shows all the indications of anemia. The face and mucous membranes are pale; the eyes are unusually clear and bright; the pulse is small, and often quick and irregular—in popular language, there is palpitation of the heart. The blood is unequally distributed, as evidenced by cold hands and feet, and the sudden flushing of the face upon the least excitement. The nervous system suffers in common with the rest. The patient is often excitable, irritable, and low-spirited. Nutrition is peculiarly affected. The patients are often in good flesh. The appetite is generally capricious, and the bowels constipated.

The diagnosis is easily made, as a rule. The *menopausis*, or change of life, and pregnancy, are the only conditions likely to come in the way. The former may be excluded by taking the age of the patient; the latter often requires more close attention. Pregnancy, where the patient desires to conceal the fact, might be taken for amenorrhœa. Regarding the diagnosis of pregnancy, I cannot here enter into full details, but will give you a classification of the signs and symptoms of pregnancy which may aid your remembrance:

1. Symptoms manifested by the general system.
2. Signs and symptoms manifested by the reproductive organs.
3. Signs and symptoms produced by the fœtus *in utero*.

When the fœtus *in utero* gives rise to the ordinary signs of its presence, then the diagnosis is sure. It is only presumed on the evidence given by the reproductive organs, and these include the mammary glands. The condition of the general system is the point of

most interest to us at present. To fully point out the differential diagnosis between pregnancy and amenorrhœa would be tedious for us now, and hard to be remembered afterwards. This much, however, you can easily keep in mind, that in pregnancy the general health is usually good, and the individual shows it; while in amenorrhœa the patient gives evidence of imperfect health, as a general rule.

The treatment of amenorrhœa from anemia should have two objects in view: first, to restore the normal condition of the blood; and second, to restore menstruation. If the first can be obtained, the second will follow, in the majority of cases. The digestive organs require to be cared for first of all. The appetite is often poor or capricious, the bowels constipated, the tongue coated, and the stomach distressed by taking food. Such conditions are most promptly overcome by giving at the outset a cathartic dose composed of pill, hydrarg. rubbed up with glycerine syrupus rhei aromat., and carbonate of magnesia. This mixture is pleasant, and will often improve the appetite and digestion at once. If there is a decided tendency to constipation, the most satisfactory results will be obtained from a pill composed of quinine sulph., ferri sulph., ext. colocynth. co.—about two grains of the first two, and half a grain of the last; with about one-eighth or one-tenth of a grain of ext. belladonna. The aqueous extract of aloes may be used in place of the colocynth. One of these pills, taken before meals, will often give the most agreeable results. The ferruginous tonics must be employed persistently until the health is restored, and much benefit will arise from changing them. I refrain from giving any formula, because you may change from time to time, until you have gone through the list. Chlorate of potash was much lauded in such cases at one time, and I have found it most useful when combined with tincture of chloride of iron. Wine or alcohol in some shape is also recommended in anemia. A small quantity may be given after meals, but remember that if it produces languor, or in the least impairs the appetite, it ought to be discarded at once. In addition to all this, those of you who practice in malarial regions will require to use quinine and perhaps arsenic. I need hardly remind you that you must include in your treatment exercise out of doors, sunshine, and change of air if practicable.

By faithfully keeping up this restorative treatment, you will succeed in curing the vast majority of your patients. Do not be discouraged if it takes a long time to accomplish the object desired. Amenorrhœa may exist for many months, and after all the menses return and continue normal. We have said that if you restore the general health, the menses will return, as a rule. There are exceptions to this. Occasionally you may get a case where the amenorrhœa persists after all the constitutional troubles have disappeared. Then it becomes necessary to use means with a view to directly excite the uterus to action. For this purpose a number of remedies, known as emmenagogues, have been used. Indeed, years ago, the causes of amenorrhœa were often lost sight of, and emmenagogues were employed as the chief remedies in the treatment of this affection. Such drugs, I am glad to say, are much less used now; they have given place to more rational treatment. They almost all act by producing irritation and congestion of the pelvic organs, and it is not too much to say that they were always uncertain and often injurious. I will not mention these old remedies, because you will not use them very often. In place of such medicines, I have for several years given the chloride of ammonium, in about five-grain

doses, every three or four hours; and I believe that good results have been obtained from it. This agent is one of the oldest remedies named in the history of medicine, and its effects have been carefully studied. It is considered to favor the rapid exfoliation of the epithelial lining of mucous membranes. Now, if this be true, we can understand how it will act well in cases of amenorrhœa—shedding of the epithelium of the uterine cavity being a part of the process of menstruation. This remedy appears to increase the flow when it is scanty, and sometimes to start it when it has been absent altogether. I must acknowledge, however, that we may be claiming too much for this agent; but this much I may say, that chloride of ammonium, in my opinion, will accomplish as much as any emmenagogue, while at the same time it is perfectly safe.

By way of concluding this part of my subject, I may remind you that perseverance is a very important element in the management of such cases. Stick to your patients, and you will always succeed. No matter how long continued the amenorrhœa may be, the rule is that the menses will ultimately be established in a normal condition. There are few exceptions to this rule.

We come now to the last section of this subject—chlorosis. This affection is closely allied to menstrual derangements, and may be legitimately discussed in this connection. The pathology of chlorosis, and its relations to the functions of the reproductive organs, are still involved in some obscurity. The earlier writers on this subject considered chlorosis as an extreme condition of anemia or amenorrhœa, but more extended clinical observation shows that such is not the case. The points of difference between anemia and chlorosis are well marked. The pathology of anemia is simply impoverishment of the blood, while chlorosis is believed to be an affection of the nervous system. This belief is held because of the presence of pain and distress located in the solar plexus, visceral neuralgia, sadness, and nervous derangement, conditions which do not necessarily occur in simple anemia. The peculiar greenish color of chlorosis differs also from the pallor of anemia. The latter occurs at all ages, while the former is limited to girls about the period of puberty. The causes of these two diseases are widely different. At least we can almost always trace anemia to some well-defined cause, whereas chlorosis generally occurs without being traceable to any special source. Treatment also proves the difference in the two affections. Anemia promptly disappears when we remove the cause and employ the proper remedies; but it is not so with chlorosis, which often proves unmanageable under the most judicious treatment.

With these facts before us, we cannot doubt that chlorosis is a disease distinct from all others; and we must seek an explanation of its symptoms from other causes than those which give rise to anemia. Years ago, Virchow observed that in cases of chlorosis the heart and large arteries were abnormally small. There appeared to be an arrest of development in the circulatory system. This condition, so constantly found *post-mortem* in chlorotic subjects, led to the belief that it was the true pathology of the affection. Now I do not doubt, on the contrary I firmly believe, that Virchow found this anatomical peculiarity in his chlorotic subjects; but I am not prepared to admit that this condition of the heart and vessels is the cause of the disorder. I rather incline to the belief that chlorosis is the result of amenorrhœa on a system thus peculiarly organized. This view of the matter is taken from the fact that the prominent symptoms of chlorosis are not

manifested as a rule until puberty, while the defective growth of the heart and arteries exists before and after that time. Again, the chlorosis may disappear in advanced life, while the circulatory system remains the same.

The diagnosis of chlorosis is easy when one is familiar with the general appearance of such cases.

The treatment of chlorosis is not specific. We might refer to what has been said regarding the treatment of ordinary amenorrhœa from anemia, merely adding that iron, so beneficial in that complaint, is occasionally useless in chlorosis. More attention requires to be given to the nervous system in this disease. Nerve tonics, including the phosphates, are called for, and ought to be used for a length of time. The fact is that the most judicious treatment often fails to overcome this peculiar affection.

Original Communications.

ON THE USE OF

CONIUM AND CROTON CHLORAL HYDRATE IN THE TREATMENT OF ACUTE INSANITY.

By HORATIO R. BIGELOW, M.D.,

HARTFORD, CONN.

IN the year 1871, Prof. O. Liebreich published, in a scientific journal of Rostock, his discovery of the chlorine combination of the aldehyde of crotonic acid—which he called croton chloral hydrate—this compound bearing no relation, however, to croton oil. Its form of white, glistening, small *tablets*, its sparing solubility in water, will readily distinguish it from chloral hydrate. Its physiological action is also different. A sufficient dose will produce deep sleep, with absolute anesthesia of the integument of the head, muscular excitability remaining unaltered. It does not affect the pulse, or respiration. In cases of acute mania, in which this remedy was administered by Prof. Liebreich,* in the stage of great excitement, there was no constitutional perturbation whatever, the patients falling quietly asleep in their chairs a very few moments subsequent to the administration of the drug, as will be shown hereafter. It is particularly efficacious in the treatment of neuralgias.

In those cases wherein, by reason of cardiac disease, chloral hydrate is contraindicated, it is invaluable, no case as yet having manifested any deleterious effects from its employment.

Prof. Liebreich ascribes its mode of action to the product of secondary decomposition (*beruhen nicht auf dem ersten sondern auf dem zweiten zersetzung producte*). Combined with an alkali, the first result is allyl-chloroform, a terchloride, which may become converted into bichloride-bichloro-allylene. The terchlorides have reference in time, first to the brain, and then to the spinal cord, to which latter implication is due the respiratory retardation. The bichlorides act on the brain, spinal cord, and medulla oblongata, leaving the muscular structure of the heart untouched, save when given in enormous doses. Mr. Benson Baker, in the *British Med. Journal*, Oct. 25, 1873, thus extols its employment:

* Schmidt's Jahrbücher.

"A. Suffered from facial neuralgia of a most severe character; it affected her hearing and eyesight. She could not rest or take food. She took one grain of croton chloral hydrate every hour. In three hours she was considerably better. After taking three more doses she was entirely free from pain.

"B. Suffered much from facial neuralgia dependent on decayed teeth, and had not been able to take food or sleep for three days. She was ordered croton chloral hydrate, in grain doses, every hour, and obtained great relief after two doses. Six doses removed the pain completely. She slept that night.

"C. This patient suffered from concussion of the spine, caused by a railway accident some years ago. She has had every variety of treatment for the pain she suffers in the spine, and the nerves proceeding therefrom. She took potassium bromide gr. 20, and croton chloral hydrate gr. 1, three times a day, with marked relief and no bad symptoms.

"D. This is a young, dyspeptic, and neuralgic patient, who suffers greatly from dysmenorrhœa. She took two-grain doses when the paroxysm of pain came on, with marked relief.

"E. Has been under treatment for various neuralgiae for some years. She has had, at one time or other, almost every external or internal therapeutic agent in the pharmacopœia—strychnia, iron, quinia, ammonium chloride, aconite, belladonna, iodine, bromine, blisters, hypodermic injections, galvanism, together with baths and other hygienic appliances, including change of air. In this case two-grain doses of croton chloral hydrate every hour afforded more speedy relief from pain than any of the above remedies. After taking eight grains she was almost free from pain.

"In thirteen patients who have taken croton chloral hydrate, not a single bad symptom has been observed. In grain doses it relieves pain quickly, causes natural sleep, no subsequent headache, or furred tongue. In several cases it acted as a gentle laxative."

Dr. J. Wickham Legg, of St. Bartholomew's Hospital, has used it in forty cases with the most satisfactory results.

From an analysis of cases reported, and from its physiological action, it would seem to be of the greatest service in many cases of acute insanity, of neuralgia, and of that excruciating cephalalgia, dependent upon syphiloma, meningeal effusion, or of intra-cranial exostoses. Chloral hydrate, in any ordinary dose, will often fail to produce any effect whatever, and is unsafe in cases of cardiac disease. The continuous use of conium is frequently attended with alarming conditions. True it may paralyze the active delirium, but I have seen it produce a condition simulating that of dementia. Opium is dangerous in many cerebral pathological conditions. I cannot understand the timidity with which specialists are stricken in the employment of a new remedy, which is eminently capable of relieving the sufferings of humanity. Is it an outgrowth of ignorance, or a stagnation of scientific ambition, with an aversion to sever from old school notions, that causes it?

The manufacture, action, effect, and dose may be tested by each one for himself, while the investigations of enlightened minds are available to any one. One insane asylum of Great Britain has placed upon its index expurgatorius chloral hydrate, because three successive deaths resulted from its use. But were these cases properly sounded for heart complaint (for it is a fact that chloral nowadays is being very carelessly used), and was the medicine understandingly administered? Even were all the requisite conditions complied with, why abolish a remedy which has bene-

fited so many thousands? Carry out the law to its ultimate issue and the pharmacopœia of that institution would be reduced to a dozen innocent inert concoctions. In many of the cases which fill our asylums, and in a large proportion of the cases of nervous irritation, this remedy—croton chloral hydrate—will supersede all others. In puerperal convulsions smaller doses will produce speedier beneficial effects than those of chloral hydrate. It is often of paramount importance in acute mania to produce sleep within a short time, and without affecting the general system. This can be accomplished by Liebreich's discovery in from fifteen to twenty minutes.

The rule by which restless patients in asylums are made to take chloral hydrate at the hands of the night watchman, ignorant of their pathological condition, could be wisely modified by scientific discrimination, and by the substitution, in certain cases, of croton chloral hydrate. It is well known that with some patients chloral hydrate produces a condition of unwonted excitement, delirium, and *muscæ volitantes*; one such case has fallen under my own notice.

None of all these effects, no excitement, depression, arrest of vital function, or of sudden death, have as yet resulted from croton hydrate; and its trial is certainly a matter of justice and scientific investigation.

In the matter of "Conium" I can supplement the valuable article of Dr. Kitchen, *American Journal of Insanity*, April, 1873, only in referring to cases wherein the drug has seemed to operate adversely.

In 1867, Dr. Manlius Smith, of Manlius, N. Y., summed up his conclusions in a pamphlet printed by the N. Y. State Medical Society, as follows: "The immature fruits of conium are far preferable to the leaves; they may be dried without serious injury, and a very active preparation may be made from them." "The only experiment yet made by the writer, in the investigation in progress, to test the therapeutic effects of the conium, consisted in his swallowing 16 minims of Squibb's fluid extract of conium seed, with a view of arriving at some idea of the suitable medicinal dose. The quantity mentioned, taken about five hours after breakfast, produced marked operative effects in about twenty minutes. The effects manifested were a peculiar sensation of heaviness in the eyelids, and as it seemed some degree of ptosis, and a feeling akin to dizziness, that made it quite unpleasant to retain the sitting posture. There appeared to be no disposition to sleep produced. The effects were at their height in about an hour, and mainly passed away after the lapse of two hours from the time of taking the dose. A moderate meal had been eaten in the interval. . . . Specimens of fluid extract of conium (U. S. P.)—that is, of dried leaves—prepared by Dr. E. R. Squibb, and also of fluid extract of conium seed, prepared by the same hands, from the dried, full-grown, but green fruits, were also tested. . . . The results attained were, that the oxalic solution prepared from the fluid extract of the leaves bore dilution with 32 volumes of water; while that from the fluid extract of the seed bore dilution with 224 volumes of water, making the seeds in this case seven times as strong as the leaves. . . . In this series of experiments, Squibb's fluid extract (of leaves) gave a solution bearing a dilution with 20 times its volume of water, Tilden's $1\frac{1}{2}$ times its volume, and Thayer's 4 times its volume; making the comparative strengths of Squibb's 42, Tilden's 5, and Thayer's 10." In a recent letter Dr. Squibb writes: "I do not think a solid extract, or any preparation made by heat, can ever be trustworthy—certainly cannot have any practically good degree of uniformity; neither can the 'succus conii' ever be twice alike ex-

cept by chance, since the plants will yield much more juice at one time than at another, from difference in age and succulence of plants, and from wet or dry weather preceding the collection, thus yielding more or less juice—while the proportion of active principles may remain more constant. The only tolerably uniform preparations are those made from the immature fruit taken at the same stage of growth each time, and carefully dried to a proper extent only, and then used to make a definite proportion of fluid extract without heat. . . . When conium is needed in a solid form—to be given in pill for example,—if a known quantity of the fluid extract be exposed in a shallow layer upon a plate for twenty-four hours so as to lose the alcohol by spontaneous evaporation, and the remainder be made into a pilular mass by the admixture of any inert powder, the resulting mass will be better than any of the conium extracts made by heat." Only until recently have we been able to use conium with any assurance of the desired result. The old preparations and the "sucus" were alike so exceedingly variable in strength, that the drug fell into disrepute. With Squibb's fluid extract, however, the satisfaction has usually been complete, and the very general employment of his preparation attests its value. In its action it is essentially different from croton chloral hydrate. By acting directly on the motor tract, conium produces that muscular exhaustion which induces sleep. It also affects the system more extensively than the foregoing. The pulse and temperature are reduced. Vertigo, dizziness, and temporary paralysis are produced. Perspiration is excited. Vision becomes dim, and the pupils dilated. Mental exertion is an effort. A sufficient dose acts very rapidly, and the acute maniac often finds himself incapable of any exertion in from ten to fifteen minutes after its administration. I apprehend that it exerts no direct primary influence upon the brain; but that the condition of exhaustion caused by the drug acting on the corpora striata is communicated to the sensorium, and thus a sleep reflex to the muscular state is brought about.

It is largely employed in our asylums and very generally commended, no ill effects having been noted. My own experience has not been altogether in accord with this wholesale testimony. I believe that its continued use in acute melancholia, hysteria, and hysteromania, etc., is frequently followed by a condition of prostration, of depression, of mal-assimilation, or of mental hebetude. And while I value it as an occasional remedy in very excited cases, or as an alternative in certain nervous conditions, I could not agree in its long-continued employment. Like chloral hydrate, it is simply palliative; exceptionally only and after a lapse of months does it *cure*. How much was due to the interval of time, and how much to the medicine? Quen sabb? It would seem to be evident that a drug which attained its consummation through such serious physical changes, must be attended with some danger when long continued.

This has been the result in several cases of hysteria, melancholia, and recurrent mania, of which I have notes. In one, depression, want of appetite, and lack of energy manifested themselves; in another, fear; in another, mental imbecility—all of which symptoms disappeared with the cessation of the conium.

MEDICAL COLLEGES.—The winter courses in the medical colleges of this city commence as follows: College of Physicians and Surgeons, October 1; University Medical College, September 30; and Bellevue Hospital Medical College, September 30.

RETRO-PHARYNGEAL ABSCESS; PHARYNGEAL INCISION; EXTERNAL ASPIRATION; CURE.

By R. P. LINCOLN, M.D.,

NEW YORK.

I was summoned in haste to see an infant, five months old, whom its parents thought was dying. On entering the chamber a robust child was found in its father's arms with his head supported against his shoulder, this being the position in which it seemed to breathe with the least difficulty. Its skin was bathed in cool perspiration and was of a dusky color. Two or three short sibilant labored respirations were followed by a comparatively long intermission. Its pulse was 140, and temperature (taken later) 100.5° F. I quickly learned the little patient had seemed to be ill for some three weeks, being very restless, nursing apparently with increasing difficulty till, during the past twenty-four hours, nothing had been swallowed. Its cry latterly had been a high pitched moan.

A homœopathic practitioner had been treating it during this period for "diphtheria."

A closer examination revealed an unnatural fulness on each side of the neck behind and below the angles of the jaw, a little larger on the right side than on the left, and evidently deep seated.

The finger in the mouth detected an elastic tumor occupying the whole pharyngeal cavity, extending above so as to press forward the soft palate, and below so as to encroach perceptibly upon the laryngeal space.

To inspection the mucous membrane of the pharynx was only a little darker than normal, and there was present considerable tenacious mucus. The pharyngeal tumor was at once incised with a properly guarded bistoury, evacuating with a jet more than an ounce of laudable pus, and giving immediate relief to all alarming symptoms.

Manipulation of the tumor on the left side of neck effected its complete evacuation through the pharyngeal incision and its consequent subsidence; a like attempt on the right side was not so thoroughly successful.

A poultice was applied to the neck and a solution of borax, carbolic acid, glycerine, and water ordered to be applied to the pharynx by means of a swab. I also prescribed cod-liver oil, and syrup of the iodide of iron.

Two days later each side of the pharynx gave some evidence of a refilling of the abscess, while externally this was much more manifest. I accordingly made an incision on each side of the pharynx, giving exit only on the right side to a little pus, with no appreciable effect on the external tumors.

Dec. 12th.—Dr. Henry J. Walker saw the patient with me, and it was decided to attempt to evacuate the remainder of the abscess with the pneumatic aspirator. In this manner on the following day I withdrew over two ounces of pus from the right side of the neck, and two days later about one ounce from the left side. Each operation immediately resulted in the complete disappearance of the corresponding tumor.

There was no further occasion for interference in the pharynx, the slight fulness that recurred here from time to time being relieved by the aspirator.

Aspiration was performed four times on the right side and three on the left, the last operation being made December 26th, when about a drachm of pus

was removed from the right side. Shortly after this the patient was pronounced well, having recovered without any disfigurement of the neck, where, under ordinary methods of procedure, ugly cicatrices must have resulted.

New York, August 1st, 1874.

A CASE OF SUCCESSFUL OPERATION FOR RECTO-VAGINAL FISTULA.

By SUSAN DIMOCK, M.D.,

RESIDENT PHYSICIAN TO THE NEW ENGLAND HOSPITAL FOR WOMEN
AND CHILDREN.

MRS. ADELA Q., 22 years of age, consulted me, June 11th, as to the possibility of an operation for a recto-vaginal fistula of sixteen months' standing, so large that the faeces passed exclusively through the vagina. On examination, the fistula was found to extend from just above the sphincter ani, two inches upward, the edges being everted and gaping. The vagina was not nearly so capacious as is usual sixteen months after the birth of a child; and, indeed, the sides of the fistula could with difficulty be approximated. The whole vaginal mucous membrane being in an irritated condition, and the patient being thin, pale, and debilitated, I advised her to wait four weeks, during which time she was put upon the most nourishing regimen of meat, wine, etc. The tartrate of iron and potassa was administered in 2 gr. doses three times daily, and a daily sitz bath given at 99°, as also a vaginal injection of a pint of water at 99°, to which a drachm of alum had been added. During the month the irritation of the vagina disappeared, and the general health of the patient was much improved.

She was accordingly admitted to the New England Hospital for Women and Children on July 13th, on which day I operated, it being seven days after the cessation of the menstrual flow. The bowels were thoroughly moved by castor-oil before the operation, and the vagina and rectum cleansed by injections. The patient being etherized, the sphincter ani was paralyzed by stretching, and the patient placed in the position for lithotomy. I then removed with the scissors all the cicatricial tissue formed at the junction of the rectal and vaginal mucous membranes; but this giving too narrow a surface for union, I separated the rectal and vaginal mucous membranes with the scalpel, thus obtaining a surface three-quarters of an inch in width, without encroaching upon the already scant vaginal walls.* The patient was then turned on the left side and, the posterior rectal wall being held backward by Sims' speculum, the rectal mucous membrane around the fistula was united by five stitches of fine silk, which were tied very tightly, in order that they might ³slack away. The patient being again placed on the back the vaginal mucous membrane was united by silver sutures, and the wires, which were doubled, fastened upon "quills" three inches in length, made of a flexible French bougie. Seven deep stitches were thus inserted, and afterwards, the edges at the lower end of the fistula gaping, two superficial stitches of single wire were used.

During the six days succeeding the operation, a camphor and opium pill was given each night, and the diet limited to tea, toast, and beef-juice. The vagina was syringed three times daily, and the urine drawn. On the 4th day the vaginal stitches were removed, as

the mucous membrane was beginning to ulcerate under the pressure of the quills. On the 7th day, the last rectal suture having been drawn away, castor-oil was given, followed by a large enema of milk. The fistula had completely healed, and the bowels moved freely without any pain or passage of faeces into the vagina. The patient's general condition has been uniformly improving since the operation, and three weeks after, she was discharged well.

The case is interesting as an illustration of a new method of operating, namely, by splitting and turning outward both rectal and vaginal layers of mucous membrane. This method is invaluable where material is scanty, as nothing is cut away except cicatrix.

Progress of Medical Science.

HYPODERMIC INJECTIONS OF BLOOD.—Considering the difficulties and dangers which are the obvious objections to the operation of transfusion of blood as ordinarily practised, it has occurred to Dr. Landenberger, of Stuttgart, that in many cases a fair substitute for it may be found in hypodermic injection. In one case where he has tried it the result was favorable. It was the case of a patient who was in a condition of collapse following long-continued vomiting, due to some form of obstruction of the bowels. Defibrinated calves' blood was used, and although only eight grammes were injected, the effect was an almost immediate improvement. The patient revived, the temperature rose one degree, the pulse became again perceptible, vomiting ceased, and a certain amount of nutriment could be again retained in the stomach. This improvement lasted forty-eight hours, but was afterwards followed by collapse again. The only cases in which absorption of the injected blood will not take place are those in which the circulation is utterly depressed, as in the asphyxia of cholera, or the very last stages of phthisis, when the injection causes simply a sugillation.—*Med. Corr.-Blatt.*, 20, 1874.

PNEUMOTHORAX FROM IMPALEMENT ON A VINE-PROP.—Dr. Rosenberger, clinical assistant at the clinic of Prof. Von Linhart, in Würzburg, relates the following interesting case:

A youth fell from a tree in a vineyard and struck in a sitting posture upon the end of a vine-prop beneath. He remained for a few seconds impaled there, when the prop broke and he fell to the ground. He drew the stick out himself, which was afterwards found to have penetrated the body to the extent of thirty-four centimetres, and measured at the point five centimetres in circumference, and a short distance lower down, where it was somewhat crooked, nine centimetres. He walked home afterward, a distance of over a mile. The next day he presented himself at the clinic, complaining of sharp pain in the left side. The bowels had moved once since the accident, and no blood had been noticed. There was no pain or other evidence of abdominal disturbance excepting slight meteorism. A physical examination of the chest discovered the signs of pneumothorax of the left side. On the 4th day fluid exudation appeared, which extended to the second rib in front, but then began to subside, the meteorism disappeared, and the patient's condition was quite good. This improvement had continued for 14 days, when he was suddenly seized with violent pain in the left side of the chest, the exudation commenced to reaccumulate and the patient rapidly sank, dying on the 26th day.

* The fistula measured after the removal of the cicatricial edge about three inches in length.

The post-mortem examination discovered pleuritis, with offensive effusion, of the left side, together with gangrene of a large portion of the lung. It was then ascertained that the prop had passed into the rectum, perforated the intestine at the beginning of the sigmoid flexure, entered the peritoneal cavity, engaged itself in the omentum, which it carried before it, then crowded the anterior wall of the stomach against the diaphragm, which was perforated, and upon being withdrawn, left the layers of omentum and stomach, that it had carried before it, engaged in the perforation of the diaphragm. It seemed probable also that the end of the stick had slightly wounded the lung, whence arose the pneumothorax. Upon disengaging the wall of the stomach from the hole in the diaphragm, a small funnel-shaped perforation was found in the part of the wall corresponding to the perforation in the diaphragm, from which the mucous lining of the stomach protruded. This perforation is supposed to have been the result of ulceration, and to have been the occasion of the fatal exacerbation of the disease in the chest. The anterior wall of the stomach was not perforated. Upon opening the intestines a cicatrix was found three centimetres above the anus, and could be traced obliquely through the entire thickness of the wall of the bowel. The outer surface of the intestine in this situation had become adherent to the jejunum. The circumstance of the canal through the wall of the intestine having been oblique and valvular undoubtedly accounts for the fact that feces did not escape and set up peritonitis, and that the part healed so readily.—*Berl. klin. Wochense.*, 14, 1874.

TREATMENT OF BRONCHIAL CATARRH BY COMPRESSED AIR.—Dr. Sommerbrodt, of Breslau, reports three cases of bronchial catarrh in which he has used Waldenberg's pneumatic apparatus with remarkably successful results. The cases were all of peculiarly distressing character, with extreme dyspnoea, incessant coughing, and inability to sleep. The patients were in each instance relieved at the first inhalations, and by daily continuance of the remedy the general improvement was decided and very satisfactory.

According to Waldenberg, the inhalation of compressed air relieves the congestion of the lungs by increasing the pressure and amount of the blood in the aortic system, and by hindering the flow of blood into the lungs from the pulmonary artery. It was presumed, in Sommerbrodt's cases, that hyperæmia of the lungs was the cause of the coughing, dyspnoea, and abundant secretion. But the writer is disposed to attribute the sudden and complete relief of the distress to something beside the direct effect upon the hyperæmia. He would suppose that in the above cases there were numerous alveoli to which the access of fresh air was prevented by the clogging of mucus in the small tubes, and hence that these alveoli contained rarefied air, which was the source of a large share of the sensation of distress. This would be at once relieved by the sudden blast of compressed air from the cylinder of the apparatus.—*Berl. klin. Wochense.*, 15, 1874.

THE TREATMENT OF VARICOCELE BY THE HERNIA TRUSS.—Hernia or the wearing of a truss have often been assigned as causes of varicocele. But Dr. Ravoth states that in 1,500 cases of inguinal hernia that have come under his observation he has never seen a single instance of well-marked varicocele. This remarkable circumstance not only disposes of the conjecture of any causative relation between hernia and varicocele, but to Dr. Ravoth suggested the idea of a curative one. Amongst these 1,500 cases it is natural to suppose that there were originally a certain number of cases

of varicocele, which may have been cured by means of the pressure made by the hernia and truss. Acting upon this suggestion Ravoth has treated 28 cases of varicocele, simply by directing the patients to wear the truss usually employed for inguinal hernia. He directs the truss to be worn during the whole daytime and laid aside at night. For two or three hours the full force of a strong spring is allowed to press upon the spermatic veins at the inguinal entrance, and during the remainder of the day only a moderate, though still perceptible, degree of pressure is maintained. What the rationale of the treatment may be is uncertain, but of its success the writer has no doubt. The immediate effect is thus described: "Under this pressure the varicocele is seen immediately, and even visibly, to grow smaller, and whatever pain may have been present at once disappears. This can be explained only by supposing that the circulation in the veins is accelerated; at the same time the testicle is drawn upwards towards the inguinal ring, which is manifestly due to irritation of the cremaster, an effect of no little importance."

The writer also thinks that the same remedy may be found of considerable service in meeting two other indications, viz.: the varicose veins of the legs and "the annoying irritation of the genitals which shows itself in inordinate emissions and onanism." His reasons for this opinion are mainly theoretical, but a certain amount of experience also seemed to justify it. For the treatment of the varicose veins of the leg he directs the pressure to be made just below Poupart's ligament over the vena cruralis at the point of junction with the saphena.—*Ber. klin. Wochense.*, 19, 1874.

DIGESTION AND ABSORPTION IN THE LARGE INTESTINE.—There has always been considerable uncertainty in regard to the question whether the large intestines are capable of digesting food. This power has been absolutely denied by several authors, as Blondlot, Frierichs, Braune, Funke, and Quinke, while others, as Zander, Schiff, and Eichhorst, have asserted quite as positively that the fluids of the large intestine are able to digest both albumen and starch, the latter being first changed into sugar. Again, in regard to the form under which these substances may be absorbed in the bowels, opinions are also at variance; some claiming that the albumen must be first changed into peptone before it can be taken up, and others that fluid albumen may be as such absorbed directly. A similar diversity of opinion prevails regarding the ability of the intestines to absorb fats.

Some recent experiments by Drs. Czerny and Latschenberger, of Freiburg, throw some light upon these questions. The experiments were made upon a man who, through a malformation, had the anus situate in the left inguinal region, opposite the sigmoid flexure. The rectum was so separated from the intestine above that matters could be introduced into it by the anus, and again washed out by a stream of water from above as from a rectum. Various articles of food were thus introduced and experimented with, and the results which were obtained are thus stated:

"The human large intestine and its secretions have no digestive action upon either coagulated or fluid albumen, nor upon fat. Coagulated albumen, although left in the intestine for two and a half months, was not appreciably altered, nor was any change effected in fluid albumen in solution. After pouring in an emulsion of fat, the latter rapidly collected at the top, flowing together in large drops. Hence the large intestine not only has no emulsifying effect, but tends to destroy an emulsion already formed."

"The portion of intestine experimented upon absorbed 40 to 50 grammes of water within seven hours.

"*In the normal condition, fluid albumen in solution in water can be absorbed unchanged, as such, by the large intestine, and will be taken up in larger quantity the longer it remains.* Any state of irritation, as, for example, catarrh, hinders absorption or prevents it entirely. Chloride of sodium likewise interferes with absorption, but is taken up itself by the intestine, in spite of an irritated condition and impaired power of absorption. The albumen of the hen's egg is in an unfavorable form for absorption. When the white of an egg is introduced into the bowel unmingled with water only a very slight portion will be absorbed, and the same is true of it, even when beaten into a froth.

"*Fat in emulsion is absorbed by the large intestine, and the amount actually taken up is proportional to the concentration of the emulsion and the length of time that it remains in contact with the absorbent surface.*

"*Starch, when hydrated, is absorbed by the large intestine, but whether directly as such or after being changed into sugar the experiments did not determine.*"

It was ascertained that 1½ grammes of albumen in a 4½ p. c. solution could be taken up in 24 hours. Since the portion of intestine experimented with was not over one-fourth the length of the whole large intestine, it follows that the latter can absorb 6 grammes of soluble albumen in 24 hours. This quantity, however, is quite inadequate to maintain the nutrition of the body, since 120 grammes is the quantity necessary for an ordinary person. It is presumed that by using more concentrated solutions of albumen the amount absorbed might perhaps be increased.—*Viechow's Archiv*, Bd lix. 2.—*Allg. Med. Cent.-Ztg.*, 49, 1874.

INFLUENCE OF CHLOROFORM IN LABOR UPON THE FŒTUS.—Dr. Zweifel, of the Obstetric Clinics in Strasbourg, has recently made some investigations that would seem to imply that the anæsthetic administered to women in labor has more effect upon the fœtus in utero than is perhaps generally admitted. Dubois has made the statement that anæsthesia of the mother causes increased rapidity of the fetal heart-beats. The writer had often observed an appearance of icterus upon newly born children after the use of chloroform but could not with certainty attribute it to the latter. His attention was first seriously arrested by perceiving in the breath of an infant, born a few hours before, a distinct odor of chloroform. The child had been extracted while the mother was under the influence of the anæsthetic, but since the delivery had lain in a room by itself, where no chloroform had been used. Shortly after this, in order to determine positively whether the anæsthetic was conveyed to the fœtus through the maternal circulation, he instituted the following test: A fresh placenta that had just been expelled by a woman to whom chloroform had been administered for only about 15 minutes, and more than an hour previously, was placed in a close-fitting vessel, having first been cleansed of all adhering clots. The following day when the vessel was opened a decided odor of chloroform was perceived and further examination proved conclusively the presence of the drug. By still another test (examination of the child's urine) the writer was able to establish the fact of the influence of the anæsthetic upon the fœtus. In conclusion, the writer observes that, since the use of narcotics in general are contraindicated in infants, it

is an important question for obstetricians to decide, to just what degree anæsthesia may be carried in women in labor with impunity to the fœtus.—*Berl. klin. Wochenschr.*, 21, 1874.

GRAY HAIR.—In discussing the question, whether it is possible for the hair to turn suddenly gray, Dr. Pincus, in the *Berliner klinische Wochenschrift* (No. 24, 1874), admits that under certain circumstances this might take place, while at the same time he rejects most of the testimony on record in reference to this point as entirely untrustworthy. As is well known, Hebra denies the possibility of the hair turning suddenly gray with much positiveness. On the other hand, a distinguished physician of this city, the accuracy of whose observation could hardly be questioned, has borne witness to the sudden appearance in his own person of locks of gray hair in a single night. This, and several other instances equally convincing require something more than simple denial on the ground of the manifest improbability of many similar reported instances.

"The appearance of gray," observes Dr. Pincus, "may be imparted to the hair by three different changes:

"1. The pigment disappears from the external layers of the cortical substance. This is by far the commonest cause of the canities senilis and prematura. By close observation it will be seen that any single hair in the course of the slow growth of years undergoes repeated alterations in color.

"In advanced canities there is either entire absence of diffused pigment, or it is present only in the outermost layer just below the external envelope. The granular pigment continues to be formed for years.

"2. There occur in all the stronger hairs in the cortical and medullary substance, little interspaces between the separate imbrications. In certain cases these spaces attain an extraordinary size in the central portions. In such cases, if there be only diffuse pigment in the external portions of the hairs, the central portions will alone determine their shade, and the hair will appear gray.

"3. The hair originally was of normal structure and shade, but after a time, *post primam formationem*, the cortical substance becomes split up in places in a multitude of brush-like divisions. These places appear as gray points; if such points lie near each other the entire hair appears gray."

In regard to the question whether either of these three changes may to any considerable extent take place suddenly, he replies that the first two can only occur during the slow process of development, but of the third the possibility of a sudden occurrence is conceded. As usually observed, this third change manifests itself only in isolated spots, and that, too, only in the course of several days. The little imbrications of the cortical substance retain their cohesion in the longitudinal direction, but are split transversely. The separation of the outermost layers can be traced for some distance above and below. Supposing that this splitting may sometimes occur over a considerable extent of the hair, the result would be an appearance of gray. The writer has never actually observed this, but holds that it is not impossible to occur. Allusion is also made to the variations which occur in the fluid contents of the hair. A single hair appears fuller at one time than another. In case the middle layers of a hair lose any considerable portion of their fluids, open spaces result, which fill with air and produce the impression of gray. The possibility of this change also occurring suddenly cannot be *a priori* disputed.

PUERPERAL FEVER IN BELLEVUE HOSPITAL.

For more than two years writers in the daily papers have encouraged the belief that Bellevue Hospital is a charnel-house, and that Dante's "All hope abandon ye who enter here," would be a fitting inscription for the gate through which so much suffering humanity has for years entered to find relief from pain and sickness. It is therefore with much interest that we read the clinical report by Professor Lusk, in the August number of the *New York Med. Journal*, of the lying-in service of this hospital for 1873. This, with the report of Professor Janeway on the prevalence of pyæmia and erysipelas in the same institution, made in the fall of 1862, and which served as the subject of an editorial by us in THE MEDICAL RECORD of Sept. 1st of that year, constitute the only published statement of facts regarding the condition of the hospital during the years 1862 and 1863. At the time referred to we had occasion to regret the absence of such records of surgical practice as one would be led to expect from a hospital of the character of Bellevue, and we therefore refer with pleasure to the fact that for the year past, at least, the lying-in service has not been amenable to criticism in this regard.

We understand that this report for the year is but preliminary to one on the outbreak of puerperal fever, which led to the recent closure of the obstetrical wards of Bellevue, and the transfer of the patients to pavilions attached to the Charity Hospital on Blackwell's Island.

In order to give our readers the facts in this report, we cannot do better than quote from it the following paragraphs:—

"As a large amount of misconception, both on the part of the profession and the public, prevails concerning the lying-in wards of Bellevue Hospital, it has

been thought good by the writer to present an accurate tabular history of the service for the year ending January 1, 1874.

"The year in question has been chosen, not because of the peculiarly favorable exhibit it presents, but because during the entire period, a complete record was kept of every woman confined in the hospital from the time of delivery to that of death or discharge.

"These records show a total of 449 patients, twenty-one of whom were confined outside and afterwards brought to the hospital. The annual mortality was twenty-five, or in the proportion of one to eighteen. The number of confinements of primiparous labors and deaths for each month is given in the following table:

MONTHS.	Confinements each month.	No. of primiparae each month.	No. of deaths each month.
January	33	14	2
February	30	13	4
March	28	26	3
April	28	9	1
May	41	17	1
June	41	18	1
July	30	17	1
August	42	24	1
September	45	15	3
October	33	14	3
November	42	16	3
December	46	20	4
Total	449	209	25

"In comparison with the above, the records from 1865 to 1872, inclusive, report the deaths for each year at 17, 30, 9, 24 (no report for 1869), 31, 33, and 16. Thus it will be seen that the year 1873 was not an exceptionally good one. The increased mortality in 1870 and 1871 is attributable to the closure of Charity Hospital to this class of cases in 1870, on account of its having been visited by a severe epidemic of puerperal fever. This closure largely increased the number of patients seeking admission to Bellevue Hospital, and at the same time the actual though not the relative mortality. As is usually the case, however, the mortality was greater in 1871, the year following the overcrowding, than in 1870.

"The year 1872 witnessed but sixteen deaths. Of these two cases died of convulsions, one of paralysis, one of Bright's disease, and one of peritonitis, developed outside of the hospital, leaving thus a total of eight cases referable to peritonitis or some form of puerperal fever, for which the hospital may be held responsible.

"An analysis of the twenty-five deaths occurring in 1873 shows that two women died from puerperal convulsions, two from rupture of the uterus (one of the patients was brought into the hospital in a dying condition), two from phthisis, one from pneumonia, one from cerebral embolism (patient brought into the hospital twenty-two days after confinement, from street), and two cases of peritonitis, consecutive to labor and

developed before admission. In estimating the influence of the hospital in developing disease, these ten cases may be left out as having no bearing upon the question. There remain, then, fifteen cases illustrating puerperal inflammations, or some form of blood-poisoning, *i. e.*, about one to thirty. Of the fifteen, twelve were primiparæ, of whom six were delivered by forceps after labors of long duration. In three instances the operations were performed by *internes*, or members of the house-staff, and in two of these the application of the forceps was made within the cervix before dilatation was completed, *i. e.*, under circumstances requiring the utmost skill and prudence.

"Death in one instance was due mainly to excessive mental depression on the part of the patient, who had been driven from her home in Michigan, and who felt herself an outcast without hope and without a future.

"Of the three pluriparæ, one suffered intense remorse at having become the mother of a second illegitimate child, another died after giving birth to twins; the third gave birth to her ninth child, after a labor lasting forty-nine hours."

Two cases are mentioned in Table II. as the only women in the fifteen designated who claimed to be married. Now the entire number of married women confined during the year was 240. *Thus the number of deaths from puerperal disease, among the class who furnish the statistics of civil practice, furnished in the hospitals a mortality of less than one per cent.*

"In striking contrast with the above are the thirteen deaths among the unmarried, of whom there were 209 all told. Thus among women whose children were born out of wedlock, the death-rate rose to five and a half per cent. The exact reason for this difference is not very apparent. That it was not entirely due to mental depression is probable from the fact that during three summer months—from the last of May to the last of August—there were no deaths, though during that period fifty-seven unmarried women were confined. The excess of primiparous labors among the unmarried fails to explain the difficulty, as, among the married women, sixty-three were confined during the year for the first time, with the loss of but one life.

"It may, however, be as well noticed here that while many of the patients who come to Bellevue Hospital are callous and indifferent, there are always certain among them who feel their position most keenly. Now any depressing agency is a dangerous element in a lying-in hospital. If, indeed, some means could be devised to provide a future for the better disposed among the unfortunates, and persons could be found to take a little humane interest in their welfare, a great addition would be made to the medical resources of the hospital. Few people realize the appalling mental condition of some of these poor outcasts. Without money, or friends, or sympathy—with the question of death or a horrible career as an alternative

before them—it is difficult to keep under control the suicidal propensities of the more desperate. The writer has had continually his attention drawn to cases of peritonitis resulting from patients getting out of bed one or two days after confinement, and walking bare-footed over cold, uncarpeted floors, when the nurse, for any reason, happened to be out of the room. In some of these cases the only impelling motive to the imprudence has been a knowledge that it is forbidden."

An elaborate table shows the total number of cases of puerperal disease from which the patients recovered.

"Here, too, the preponderance of disease among the unmarried is very apparent (fourteen out of twenty-two). The cases of convulsions, the case of nephritis, and the two cases of puerperal mania were accidental occurrences, attributable to the antecedents and physical conditions of the patients who seek admittance to a great hospital.

"While the hospital receives so large an amount of wretchedness, absolute immunity from puerperal disorders is unattainable. Even disastrous epidemics are liable to occur under most careful management. The occurrence of such epidemics does not demand the destruction of the hospitals in which they break out, but their temporary closure.

"In Charity Hospital the present condition of the lying-in service is said to be excellent, yet in 1871 it had to be closed on account of puerperal fever. In 1872 there were twenty deaths out of 205 patients at the Nursery and Child's Hospital. The hospital was closed for a time, and the next year there were but four deaths from all causes among the women confined there. Over and over again operations have been suspended at the Woman's Hospital on account of a temporarily unhealthy condition of the atmosphere.

"But what are the means by which all this evil may be abated? It is folly to assume that no reform can be accomplished. Certainly it is unworthy a great city like this not to have a special hospital separate from a general hospital for the reception of lying-in patients. Such a hospital ought not to be an old rookery, purchased to meet an emergency, but should embody the practical results of the studies of the most eminent hygienists of the day. The selection of the site of such a hospital should be subordinated entirely to the interests of the patients. *But when this has been done it will be found that success lies chiefly in the internal economy practised.* An abundance of light and air, plenty of free space, generous diet, plenty of washing, a rigorous discipline maintained in the management, intelligent nursing, and constant watchfulness on the part of the attending physicians, are among the most important means of preventing and suppressing epidemics. *Per contra*, with limited room, ignorant nurses, and lax discipline, fatal results will prevail, in spite of pavilions or the most expensive machinery for ventilation.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 10, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

PERITYPHLITIS—OPERATION—RECOVERY.

DR. SANDS presented four small fecal calculi discharged from the cavity of an abscess, the result of perityphlitis, depending upon ulceration of the vermiform appendix. The patient was a gentleman, aged 41, who was attacked with illness on Thursday, April 23. He left the house to go to his place of business, in his usual health, which was excellent, but while returning home that afternoon he suffered from pain which was diffused over the abdomen. At that time he had nausea and vomiting, and he also felt cold, but did not have any chill. The vomiting subsided after a few hours, as did also the nausea, but the pain in the abdomen continued and became most severe in the right iliac fossa.

The patient was seen by Dr. Ball the following evening, when he presented the symptoms of localized peritonitis in the right iliac fossa. Dr. Sands saw the patient with Dr. Ball on Sunday, April 26, three days after the attack. There was then no decided change in the symptoms. The belly was slightly swollen throughout, but it was not very tense. A tumor the size of the fist could be felt, although not seen, in the right iliac fossa, in the situation of the cæcum. This tumor was quite firm, even, non-elastic, and very sensitive to pressure.

The question arose as to the nature of this swelling, and four different diseases were thought of. It was thought possible by Dr. Ball that the case might be one of intussusception, of internal hernia, of impaction of feces in the cæcum, or finally, connected with disease of the vermiform process. To the latter diagnosis both gentlemen were strongly inclined. The signs of intussusception were wanting; no bloody stools—in fact, no discharge from the bowels—since the attack. Hernia was excluded because of the disappearance of vomiting after the first day or two.

For a week from the time of his attack the patient presented the signs of peritonitis. This disease at no time was extensive or severe. The temperature ranged from 101°–102°, and the pulse from 90°–100°. The distention of the abdomen increased until the fourth day, and then began to subside. The bowels were not moved until the sixth day, when it was thought best to give a cathartic of castor-oil, followed by an enema. By these means three copious evacuations were obtained, which produced at first a feeling of exhaustion, but the ultimate effect was salutary.

On Thursday, one week after the attack, there was a very evident amelioration of the symptoms. The swelling of the abdomen subsided; there was no tenderness except in the right iliac fossa, and the pulse and temperature became normal. The tumor did not disappear, but there was reason to hope that a cure might occur by resolution. From Thursday until the Monday following, nothing unusual occurred; but on the latter day (the twelfth of the disease) the patient had a chill, marked but not severe, and on Tuesday another chill of the same character. The temperature then rose to 102°, and coincident with this change in the symptoms there was a change in the tumor, which became larger and softer, reaching well

up toward the umbilicus and the lower margin of the thorax.

The concurrence of these general and local symptoms was considered sufficient to warrant the operation by incision proposed some years since by Dr. Willard Parker. The operation was performed by Dr. Sands, and an abscess was found and emptied. The abdominal walls were very thick, and it was not until the transversalis fascia was reached that any fluctuation could be discovered. A hypodermic syringe was then introduced into the tumor, and the presence of pus ascertained, when an opening large enough to admit the finger was made and six ounces of fetid pus evacuated. After this opening had been made and the pus had escaped, the cavity of the abscess was explored, all its limits being reached except above. During this examination several fecal concretions were removed, and subsequently, day by day, as the result of washing the abscess with warm carbolic water, more concretions escaped, making eight or nine in all. The largest of these was equal in size to a large pea, and, on being cut open, was found to contain a nucleus of fecal matter arranged in concentric layers.

The symptoms were immediately relieved by the operation. The contact of the discharges with the connective tissue produced some sloughing, but this did not interfere with the general well-being of the patient. He recovered so as to be able to sit up on the fourteenth day, and at the time of reporting the case the patient was quite well, and on his way to Europe.

When the concretions continued to escape there was some fear that a fistula might exist, which it would be difficult to close. The sequel, however, proved that these concretions existed in the vermiform process at the time of its ulceration, and that they had merely escaped into the cavity of the abscess.

In conclusion, Dr. Sands remarked that the question had often been asked, when it was proper to perform this operation? The experience gained since the operation was first performed has taught us that not unfrequently cases of this sort terminate by resolution. He had seen two of this kind himself, and had met with a physician who had had two in his own practice. He thought that the signs which were present in this case were the ones which would generally be found to guide us; that is to say, a patient has an attack of circumscribed peritonitis in the right iliac region, from which he recovers under treatment, when of a sudden he is seized with a chill, a rise of temperature, a rapid diffusion of the swelling and the other symptoms of abscess. If he was not mistaken, these were the signs which determined Dr. Parker to perform his first operation. There was no question that the operation should be performed when the proper indications were present, as otherwise death would ultimately result either from the bursting of an abscess into the peritoneum, or by extensive burrowing throughout the abdomen.

DR. JANEWAY had seen two cases of this trouble in which a thrombus of one of the small branches of the portal vein resulted, leading to secondary abscess in the liver.

DR. KNAPP presented a female patient upon whom he had performed an autoplasic operation for rodent ulcer in the lachrymal region. He had exhibited the patient to the Society at the meeting of Jan. 28, 1874 (*vide MEDICAL RECORD*, vol. viii., p. 210), on which occasion he gave a full history of the case. He wished merely to show the results of a plastic operation demonstrating the steps of the same upon the patient. The tumor on the forehead was taken away later, and proved to be a typical specimen of alveolar cancer. A

tumor of the jaw, which, at the time she was previously exhibited to the Society, was supposed to be of like character, was removed by Dr. Sands. That gentleman found it to be a mere cavity in the bone containing matter, but whether it was originally a cyst which had suppurated or a simple alveolar abscess, was not determined. The operation for its removal comprised the removal of the shell-wall, the opening being made through the mucous membrane of the mouth.

PACHYMENINGITIS.

DR. LOOMIS presented a specimen of pachymeningitis, removed from a male patient, aged forty-three, who was admitted into Bellevue Hospital, June 3. From the friends who came with him it was found that he had been of intemperate habits, given to all sorts of excesses, that he had had gonorrhea a number of times, and that two years ago he had had a primary sore on the penis which was followed by all the characteristic symptoms of constitutional syphilis. It was further found that he had been able to work every day up to eighteen months before his admission, when he was suddenly seized with paraplegia, which, although only partial, was sufficiently complete to prevent him from going up stairs, and if he attempted to walk very far his limbs gave way and he fell. This attack confined him to his room for about three months, when it suddenly disappeared and he was able to walk as well as ever. Soon after that he began to have convulsions. These were not of an epileptiform character, as at first he did not lose consciousness, but this latter was not the case when the convulsions increased in frequency. About three months before his admission he had severe convulsions in succession, and after these convulsions had ceased he appeared, according to his friends' statement, more intelligent than he had been previously. Three days before his admission he had five convulsions in succession, and had been in a partial state of coma from that time until first seen by Dr. Loomis, a few hours after admission. The patient could be roused to answer questions, but if left to himself would lapse off in his drowsy, stupid state. His hearing and sight were perfect, and there was no facial paralysis. If he was stood upon his feet he would walk without support for a short distance only, when, if the support was not continued, he would fall backward and to the right. There was less muscular power in the right arm than in the left. He could get out of bed himself with very little assistance, and when he was standing on his feet seemed to be much better than when lying down. His pulse was 50, and temperature 97°. There was no trouble about urine or feces, and he was able to swallow without any difficulty. He complained, however, constantly of pain in the head and upon the right side. The examinations of heart, lungs, and abdomen were negative. The history of the case, with the persistence of the symptoms, caused the diagnosis of pachymeningitis to be made. The patient was accordingly directed to take three drachms of the iodide of potassium within twenty-four hours, but it was found that he vomited everything, and that the vomiting was projectile in character; medication was accordingly carried on per rectum. Twenty-four hours after admission his coma had very much deepened. He was not more paralyzed on one side than the other, except with the right arm. He gradually sank, and died in a state of coma, his pulse and temperature running up very rapidly towards the last, and the urine being suppressed for twelve hours before death. At the autopsy, the thorax, abdomen, and all the

organs were healthy, with the exception of a slight pulmonary edema and interstitial nephritis. On opening the cranial cavity the right hemisphere was found very much adherent, the dura mater very much thickened, and the corresponding portion of bone much eroded. This thickening extended over a space of about two inches in diameter and two inches in length. Underneath and attached to this thickening was found a gummy tumor, which is firmly attached to pia mater as well. This thickening and erosion extended in every direction from the centre of the tumor, but fading away as it recedes. There was very little fluid underneath the arachnoid; no fluid in the ventricles. In the left corpus striatum were the remains of an old extravasation.

DR. JAKENWAY referred in this connection to three cases of pachymeningitis, caused by a rupture of one of the large veins going into the longitudinal sinus.

DR. KNAPP, having asked the question of Dr. Loomis whether there was any defects of sight or hearing in this case, and being answered negatively, remarked that neuro-retinitis was sometimes present without much diminution in visual power. He believed that in the great majority of such cases as the one presented, if an ophthalmoscopic examination were made, retinal lesions would be made out.

THE DEATH OF DR. SPRAGUE.

DR. POST gave a short account of the last illness of Dr. H. M. Sprague, of Fordham, N. Y. Dr. Sprague was in his usual health until the day before his death, when he rode to a public institution not far from his residence. On his way thither he was attacked with nausea and vomiting, and on his arrival he was so decidedly indisposed that he was not able to leave, and died, with gradually increasing coma, within twenty-four hours from the time he was taken. He was not seen by any medical man until shortly before his death, and by the history of the case it was believed to be one of uremic poisoning.

At the autopsy both kidneys were in such a condition of intense hyperemia as to make it difficult to distinguish the cortical from the tubular portions. There was a rupture of the blood-vessel in the pelvis of the kidney of the right side. The vessels of the brain were somewhat turgid. The bladder was distended with urine, but did not contain any albumen.

DR. LOOMIS thought that the cause of death might have been a congestive chill.

DR. POST replied that the spleen was not in a condition to warrant the supposition.

EXCISION OF BURSAL SWELLING.

DR. POST presented a bursal swelling which he had excised from the ligamentum patellæ; also the cast of a foot of a young lady, showing subluxation of the first phalanx of the second toe, for the removal of which he was forced to excise the distal extremity of said phalanx. The bone was easily reached by splitting the tendon, and the wound healed by first intention.

MORBUS COXARIUS.

DR. SAYRE exhibited the upper extremity of the femur of a child, aged six years, who was brought to Bellevue Hospital in January last with a large abscess on the outer side of the left thigh, the result of a kick. When admitted, the patient was very much exhausted, presented all the appearances and gave the history of morbus coxarius. The abscess was opened and gave exit to a large quantity of pus. Nothing more was done for it in the shape of an operation until Dr. Sayre came on duty in May, when the patient was exceedingly emaciated and was in great danger of dy-

ing of the disease. The operation of exsection was performed a month before the meeting of the Society, and the head and neck of the femur were found to be gone, and the upper extremity of the shaft, including the trochanter major, was pushed through the opening and sawed off. A large perforation was found in the acetabulum. The abscess on the outer end of the femur went within an inch and a half of the external condyle, and was opened throughout its entire extent. Up to the time of reporting the case, the patient was doing well.

Dr. S. also presented a second specimen removed by operation from a child only three years of age. In July, 1872, after violent exercise, from fatigue, she lay upon the grass and fell asleep, and was soon after attacked with what was thought to be rheumatism, but which was evidently severe inflammation of the hip-joint. In October following she became so much worse that her foot was drawn up, adducted, and shortened. She remained in this condition for sixteen months. She was brought to the hospital three weeks ago, and at that time there was a large abscess on the inner aspect of the thigh, through an opening in which pus escaped. The abscess was laid open. Although no evidences of crepitus could be discovered, Dr. Sayre felt convinced that the bones were bare and that exsection was advisable. The operation was performed, when the head of the femur was found to be absent, and the neck of the bone very much reduced in size and roughened. The first section was made through the neck of the bone, but it was necessary, in consequence of extension of the disease, to remove an inch and a half more. The patient was on a fair way to recovery.

EMBOLISM OF PULMONARY ARTERY.

DR. NEWMAN—The specimen I present is an embolism of the pulmonary artery; the clot has been removed at the autopsy, which has been conducted with great care by Dr. Briddon. All gentlemen present at the post-mortem were so well satisfied with the cause of death by finding the embolism filling the entire volume of the pulmonary artery and its bifurcations, that it was thought superfluous to examine the cranial cavity. As minute recorded cases of this accident are rare, I take the liberty to give you the full history of the case, followed by Dr. Briddon's notes of the autopsy, and his remarks, to which I can add nothing.

Mrs. E. A. was born at the seventh month of gestation, as one of twins. Her twin brother died, and she was raised with great difficulty and care. Afterwards during her life was healthy, but retained a delicate appearance. She was married in June, 1873, at the age of twenty. She menstruated last Sept. 8th, 1873, when she flooded profusely for one hour, the flow ceasing suddenly. It was thought that conception had taken place Aug. 8th, and the flow of Sept. 8th was considered as a hemorrhage from the cervix. If the supposition was correct, confinement might be expected on May 15th, 1874, at 280 days' gestation.

Dec. 1st, 1873.—Sudden fainting, pain in back and abdomen, extending to the limbs. Dizziness and feeling of syncope. Slight hemorrhage from uterus. Two nights before she had exerted herself dancing, and now the symptoms indicated abortion. Ordered recumbent position, and gave an opiate. After two days' rest she rallied without further medication, and was able to sit up. Rp. Potass. chlorat. grs. viij.; Elixir calisaya, 5 ss., was given three times a day for two weeks. After this she took iron for a few weeks. She then enjoyed good health until the end of her term.

May 12th, 1874.—Irregular pains commenced early

in the morning, and troubled her the whole day and the following night.

May 13th.—Pains became more regular, and the os began to dilate slowly but steadily. The presentation was vertex; position, L. O. A. The second stage began at 1 P.M.; at 3 P.M. descent commenced. Progress was slow but steady until 5 P.M. At that time the head had advanced into the vagina, and rotation was not quite completed. The pains were regular and strong, but from that time the head made no further advance. At 6 P.M. it was evident that nature would not accomplish the delivery, as the head was too large for the unyielding parts of the primipara. At 7 P.M. chloroform was administered by Dr. Elsborg, and with the kind assistance and counsel of Dr. Chas. A. Budd, the patient was delivered with the forceps of a live and large male child. A small laceration of the perineum was unavoidable. The placenta followed in thirteen minutes. The uterus contracted firmly at external manipulation, and 5 ij. of the fluid extract of ergot. Patient feeling comfortable.

May 14th.—Patient is in good spirits; has had a good night's rest; passed water without difficulty, and has appetite. Lochiae normal.

May 15th.—In excellent spirits; good appetite; secretions normal. Has been nourished well since beginning.

May 18th, 5th day.—Took almost too hearty a meal yesterday, and feels a little indigestion. Milk appears and causes feeling of heaviness, but not a marked fever.

May 19th, 6th day.—Feels better. Lactation is fully established, but the breasts are rather flaccid, as if the glandular formation was deficient.

May 20th.—Tongue furred. Pulse 92. Breasts were well drawn, and rubbed with warm olive oil. There is a secretion of milk, but not in the desired quantity, and it seems as if all efforts in that direction would prove fruitless.

May 21st.—Weakness. Pulse 120; tongue furred; no appetite.

May 22d.—Same condition as yesterday. Lochiae normal in quality and quantity, but have a fetid odor. Involution of uterus going on well. Complaints of a soreness in throat, difficulty in deglutition, and a general malaise. Found on examining the throat a redness of the mucous membrane, like a pharyngitis from sudden change of weather. Ordered a gargle of Potass. chlorat. 5 i. to 3 i. to be used frequently. Rp. Sol. acid carbolic per atomizer. Rp. Quinine sulphat. gr. iv. three times a day. Rp. Acid carbolic 3 i., Aque. Oj., for vaginal injections.

May 23d.—Somewhat improved, but has had no sleep. Pulse 110. Rp. Morph. sulph. gr. 1/4 at night. Frequent gargles urged. Passages loose, frequent, and of a diarrheal character.

May 24th, 11th day.—Marked improvement; had a good night's rest. Pulse 100. Throat well; appetite better.

Vaginal examination shows that the laceration of the perineum gives no trouble; no sore or ulcerated surface, and no fetid odor. No tenderness over abdomen or on pressure. Skin moist. Is sitting up in a chair a little while for the first time.

May 25th to 27th.—Patient's condition changeable. At times she feels very well, at others has an unusual weakness, which necessitates her remaining in bed. The pulse varies between 86 and 100. Tongue is coated, and appetite capricious. The diarrhea is gradually getting better. Urine is normal in every way; bladder does not give the slightest trouble.

Rp. Quinine in doses as indicated by the pulse.

Takes every night morph. sulph. gr. $\frac{1}{2}$, after which she always has a good night's rest.

May 30th, 17th day.—Bimanual examination of uterus. The fundus is below the pubes; involution progressing normally in every way. The cervix is hard, well contracted, and stands low in pelvis. Vagina clean, not the slightest odor; all discharges almost ceased; no tenderness on digital examination.

No typhinitis, and not the slightest tenderness over abdomen on deep pressure and percussion. No pain anywhere. Bowels regular. Never had a chill during the whole sickness.

June 1st.—Appetite has returned, and she feels well in every way, with the exception of a general weakness. Examination shows nothing wrong. Is sitting up a little. Pulse still 90.

June 2d, 20th day.—Saw her at 12 M. Very much improved, feels well, and is in good spirits. Everything normal. Pulse 86. Appetite better.

At 2.30 P.M. relished a plate of soup in bed. Got up, saying how well she felt; walked only a few steps from the bed to the lounge, when she suddenly fainted, uttered one scream, and fell on the lounge. Almost at the same moment I was at her side; found her becoming very pale, pulse only 42. The whole skin getting as white as a sheet. The next minute the pulse was 30, and a few parts of the skin changing to a yellowish hue; nails turning blue; countenance of extreme anxiety, changing to facies hippocratica. The eyes alone remaining natural and open.

A few spoonfuls of wine were given, and swallowed with a little difficulty. The pulse growing slower with every moment, the heart fluttering unsteadily. At this moment Dr. C. S. Wood entered, and while we were consulting she expired. From the beginning of the sudden attack until the complete cessation of pulse and heart-beats, not more than five minutes elapsed. She had not complained of anything, nor did she speak a single word. The only motion she made was to raise the left hand and point the finger to the second intercostal space of the left side.

Autopsy by Dr. BARNES, June 2d, 1874, 9 P.M., in the presence of Prof. Chas. A. Budd, Drs. L. Elsberg, R. Newman, Howe, and C. S. Wood, on the body of E. A., a young married female:

Rigor mortis incompletely developed; trunk still warm; surface pale; integuments of abdomen wrinkled.

Abdominal cavity contained less than a pint of perfectly clear, straw-colored serum; intestines were moderately distended; their peritoneal surface was free from trace of inflammatory action save at a point of the ileum distant six inches from its junction with the colon, where adhesions bound the gut to the right ovary.

All the solid abdominal viscera were sound. The bladder was about half full of urine; the uterus measured four inches and a half in its long diameter, two and a half transverse at the fundus, and antero-posteriorly one and a half. At the fundus were seven small subperitoneal collections of pus, varying in size from the dimensions of a pea to that of a bean. These deposits were aggregated about the cornua or angles, three on one side and four on the other, one encroaching on the broad ligament. There was a rent on either side of the os externum uteri two or three lines in length; the cavity was empty and odorless; the site of placental attachment could be recognized by a slightly granular surface, the internal surface and walls of the organ were perfectly healthy.

The right ovary was the seat of a thin walled abscess containing well-elaborated pus; it was bound down by recent deposit of inflammatory character, and was also

adherent to the small intestine; the left ovary was healthy.

The inferior vena cava, iliac, and their tributary veins from the pelvic viscera, contained fluid blood, but no thrombi that we could discover; everywhere, as far as traced, the lining membranes of these vessels were smooth, glistening, and free from any appearance that would indicate their having been the seat of thrombus for any considerable period of time.

Thorax.—Left lung bound to parietes by old adhesions; surfaces of both were markedly exsanguine; small linear patch of hypostatic congestion at inferior border of right base. The heart was small; left ventricle contracted; right ventricle flaccid; it was almost empty, containing only a very small dark clot entangled in the pulmonary columns; no defibrinated clot.

The pulmonary artery was completely occupied by a dark-colored dense clot, which could be traced from the summit of the conus arteriosus to the secondary division of the vessel within the tissue of the lung itself; the lining membrane of the main channel was in immediate contact with the clot. This portion of the clot was of a dark maroon color, but that portion that occupied the bifurcation of the artery was nearly of the color of arterial blood; the lining membrane of the vessel was stained by transudation of blood pigment.

Remarks.—During the week that has elapsed since the autopsy was made considerable changes have manifested themselves in the external appearances of the clot. Immediately after removal it was noted that the portion that plugged the artery passing to the left lung was of a bright rosy hue, whilst the larger mass contained in the main trunk was dark in color; soon after removal and exposure to atmospheric air it also became lighter in color, and during the subsequent maceration in dilute alcohol the escape of blood pigment has still further modified the color. I purposely avoided making a division of the clot, so that the members of the Society might judge from the appearance of the fresh section.

I have no doubt that the larger mass was formed before death. It had none of the appearances of the heart clots met with in cases of slow dissolution. My own impression is, that the smaller and lighter-colored clot found at the bifurcation and in the left pulmonary artery, was an embolus originating in a thrombus formed in some of the pelvic veins, and that the larger clot that filled the main vessel had formed in the location in which it was found.

That death was the result of occlusion of the pulmonary artery, I have no doubt, and I think the exsanguine condition of the lungs bears ample testimony of the fact.

One condition met with surprised me. I refer to the flaccid and almost empty right ventricle. It contained but a very small portion of loose clot that was not continuous with that found in the artery. The contrast between the right and left chambers was marked; the left looked as if its last contractions had been tetanoid, it was so firmly contracted.

I think the multiple abscesses met with at the fundus uteri originated in the superficial layer of lymphatic vessels met with beneath the peritoneum.

THE MEDICAL SOCIETIES OF NEW YORK.—The different medical societies of this city will commence their regular meetings during the present month.

Dr. W. O. TORREY, of Hannibal, Mo., has been elected President of the Missouri State Medical Society.

New Instruments.

A NEW ASPIRATOR.

By J. A. STEURER, M.D.,

HOUSE-PHYSICIAN TO BELLEVUE HOSPITAL, NEW YORK.

HAVING had considerable experience in the use of the various forms of aspirators, and with a thorough appreciation of their inestimable value, we have constantly been annoyed by several defects in the several forms of instruments until now employed. Stimulated by the desire to possess an instrument which, after answering all the requirements, would be safe in every respect, I was induced to construct an apparatus which, when accurately described with the detailed method of its usage, would, when once understood, no doubt be appreciated by the profession. Formerly I could not suppress the feelings of anxiety for fear of wounding an internal, perhaps vital organ, as I held the dangerous needle, through which fluid was to be aspirated; hoping no pus, shred of mucus or other product of transformation would instantly render my instrument useless and subject my perhaps dying patient to further torture.

What then are the requirements, other than those furnished by the valuable instruments of Dieulafoy, Pontain and others? We have found them principally as follows: First, *there must whilst aspirating be no danger of wounding an internal organ.* Second, *and there must be a means of clearing the canula with the instrument in situ.* Now, after having obtained these, and therefore done away with the danger accompanying the use of the aspirator, we offer an instrument in which the evacuating force can be accurately appreciated and regulated by the operator, hence more acceptable to the patient, and venture to suppose this apparatus at last approaches perfection.

Having given it a thorough trial in a variety of cases, I take the liberty of presenting the aspirator as described in the accompanying figure:

A is a glass cylinder of 8 oz. capacity. B is the piston-rod which works with the rack C, by means of key D.

The rod C can be pushed out, so that the piston can be worked as in an ordinary syringe.

G is a stop-cock at the inlet, and G' one at outlet.

The cylinder A is connected with the little apparatus F, by means of a rubber tube K, with unusually thick walls to prevent collapse when a vacuum is made.

The trocars, I, are screwed on the rod E, which is placed in the tube F, and passes through the cap J, which contains a rubber packing, so that the more the cap is screwed down the tighter the packing becomes.

The canulas II are screwed on the tube F at L. By this little arrangement different sized trocars and canulas can be adapted to the same instrument.

The method of using the instrument is as follows: The stop-cocks G and G' are closed. A suitable trocar and canula are chosen and screwed on the rod E and tube F. The trocar and canula is introduced in the part to be aspirated, and the rod E is withdrawn about 4" so as to clear the point of the trocar and calibre of the inner end of the canula.

Should the canula become plugged, all that is necessary is to push down the rod E, which drives the trocar through the canula and so removes the obstruction.

If it is wished to make an injection or wash out a

cavity, close the stop-cock G, open G', and fill the cylinder with the fluid and then inject after reversing the order of the stop-cocks.

The whole instrument is neatly packed in a case and perfectly made by Messrs. G. Tiemann & Co. Concerning the importance of the Aspirator it is almost useless to attempt to add to the long list of its brilliant achievements and to what has been so ably written upon the subject by its inventor and master, Dieulafoy; but for the sake of completeness I will state several instances where the above described instrument was proven to be of particular value. I have demonstrated upon several cases in the wards of Bellevue Hospital, in the presence of several of my honored professors and many colleagues, the advantages of the *trocar and canula* over the needle. The needle not only presents a sharp point, endangering the vital organs, especially lungs and heart, but frequently, punch-like, cuts out a plug of tissue which effectually closes the opening, necessitating its removal to cleanse it. With the trocar and canula, however, the puncture is star-shaped, and as the trocar can be withdrawn and concealed, leaving the blunt canula free, no injury to the organs will be possible.

Supposing the canula becomes plugged from any cause, the trocar can be carefully pushed down and the canula *in situ* thoroughly freed from any obstruction. For instance, in a case of "serous pleurisy," the use of another instrument was attempted, but to no

purpose. The patient, in a state of apnea, was sitting up in bed. Respiration hurried and superficial, pulse scarcely perceptible. After the introduction of a needle into the pleural cavity the fluid, being too tenacious, plugged it, rendering further operations impossible. My instrument was then used, and notwithstanding the cannula becoming plugged several times, it was easily cleansed; and without the appearance of any blood or much irritation to the lung, 68 ounces of fluid were withdrawn, which immediately coagulated on exposure to the air. In another similar case the needle scratched and punctured the lung until the fluid withdrawn was tinged with blood, not mentioning the irritation, which produced violent paroxysms of coughing, better imagined than described.

Besides the above-mentioned diseases, this instrument has been successfully used in aspirating collections of fluid in the different cavities of the body, strangulated hernia, etc. It can also be used as an instrument for direct transfusion of blood. Fearing to occupy too much valuable space I simply submit the instrument to the profession, hoping time and experience may prove its utility.

EXTRACTION OF FOREIGN BODIES ACCIDENTALLY INTRODUCED INTO THE BLADDER.

DR. A. AMUSSAT has published two cases of removal of foreign bodies from the bladder, by means of a small lithotrite with flat blades and rounded edges, such as is employed for calculi in children.

CASE 1 was a man, 82 years old, who, in using a gum catheter, broke it off in the urethra; he succeeded in extracting a portion of it himself (Fig. 1. C), but, being unable to extract the remaining portion, he pushed it into the bladder with another catheter.

He then consulted Dr. Amussat, who introduced his lithotrite, and seizing the fragment of catheter near the middle (Fig. 1. A, B), he withdrew it slowly, in order to give the tissues time to dilate, and thus extracted it without difficulty.

CASE 2 was a man, 26 years old, who was in the habit of introducing a staff of wood into the urethra for the purpose of masturbation. One evening while indulging in this habit, the staff broke, and the patient came to Dr. Amussat five days afterwards to have it removed.

He was unable to find anything in the urethra, but found a fragment of the staff in the bladder. With his lithotrite he placed it obliquely against the right wall of the bladder; then seizing it by its extremity, as nearly as possible in the direction of its axis, he was enabled to extract it without difficulty, and without pain to the patient.

(Fig. 2 represents the two fragments of the staff. The longer fragment is the one extracted from the bladder. One extremity was surrounded by a sort of calculus, which was firmly adherent; it was by this extremity that it was seized with the lithotrite.)

In neither of these cases did the patient experience any ill effects after the operation.

In the first case, the bladder was large and could not be emptied without a catheter; in the other case, it was irritable, and contracted energetically, expelling all the urine.

It is especially in cases such as the latter that Dr. Amussat insists upon the superiority of the small lithotrite over any other instrument, on account of its small size and its shape, which render it easy of manipulation. — *Gazette des Hôpitaux*, 1871, pp. 497 and 501.

THE ARCHIVES OF DERMATOLOGY is to be the title of a new quarterly journal, to be edited by L. Duncan Bulkley, M.D., of this city. The first number will be issued October 1. G. P. Putnam's Sons are to be the publishers. Subscription three dollars per annum.

Correspondence.

CASE OF HYDROPHOBIA.

By FREDERIC D. LENTE, M.D.,

OF COLD SPRING, N. Y.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the interest of those who are studying the painful subject of hydrophobia, and as a contribution to the statistics of the disease, as well as with the hope that at some future day some useful light may be thrown on its pathology and therapeutics, I ask the publication of the following interesting case, a *genuine* case of hydrophobia. At the time I made the remarks on the subject, at a recent meeting of the Neurological Society, I referred to the history of this case, but as I had mislaid my notes, I omitted the most important particulars.

Was called to the child August 13th, 9 P.M.

M. H., aged $3\frac{1}{2}$ years, with the following account of her case from her parents, who are very intelligent people: Thirteen weeks ago, was teasing a puppy, two months old, and was bitten on the wrist, the slight scar still marking the spot. The puppy had been sick for nearly a week previous to biting her, exhibiting the following symptoms: Commenced moping; could not be attracted by the usual inducements to play; was restless and uneasy; ate and drank as usual at first, and up to his death *partook moderately of both solids and fluids*; was shivering most of the time; was snappish, but not more so than usual, and not disposed to bite unless disturbed; no frothing at the mouth or spasms; died apparently of exhaustion. The father of the child thought there was something peculiar about the sickness of the animal, and says that he felt uneasy about the child from the day she was bitten until the lapse of a couple of weeks. Four other persons were bitten at about the same time by the dog; in three the skin was broken. The father was among them, and shows a very slight scar on his wrist to mark the spot. On Wednesday, August 10th, the mother noticed that the child had a slight cough and that her tongue was lightly coated; but she ate and drank as usual, and exhibited no other symptoms of illness until this morning, when she did not care to get up to be dressed, and seemed dull. She would not eat any breakfast, but did swallow by persuasion a scrap of meat. She called for water; took the vessel containing it, put it rapidly to her lips, got a little down apparently, and then dashed the vessel down. She asked for water several times during the day, but generally pushed away the cup as soon as it approached her lips; once she took a teaspoon filled with water, put it rapidly into her mouth, and swallowed the water as rapidly, and laughed, apparently at her success in surprising her throat. She cried when pressed to take any food. Dr. Murdock, who saw the case a few hours before I did, got her to swallow a teaspoonful of water, but it was with a great effort, and brought on a sort of spasm. When asked if she is thirsty, she answers, yes; but if asked if she wants water or milk, she says no, and appears distressed at the idea of taking it. Since her efforts at swallowing during the afternoon, she evidently fears the water, or the attempt at taking it. She was feverish during a portion of the day, her mother says, but has complained of no distress except at times in the abdomen; if asked where she has pain, she puts her hand on the lower part of the abdomen. She has no fever now; pulse is 123, and regu-

lar. Her father says she has been disposed to spit a good deal during the day. She lies quietly for a few minutes, this evening, and then starts suddenly, straightening her arms and legs out at the same time, and looks up with a startled expression, but says nothing. She has shown an evident dislike to company during the day. She is an intelligent child, but always very nervous, although always enjoying good health. Her mother states that she is usually inclined to start suddenly, in the manner above described, if anything is amiss with her. Dr. Murdock directed a laxative enema on seeing her, which has operated, and injections of Elix. McMunn, if necessary to quiet her, also strict avoidance of company. I ordered injections of strong beef-tea (Liebig's Ext.) $\frac{2}{3}$ ss., g. 2 h., with the anodyne when needed.

August 14th, 10 A.M.—Took three anodyne injections at intervals of two hours, ten, fifteen, and twenty drops of Elix. opii, but they only seemed to excite her, and they were abandoned. She has slept none. Her condition has not very materially changed, except that her lips are pale, especially when she is under excitement. If asked where she has distress, she puts her hand on the top of her head and on the hypogastrium. She cannot be quiet for more than a few minutes at a time, and when she moves, does it quickly and hurriedly; she has expressed a wish for water and asked her mother to drink some, and said that when she got well she would drink it, and wondered why it was bad. She cries and gets excited if asked to eat anything; occasionally a shudder passes over her, and she sighs frequently. She has always been fond of fanning herself, and has taken a fan several times to-day and attempted to use it, but as soon as she feels the air she "catches her breath" and throws the fan away. If any allusion is made to giving her anything, or to using the injection, she springs up in bed with a horrified look and almost in a spasm. Mixed forty drops of McMunn's Elix. in half an ounce of beef-tea, and the mother gave it to her after quite a struggle, but about half of it was passed away. Mixed twenty drops in $\frac{1}{2}$ j. of beef-tea, and after reasoning with her, and explaining that it was for her relief, she submitted quite well. At 2 P.M., called to child with the news that she was in "dreadful spasms." Found that she had been rapidly growing worse. The anodyne injection had been repeated three times, thirty drops, then forty, with no effect; pupils widely dilated; has been at times, for a minute or two, talking rationally, and saying that she would drink water when she was well, and that she could not drink because "her throat jumped"—evidently thinking more of water than anything else. She is now frothing at the mouth, looking wild and excited, and throwing herself with great suddenness and violently against the sides of the sofa and wall, notwithstanding the watchfulness of the attendants; once, she rushed from the sofa towards the door, and fell on the floor. There are no convulsions, but only *intense restlessness*, dreadful to contemplate. Her pulse was very frequent and feeble. She had just had an involuntary discharge from her bowels; had passed her urine in the morning; put her under chloroform, and injected morph. gr. $\frac{1}{4}$ hypodermically. She was quiet, her pulse falling to one hundred and sixty and stronger, for twenty minutes; then had a struggle. Repeated the chloroform at intervals, as she required it, until five minutes to three; then gave morph. gr. $\frac{1}{4}$ hypoderm. At thirteen minutes past three, a violent struggle, pupils dilated; gave morph. injec. gr. $\frac{1}{4}$. In a few minutes another struggle; gave chloroform, and soon after receiving it she ceased to breathe. Her pupils never became more than very moderately contracted,

and there was no positive evidence that the morphine had any considerable influence over the disease. When she was fully under the influence of the chloroform, and breathing stertorously, she would *instantly*, and without the least indication of returning sensibility or pain, spring from the sofa to the floor. It was impossible to maintain quietude except by keeping the chloroform almost constantly to the face.

COLD SPRING, August 20th, 1874.

DIVIDED TENDO ACHILLIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In No. 206 of THE RECORD Prof. Kearney, of Cincinnati, detailed a case of wound of the tendo-achillis, and seems, in the course of his remarks, to question, by implication at least, the results of a case recorded by Dr. G. H. Mitchell, in No. 202 of the same journal.

This induces me to place on record a case of a similar nature, that occurred in my practice in the year 1861. There is, however, this difference; that the cases reported by Dr. Mitchell and Prof. Kearney both occurred in subjects in or beyond the period of middle life, while the subject of my case was only four years of age.

B—11—, aged four years—American—male—while running around the yard, where his father was grinding scythes, stepped just over the blade of one that had been sharpened and hung to its snath, and the father fearing the child would step backward and cut himself, immediately caught hold of the snath and jerked it (as he supposed) away from the child's foot, but in his hurry and excitement failed to make any calculation for the circular form of the edge of the instrument, and drew it directly across the right tendo-achillis, incising that tendon clearly and completely through. The child, of course, fell to the ground, and the father, greatly frightened, despatched a messenger for me immediately.

On arriving at the house, half an hour after the injury had been received, I found, upon examination, an incised wound, about one inch above the insertion of the tendo-achillis into the os calcis, one and a half inches long and sufficiently deep to neatly and entirely divide that tendon, together with the long tendon of the plantaris muscle. Very little hemorrhage had occurred, as the foot and leg had been enveloped in a cloth wet in cold water soon after the injury was received; and as none took place upon opening and thoroughly sponging the wound, I proceeded to dress it by bringing the lips of the incision together with an interrupted suture. I then procured a piece of siding long enough to reach from the tuberosity of the tibia to about an inch beyond the ends of the toes—the foot being brought as nearly on a line with the leg as possible without positive pain—and wide enough to take off the greater part of the pressure from the sides of the foot and calf of the leg.

This splint was thoroughly padded with cotton at its points of contact, and *firmly* secured to the foot with a roller bandage. Another roller was now applied to the upper end, commencing at the knee-joint and going downward. The reason for this was a hope that by firmly bandaging the muscle from above downward, I could overcome the retraction that existed, and thus more nearly approximate the ends of the divided tendon, and also prevent any subsequent contractions that might take place. The result fully sustained the opinion, for upon covering the belly of

the *gastrocnemius* with the bandage, I found the cut ends of the tendon very nicely in contact. Leaving now a space between the first and second bandages, which included the wound and gave ample opportunity for observation and examination, I took two corks, each about one half an inch in diameter and one inch long, and smoothly rounding off their ends, applied them as lateral splints to the tendon at the point of division, securing them in position with strips of adhesive plaster. Over this I applied a compress saturated with cold water, with directions to renew whenever it became dry, or the wound hot and painful. Three days after the first dressing the sutures were removed, and the edges of the wound held in apposition by adhesive straps. The corks were readjusted so as to support the tendon laterally, and the nurse directed to continue the cold water dressing as before. Directions were also given that the boy should be brought to my office upon detecting much fever about the wound. One week after the injury, the patient was brought to me, not so much because of any unpleasant symptom as on account of the anxiety of the parents to be assured that all was right. The compress was removed and there was found, instead of any considerable amount of suppurating, the wound nearly healed by first intention; only a few granulating spots being observed, and those at the points of the sutures. The compress was omitted, but the cork splints to the tendon retained, and no further medication made use of. The patient was furnished with a pair of crutches and permitted to go about as usual.

Three weeks after the reception of the wound, all dressings and splints were removed, and, examination revealing the fact that the tendon was completely united, the boy was allowed to lay aside his crutches and make the best use of his foot possible. The result was that after a few days necessary for the restoration of the functions of the extensor muscles, so long kept stretched and inactive, the child was able to walk as well as ever, and from that day to this has never suffered any inconvenience from the injury.

The tendon seemed to unite in a manner not unlike the union between two fragments of fractured bone—by a sort of provisional callus—and to this day there may be felt a hard ring or band around the tendon at the point of injury; yet its function is not, nor ever has been, impeded by it.

I did not at the time, nor do I now, consider the results obtained in this case as anything remarkable, neither do I regard it as necessary that from three months to a year should elapse after such an injury, before good use can be had of the limb; *provided* the cut ends of the tendon are properly approximated and coapted, and *retained in that position*, and the patient's constitution be in a condition favorable for union of any tissues.

I know of no reason why tendons, and especially the tendo-achillis, should not unite nearly as readily as bone, if there can be secured proper coaptation and complete immobility of the parts. Gray, in speaking of tendons (Anatomy, Second American Edition, page 237) says, "Nerves also are not present in the smaller tendons; but the larger ones, as the tendo-achillis, receive nerves which accompany the nutrient vessels."

Here then are the conditions of repair; the tendo-achillis being supplied with nutrient vessels, and nerves, if the surgeon will properly approximate and coapt the divided extremities, and so secure them, together with perfect immobility of the parts, nature will repair the injury, without appreciable deformity

in a reasonably short time, or very nearly as quickly as she will repair a fractured bone.

D. A. SHEFFIELD, M.D.

APPLE RIVER, ILL., July 24th, 1874.

POISONOUS ADULTERATION OF FOOD.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: I see by your last number that the cases of poisoning in East 32d street have been deprived of any air of mystery that may have hung around them, by the discovery of the true cause in the careless use of Paris green.

But I fear that much of the chow-chow that is put upon the market is hardly a safe article for indiscriminate consumption. In a conversation with a friend connected with one of the largest drug houses in Chicago, he gave me some of his experiences with those who get hold of a drug, and not knowing its name or nature, go to the druggist for information. One of these earnest seekers was a manufacturer of the relishes that the community so frequently buy at the grocers, and so unsuspectingly consume.

It seems that a rival had got hold of an article that had added great piquancy to his chow-chow by reason of the improved twang imparted to it. Fearing to lose his trade by inferiority of production, he had bribed an employee of his rival, and had obtained the drug, which he produced. The secret proved to be aconite root, and a good, strong article at that. The assurances of the druggist as to its poisonous qualities only aroused the incredulity of the enterprising mixer, who was certain that such increased gustatory advantages must be legitimate, and could not possibly be productive of any injurious results, as the improved article had already been some time on the market and no unpleasant surprises had arisen. He probably had his order filled by some less conscientious or inquisitive druggist, and doubtless the compound is on its travels. When I first read in the dailies of the poisoning of a family in New York by chow-chow, I presumed that the cause could be easily explained. If these few words shall serve to guard any one in their selection of this relish, or help to solve any doubts arising from any future case of poisoning by this sophistication, they will have served the object intended.

CHARLES W. OLESON, M.D.

BLOOMINGDALE, ILL., Aug. 2, 1874.

ACCIDENTAL POISONING.

TO THE EDITOR OF THE NEW YORK MEDICAL RECORD.

SIR: Will you kindly accord me a little space in your journal to call attention to one point, which I think concerns not only the public at large, but ourselves as physicians? I refer to the entirely reckless and irresponsible way in which the most active poisons are dispensed by apothecaries to whomever chooses to ask for them, irrespective of the risk and danger attendant upon their use. The moral of my remarks is pointed by the late case of poisoning in 32d street, where, out of four persons who, on Sunday, the 19th July, sat down to dinner, three died within the week, and by the case of the two children who, since that time, died in 11th street from the careless use of poison. In both cases Paris green was the cause of death. In the first of these, the details of which I am thoroughly conversant with, the poison was purchased, without a physician's order, for the purpose of poisoning cock-

roaches, and so carelessly was it used that it was found scattered in the knife-drawer, about the sink, and upon the dresser. The only wonder is that with such recklessness more fatal accidents do not occur.

To us, as medical men, devolves the duty of calling attention to the danger arising from these poisons, and to urge that measures be adopted preventing apothecaries and others from selling poisons, or, in fact, *any* medicines whatever, without a responsible physician's prescription, and that certain penalties be inflicted upon those who disobey this law. It was only a short time since that a French apothecary was heavily fined for selling calomel without a prescription. Why should his American confrère be permitted to sell virulent poisons to any person who chooses to ask for them? Not only would I hold it penal to sell poisonous drugs without a physician's prescription, but I would restrict the druggist from renewing or copying a prescription without the physician's order to that effect. The reason, upon a moment's reflection, is clear enough for two reasons: in the first place, the prescription is given to the patient at a certain time, for a specific purpose, and in accordance with certain symptoms. Those conditions being fulfilled, and the medicine taken, it is certainly neither within the province of the patient to decide whether the prescription should be continued nor of the apothecary to renew it without orders; and in the second place, many drugs enter into prescriptions which should not be taken except under the guidance of some responsible medical man—certainly not left to the decision of persons entirely ignorant of their properties or action.

If physicians would be more careful to attend to these matters (and upon them rests the blame), we should hear less of such accidents as daily meet our eye in the public prints.

I remain, dear sir,

Very faithfully yours,

FRED. R. STURGIS, M.D.

16 WEST 42D STREET, NEW YORK.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from August 5, 1874, to August 18, 1874.

HEIZMANN, C. L., Assistant Surgeon.—Assigned to duty with expedition under Captain Anson Mills, 3d Cavalry, and, upon return of that command, to rejoin his proper station, Fort McPherson, Nebr. S. O. 111, Dept. of the Platte, Aug. 10, 1874.

LAUDERDALE, J. V., Assistant Surgeon.—Assigned to temporary duty at Fort Leavenworth, Kansas. S. O. 125, Department of the Missouri, Aug. 10, 1874.

WIGGIN, A. W., Assistant Surgeon.—Assigned to duty at Fort Stevens, Oregon. S. O. 98, Department of the Columbia, July 29, 1874.

McLAREN, A. V., Surgeon.—Died August 1st, 1874, at Boston, Mass.

Medical Items and News.

A CASE OF ACUTE ERGOT POISONING.—Dr. E. R. Henschel writes: "A lady, 240 days pregnant, stepped suddenly from a car; eight hours later she gave birth to a male child weighing 5½ lbs.

"By a misunderstanding the child received half a teaspoonful (gtts. xxx.) of Squibb's fl. ext. of ergot. Irritation of the fauces failed to excite vomiting. An hour after having taken the ergot, the boy was seized with severe paroxysms of abdominal pains, recurring every fifteen minutes, and lasting hardly sixty seconds. Slight tetanic contractions of the face and extremities were present, and four hours subsequent to the administration of the dose a sharp diarrhoea set in. This, as also the muscular contractions, yielded to repeated hot baths. In twelve hours all urgent symptoms had subsided; for two weeks there was a constant tendency to diarrhoea.

"I mention this case in support of the opinion that it is the uterine contractions the ergot induces, and not the ergot, which causes the death of a child during labor."

Dr. D. H. KITCHEN, formerly Assistant Physician of the State Asylum at Utica, has been appointed Chief of Staff of the Charity Hospital, New York, *vice* Dr. McDonald, transferred to the City Asylum on Ward's Island.

INTERNATIONAL SANITARY CONFERENCE.—This international, according to *The Lancet* of June 27th, is shortly to take place at Vienna, under the presidency of the Baron von Guggen. The delegates from the different countries are: For France, Dr. Fauvel; Germany, Dr. Pettenkofer and Dr. Hirsch; Russia, Dr. Lunz; Italy, Dr. Luciani; Greece, Dr. Orfanides; Persia, Dr. Pollack; Belgium, Dr. Heurard; Sweden and Norway, Drs. Kierulf and Berlin. The delegates of Great Britain, and the United States, and the Netherlands have not as yet been appointed. Austria has entrusted the office to Dr. Draseh, and Hungary, to Drs. Sigmund, Gross, and Cattanei.

Two points are principally to be discussed: 1. The quarantine regulations to be adopted according to the progress of science; and 2. The appointment of an international committee whose duty would be to cause epidemics to be studied wherever they may arise by special delegates, and to certify either to the making out of such epidemics, or to their disappearance. The expenses connected with this committee would be borne by the nations who shall take part in the conference.

ENGLISH NAVAL MATTERS.—Sir: The Navy List for June exhibits a deficiency of no less than thirty-seven surgeons! How is it that the first service in the world has become so discredited that, although there are so many vacancies, one man only had the courage to enter in 1874? The causes indeed are not difficult to find. Besides the ever-increasing *désagrémens* of a sea life in submerged and dangerous iron-clads, the Navy List itself tells a woful tale. It intimates plainly enough that no step in rank can be gained under thirteen years, and when that is attained, the aspirant must vegetate on half pay for a couple of years or so, or continue to do duty with his new rank in the same subordinate position he has filled for thirteen years already. When he becomes a senior staff surgeon after twenty years' service he will find that he cannot retire as in the army; that he cannot attain the rank of deputy inspector, the list of these being a stagnant pool from which there is no outlet; and that, gray-haired and spectacled, he must continue to brave a sea life among youthful and now uncongenial messmates, his *quondam* companions having long passed into the captains' and admirals' lists, etc., etc., etc.—Letter to *The Lancet* of June 13th.

CICATRICIAL CONTRACTIONS FROM
BURNS, INVOLVING THE FACE AND
HAND.

By GURDON BUCK, M.D.,

Visiting Surgeon to Presbyterian Hospital, and Consulting Surgeon
to Roosevelt and St. Luke's Hospitals, N. Y.

H. C. W., æt. four years and seven months, a resident of New Jersey, of sound constitution and enjoying good health, was extensively burned when sixteen months old by overturning upon himself a kerosene study lamp. At the expiration of about fourteen months the burnt surfaces had mostly healed. The parts involved in the cicatricial contractions which resulted from the burns were the left half of the face and scalp, and the dorsal surface of the left hand and forearm. When I first examined him, in February, 1872, his condition was as follows:—The left half of the scalp, as far back as the occipital region, was bare, and the surface presented a pale, shining, cicatricial aspect; the skin, however, was pliable, and moved freely on the underlying parts. The left ear, though diminished in size by the loss of its rim, retained its natural shape, and was not adherent to the scalp. The skin covering the left half of the forehead and temple, though cicatricial on its surface, was still movable on the subjacent parts. The outer half of the left upper eyelid was everted to an extreme degree, and spread out upon the eyebrow; the inner half of its tarsal border alone came into contact with the lower lid. The conjunction covering the everted portion of the lid being relaxed and swollen, filled up the space between the lids when closed, and thus protected the cornea, which otherwise would have become opaque from constant exposure. The eyelashes, as well as the tarsal edges of both lids, had escaped injury. The eyebrow was denuded of hair. The eyeball itself had sustained no damage, the cornea retaining its natural lustre, and vision being unimpaired. The surface of the left cheek and side of the nose was cicatricial, and the contraction consequent thereupon had drawn the underlid away from contact with the eyeball, but without producing any eversion of its tarsal margin. The left angle of the mouth was somewhat drawn upward by a vertical fold of cicatricial skin upon the cheek immediately above it. In consequence of the condition of the lids of the left eye, patient habitually held his head inclined forward and to the left side, so as to avoid direct exposure to bright light, and had thereby acquired a peculiar expression of countenance (see Fig. 1). A description of the left hand and forearm will be reserved to a subsequent part of the narrative.

On the 6th of February, 1872, an operation was performed in the presence of Dr. James A. Davis, the family physician, from Bloomfield, New Jersey, Drs. John Beckman and Thomas Satterthwaite, and Prof. A. C. Post, M.D.

First Operation.—The object of this operation was to restore the upper lid of the left eye to its normal relations and functions. It was attempted as follows:—Two incisions were started from a single point high up on the forehead, above the middle of the left eyebrow, and continued downward in lines diverging from each other and terminating, one at either canthus of the eye. The inverted V-shaped patch of skin, included between these incisions, was dissected up from

the pericranium as low down as the bony margin of the orbit. The upper lid was thus liberated and brought down so as to allow its tarsal margin to be adjusted in contact with that of the underlid. Before proceeding further, a transverse fold of the redundant conjunctiva, lining the upper lid, was excised as far back from its tarsal margin as possible. With the descent of the upper lid, the inverted V-shaped patch of skin, which had been raised from the forehead, was brought down and secured at a lower level by a pin suture inserted on either side, together with additional thread sutures above the pin sutures. The surface left bare on the forehead by the descent of the patch was closed by approximating the opposite edges of the wound and securing them in contact by thread sutures. To relieve these last sutures from tension, parallel incisions were made through the skin on either side, the one over the left temple being three inches, while the other, toward the middle of the forehead, was only one inch in length. The edges of these incisions yawned wide apart, and the desired relief was thus obtained. The bare surfaces left were coated with a collodion crust, formed by applying, first, a

FIG. 1.

layer of dry lint, and then over it a second layer of lint saturated with collodion, which soon stiffens and adheres closely to the surrounding surface. In order to hold the tarsal edges of the lids more exactly in coaptation, a beaded silver-wire clamp suture* was passed in a vertical direction through both lids towards the outer canthus, and out of the way of the cornea, and left in situ for three days. Wet dressings were avoided, and a layer of woven lint of double thickness was kept applied to the parts. Moderate febrile reaction followed the operation, but subsided on the third day. On the fourth day the last sutures were removed. Sloughing, however, had already taken place, and had involved about three-fifths of the trans-

* This suture is constituted as follows: A flexible silver wire, knotted at one end, and strung, first, with a small perforated disk of leather, and then with a smooth, round, glass bead, is armed at the other end with a suitable needle. This is passed through the parts that are to be held in contact, and then a second bead is strung upon the wire. The parts are now supported in contact, while the wire is drawn upon and the second bead pushed on to its place, and secured there by winding the end of the wire two or three times around a friction match, which is then to be cut short with strong scissors.

planted patch. Healthy suppuration succeeded the separation of the sloughs, and the ulcerated surface progressively diminished in size. The collodion crust separated from the forehead on the sixth day, and from the left temple on the tenth, leaving healthy granulating surfaces to heal by cicatrization. The eyeball had in no way suffered from the presence of the silver wire which traversed the lids. Patient rapidly regained his spirits and at the end of one week resumed his accustomed amusements, enjoyed his meals, and rested well at night. The sloughing which had taken place was no doubt to be attributed to the cicatricial condition of the transplanted patch of skin.* The ulcerated surface above the left eyebrow progressively diminished in size, and at the end of the fourth week measured one inch in its transverse diameter, by three-fourths of an inch vertically. If left to itself it was feared that the contraction consequent upon cicatrization might reproduce, to a greater or less degree, the original eversion of the upper lid. To prevent this it was determined to transfer a portion of sound skin from the right half of the forehead and engraft it upon the ulcerated surface. The operation for accomplishing this object was performed on the 8th of March.

Second Operation.—The ulcerated spot itself was prepared by first excising the granulating surface down to the level of the pericranium, with scissors, applied flatwise, and then paring afresh the edges, and evertng them slightly. A transverse incision was then carried across the forehead, on a line continuous with the lower margin of the spot just prepared, and as far as the inner extremity of the right eyebrow. The upper edge of this incision was dissected up to afford a bare surface of one finger's breadth, which would be continuous with and form a part of the space above the eyebrow. A pattern, cut from oiled silk, of the size and shape of the space just prepared, was applied upon the right half of the forehead, in a vertical position, with its base resting upon the inner half of the eyebrow, and its free extremity involving the hairy scalp above, which had been previously shaved clean. An incision was then carried around the margin of the pattern, and the included underlying patch of skin was dissected up from the pericranium, but left connected, for support, at the margin of the orbit. The pedicle of the patch, at its inner edge, toward the median line, was adjacent to the bare surface which it was intended to cover. Additional room had to be made for the transfer of the patch, by dissecting up the skin from the forehead, above the nose, and displacing it toward the left side, where it remained attached, and was reserved for subsequent use. The patch was now brought down edgewise from right to left, and adjusted accurately to the edges of the space prepared for it, with sutures inserted close together. In order to utilize the portion of skin displaced from above the nose, for the purpose of covering the surface left bare on the right half of the forehead, it was carried upward from left to right and adjusted to the lower part of the bare surface by means of sutures. The remaining upper portion of the bare surface was coated over with a collodion crust, and left to heal by granulation. Before proceeding to the operation just described, a transverse fold was excised, for the second time, from the still redundant conjunctival lining of the upper lid, and the lids themselves were secured together

by a single thread suture inserted through the skin alone, near their tarsal edges, and toward the outer canthus. A strip of woven lint, saturated with collodion, was applied across the outer half of the closed lids, to afford additional support. The entire operation occupied one hour and a half, and was well borne, the loss of blood having been inconsiderable. A layer of woven lint, of double thickness, was spread with cerate, to prevent its sticking to the surface, and laid upon the forehead. Elixir opii, gutt. x., and weak brandy and water were directed. March 10.—*Second day.*—Slight febrile reaction and moderate inflammatory tumefaction. Removed three pins and changed the yarn on the remaining ones. 12th.—*Fourth day.*—All the sutures have been removed in succession, including the one holding the lids in contact. To supply the place of this last suture strips of adhesive plaster were applied. Primary union has taken place at almost all points, and without any sloughing. 20th.—*Twelfth day.*—The collodion crust came off from the forehead, exposing healthy granulations at the circumference of the sore, but in the centre a brownish patch of sloughing pericranium, which had been unintentionally divided in the operation. No exfoliation of bone, however, followed the sloughing of the pericranium; healthy granulations covered the spot, and cicatrization followed. Iron and quinine were ordered as a tonic.

Third Operation.—The patient being in excellent condition, from a stay of three weeks in the country, a third operation was performed on the 20th April, for the purpose of removing a conspicuous distortion of the left angle of the mouth. An incision, commencing at a point on the left cheek, bordering on the middle of the nose, was carried downward and outward across the cheek to a point a little anterior to the angle of the jaw. In its course the incision divided the cicatricial fold which distorted the angle of the mouth, and so allowed the latter to regain its natural shape. The edges of the incision, after having been dissected up, receded from each other and left a space between them of about one finger's breadth. To fill this up with sound skin, the following method was adopted: A patch of skin of the required shape and size was dissected up from the side of the neck below the edge of the jaw, its free extremity being below the symphysis, and its pedicle of attachment adjoining the space to be filled up. This patch was then transferred edgewise to its new locality, and there accurately adjusted by sutures. The wound left on the neck was closed by approximating its opposite edges, and securing them together with sutures. The treatment was the same as after the previous operations. Union failed to take place, and sloughing of about three-fifths of the patch followed. On the fourth day the slough separated, and healthy suppuration succeeded. It was now important to prevent shrinking of what remained of the patch, and to maintain it in place. This was done by adhesive straps carefully adapted and frequently removed. April 25.—A mild attack of erysipelas developed itself upon the left ear and neighboring surface of the scalp, but soon passed off without any serious consequences. From this time his general health improved, and cicatrization of all the sore surfaces progressed steadily till June 8th, when all had finally healed. The result of the last operation, notwithstanding the loss of so large a portion of the transplanted patch of skin, was not without some improvement of the angle of the mouth. As no further operations would be undertaken till the autumn, patient's nurse was instructed to manipulate the parts upon the forehead and left cheek daily, so as to increase their pliability and prevent contraction from taking place. The good effect of

* The experience of this case, as well as of others similarly conditioned, establishes conclusively the rule that a portion of skin which has undergone cicatricial change on its surface from the effects of a burn cannot be used successfully for transplantation, for the reason that when it is detached from its underlying connections its supply of blood from periphtric sources alone is not sufficient to maintain its vitality.

these manipulations was manifest when patient returned in October to spend the winter in the city with his family.

The treatment of the left hand was now to be undertaken. Its distorted condition had resulted from the same burn which disfigured the face, and was as follows:—The surface of the entire forearm and dorsum of the hand was cicatricial. The skin on the dorsum of the forearm was thickened and contracted longitudinally, while in the direction of the circumference it was lax and could be gathered up into folds. The hand and all the fingers were drawn up to an extreme degree in the direction of extension; the thumb and index finger, however, to a much greater degree than the other fingers. To such an extent were they drawn backward that at their metacarpo-phalangeal articulations the articular surfaces no longer confronted each other, but the phalanges rested upon the dorsal surfaces of the ends of their supporting metacarpal bones. The fingers were maintained in their distorted position by separate corded folds of cicatricial skin proceeding from the dorsum of each and converging at the wrist, where they were continuous with and formed a part of a broad fold of skin, which extended up on the forearm toward the elbow. The middle, ring, and little fingers were drawn backward to an equal degree, and remained in contact with each other; while the index finger, being drawn further backward than its fellows, was also widely abducted from the middle finger. The thumb was drawn the furthest backward of all, its first phalanx riding upon the dorsum of its metacarpal bone. The phalanges being all capable of flexion upon each other, the fingers still performed useful service. Flexion and extension at the elbow-joint, as well as pronation and supination of the forearm, remained unimpaired.

FIG. 2.

Preparatory to an operation on the hand, a guttered splint, made of tin, was adapted to the palmar surface of the forearm and lengthened out at the wrist by the addition of a flat piece, bent flatwise in the direction of flexion, and adapted for the support of the hand. On the 24th October, 1872, a fourth operation was performed.

Fourth Operation.—The second, third, and fourth fingers being similarly involved, their treatment only was to be attempted in the present operation, which was executed as follows: By flexing the fingers and putting on the stretch the cicatricial folds on the dorsum of the hand, a broad longitudinal fold of skin was also rendered tense and salient upon the forearm above. This was transfixed at its base, near the middle of the forearm, while gathered up between the thumb and fingers, and a tongue-shaped flap of skin formed by cutting downward toward the wrist and outward through the surface. The detached flap receded toward the elbow, and the three fingers could be flexed to a right angle at their metacarpo-phalangeal articulations; the phalanges themselves, however, could not be flexed upon each other, owing to the resistance of the edges of the wound just made upon the forearm, which became very tense and unyielding whenever flexion was attempted. These edges were therefore freely divided across at selected points till there remained no longer any resistance, and complete flexion of all the phalanges could be effected. No tendons or muscles were exposed; the surface laid bare consisting of adipose and connective tissue. A single vessel only required to be ligated. Here and there a suture was inserted to hold the detached skin in place, but without any attempt to procure adhesion. The limb was then placed upon the splint prepared for it, and the three fingers were secured by adhesive plaster to the flat piece that joined the splint, at an angle of flexion opposite to the wrist-joint. The raw surface, which involved the dorsum of the hand and lower two-thirds of the forearm, was coated with collodion crust. After completing this operation, advantage was taken of the anæsthetic condition of the patient to perform another operation for the further improvement of the lids of the left eye. The outer half of the tarsal edge of the upper lid was still disposed to evert, and this disposition was promoted by the presence of a small mass of granulation growth in the conjunctival cul-de-sac at the outer canthus. The commissure of the lids had also become lengthened in a marked degree, so as to exceed the length of the commissure of the lids of the other eye by about one quarter of an inch. The mass of granulation growth was first excised by seizing it with a fine-clawed forceps and clipping it off at its base with scissors curved flatwise. The attempt was next made to bring about permanent adhesion between the tarsal edges of the lids at the outer canthus. While the lids were held wide apart and the ball of the eye was protected by a wet rag, a cautery iron, with a ball-shaped end of the size of a pea, heated to redness, was buried in the cul-de-sac of the conjunctival cavity at the outer canthus and applied thoroughly to both tarsal edges of the lids for a distance of nearly two lines from their junction with each other. Compresses wet with ice-water were immediately applied, and afterwards frequently renewed. On coming out from the anæsthesia patient did not appear to suffer from this severe application. No febrile reaction followed. He passed a good night without an anodyne, and the next day sat up with his arm supported in a sling. Scarcely any redness or swelling of the hand or forehead supervened. On the fifth day, Oct. 29, the collodion crust came off from the wrist and forearm, leaving a healthy granulating surface which thereafter was dressed with simple cerate, the limb being kept upon the splint. A moderate degree of inflammation followed the application of the actual cautery to the conjunctiva and tarsus. No injury was sustained by the cornea or ball of the eye. Superficial eschars separated, and healthy suppuration followed. Upon the forearm portions of cicatricial skin which had

been detached from their underlying connections sloughed. Nov. 5.—The exuberant granulation growth has required the energetic application of solid nitrate of silver at every daily dressing. Forcible flexion of the fingers and wrist has been daily practised: this, though a severe process during its performance, was not followed by any lasting pain afterwards.

It now became apparent that a great advantage would have been gained, by liberating the index finger and restoring it to its normal relations at the same time with the other three fingers; it was accordingly decided to do it without further delay. The operation was performed on the 5th of November.

Fifth Operation.—Two incisions, beginning one at the commissure between the thumb and index finger, the other between the index and middle fingers, were carried through the skin, upward, in converging lines, until they met at a point above the cicatricial fold of skin which held the finger extended. After these had been made, the index finger could be fixed at its metacarpo-phalangeal articulation, but not at its phalangeal articulations. By dissecting up the skin on the dorsum of the first phalanx from its underlying connections, the power of flexing the finger at these articulations was fully restored. The index finger was then brought down by the side of its fellow, where it was secured, and thereafter treated in common with them. The canterized surfaces at the outer canthus of the left eye being now in a state of healthy suppuration, and all swelling having subsided, the tarsal edges of the lids were secured in exact contact by a silver wire-headed suture (see page 473) inserted in a vertical direction through both lids, at a distance of half an inch from their tarsal edges, and at the same distance from the outer canthus. Two fine thread sutures were also inserted at the edges, after first scraping them with a dull-edged knife. The thread sutures were removed on the third, and the wire suture on the eighth day. Permanent adhesion was thus secured between the tarsal edges for a distance of nearly three lines from the outer canthus, thus shortening the commissure so as to correspond with that of the other eye. Early in the month of January, 1873, the wound surfaces on the dorsum of the hand and wrist had healed. The manipulation of the wrist and finger-joints had been continued daily with decided benefit, and the limb had been kept constantly secured to the splint. The thumb, not having yet been subjected to any treatment, remained unchanged. To remedy this deformity was the object of the

its supporting metacarpal bone. In order still further to liberate the thumb, and reduce the dislocation, a longitudinal incision of the skin was carried between the metacarpi of the thumb and index finger upward to join the incision across the wrist, and the skin was dissected up on the dorsal surface of the metacarpus of the thumb. All resistance was at length removed,

FIG. 3.

FIG. 4.

Sixth Operation.—Feb. 12, 1873. By stretching the thumb in the direction of flexion, a longitudinal fold of cicatricial skin was brought into prominence upon the radial border of the wrist and forearm. At first broad and embracing the root of the thumb, this fold grew narrow as it extended obliquely upward on the palmar surface of the forearm, in the middle of which it became corded, and continued so to the elbow. This fold in the process of its formation had evidently drawn up the thumb into its distorted position, and was still the chief obstacle in the way of its performing complete flexion. This fold was divided, while held on the stretch, by a transverse incision passing one-third around the wrist, and at a distance of one inch above the joint. The tissue creaked under the knife, and the edges of the wound receded wide apart, but without affording much relief to the thumb. The subjacent aponeurotic layer was also found tense and resisting, and had to be divided across. Some degree of flexion was thus obtained. It was now ascertained that the proximal end of the first phalanx was dislocated, and rested on the dorsal surface of the end of

and the thumb could now be brought down and flexed in all its articulations. To the splint that had served hitherto for the treatment of the fingers, an addition was made of a separate digitation for the support of the thumb, which required to be maintained in an abducted as well as a flexed position. The newly made raw surfaces were treated in the same manner as after

the previous operations. Patient did well after this, as he had done after the previous operations. The same process of forcible flexion and stretching was employed upon the thumb as had been used upon the fingers with such good results. In order to reduce the size of the thumb and improve its shape, it was kept tightly wound with strips of adhesive plaster. The commissure between the thumb and index finger was also kept crowded up towards the metacarpus by strips of adhesive plaster applied tightly over a saddle-shaped compress made with several thicknesses of woven lint.

On the 1st of May a spot of the size of a finger-nail, on the wrist, at the root of the thumb, was all that still remained unhealed. Under the constant use of the manipulations already described, and the wearing of the splint, the thumb and fingers had regained their natural shape and freedom of motion, and were gradually recovering their power to grasp objects. The thumb, however, in consequence of its greater degree of distortion, originally had not recovered the power

FIG. 5.

of flexion so perfectly as the other fingers. The face had also much improved; the commissures of the eyelids were alike in length on both sides, and the tarsal edges of both lids of the left eye were perfect in their adjustment to each other. A spot upon the forehead, above the left eyebrow, of the size of a thumb-nail, was covered with a growth of hair that required to be shaved two or three times a week. It was a portion of the hairy scalp, and formed the extremity of the patch of skin which had been transplanted from the right to the left half of the forehead. On the 10th of May he accompanied his family on a visit to Europe. From that time to the present (January, 1874) the daily manipulation of the fingers has been kept up regularly, and the splint has been worn at night only, the hand being left free in the daytime to be exercised in every possible way. The father, in a recent letter, says: "His hand has improved, and he now uses the thumb quite a good deal; in fact for all practical purposes it is about as useful as the other. We

still keep it in the splint at night, and continue the manipulations daily on the hand and also on the face."

Figs. 3, 4, 5, showing the results of treatment, are from photographs taken in Florence in January, 1874.

46 West 29th st., May 26th, 1874.

A FEW REMARKS REGARDING CERTAIN ABNORMAL CONDITIONS OF THE SUPERIOR AIR-PASSAGES, AND SOME OF THE CAUSES OF CHRONIC INFLAMMATION OF THESE PARTS.

WITH A FEW SUGGESTIONS CONCERNING THE TREATMENT.

By W. H. BENNETT, M.D.,

NEW YORK.

1st. I think it may be demonstrated that dust from ordinary sources, as met with in the air which all of us breathe, and not referring to any particular calling, enter the larynx and trachea in considerable quantities, under certain circumstances, and may remain adherent to the walls of these organs many hours, and even a whole day.

2d. A healthy mucous membrane covering the nares, pharynx, and larynx is less frequently met with in the city of New York than is commonly supposed; certainly in every third adult it will be found diseased at some point, and in children above the age of ten nasopharyngeal catarrh is exceedingly frequent.

3d. Although the apparent effect of a foul stomach is only visible on the tongue (coated tongue), the irritation is equally felt by the whole mucous surface in the immediate vicinity, and it is frequently impossible to cure a chronic catarrh of these parts without treating the stomach also.

4th. A partial constriction or obstruction of either of the nasal passages, or at the anterior nares, has, to a certain extent, the same effect upon the parts immediately behind it as a stricture of the urethra, or at the external meatus, has upon the parts immediately behind it.

5th. Although it is impossible to make a diagnosis of incipient phthisis solely from the condition of the larynx, we may nevertheless be greatly assisted in our diagnosis by the appearance of this organ.

6th. The chink of the glottis may be so nearly closed, if the narrowing take place gradually, as to present an opening scarcely a line and a half in diameter when stretched to the utmost, and yet sufficient air will find entrance to the lungs to prolong life for the time being, and even for some days.

7th. All diseased membranes absorb moisture from the air in damp weather, but particularly the mucous membrane of the superior air-passages, which may become considerably swelled from this cause, the vessels dilated, the circulation sluggish, and the secretion markedly increased.

To return to my first statement regarding the entrance of dust particles into the larynx and trachea; I have seen several cases where the interior of these organs was discolored in spots, here and there, by a black deposit, and in two of these cases the patient had not been exposed for some hours to an atmosphere of dust. I am confident as to the nature of the deposit, for I took the precaution to wash out the larynx, collect the sputa, and examine it under the microscope. Every one of these several cases suffered from catarrh

of the parts alluded to, and in two of them there was ulceration of the membrane covering the arytenoid muscle. The circumstances which favor the introduction of the suspended matter of the atmosphere into the larynx are a diseased condition of the parts above the pharynx and nares, either a dry condition of these parts, a lack of secretion, or some constriction or obstruction of the nasal passages which forces the patient to breathe through the mouth, and this latter condition is the most favorable. In the first instance, where the person breathes through the nares, he must be exposed to an atmosphere highly charged with dust, and for a long time, before sufficient will collect to demonstrate its presence. I do not think that in a normal condition of the naso-pharyngeal membrane, and when there is no obstruction to free respiration through the nares, dust ever penetrates so far as the larynx or trachea, certainly never in any quantity, unless the atmosphere inhaled is excessively loaded, for the moist membrane, over which the air passes and impinges against at so many points, must certainly filter it of the greater part of its suspended matter. It is only when the larynx itself has been diseased that I have ever found dust in sufficient quantity to prove its presence, even though the parts above were in a favorable condition for its entrance. This, however, I think, is easily explained; for in a healthy condition of the mucous membrane the dust particles would be quickly thrown off and coughed up; while, on the other hand, if there existed ulceration or abrasion or laryngeal catarrh, with scanty viscid secretion, the accumulation of dust would be favored, and it would not so readily be thrown off and expectorated.

Concerning my second statement, relating to the frequency of disease of the superior air-passages, I allude especially to chronic inflammation (so called) of the lining membrane of these parts. Chronic laryngitis is certainly frequent enough, but catarrh of the nares and pharynx is still more common. Why professional singers, stockbrokers, etc., should develop disease of the organ of voice is easily understood; but why at least four or five out of every twelve adults in this city, irrespective of their calling or profession, should suffer from chronic inflammation of some part of the respiratory membrane situated above the trachea is not so apparent, although upon a close study of the matter other important causes may be discovered than the frequent catching of a cold. I do not hesitate to state it as my belief, that the inhalation of a vitiated atmosphere has much to do with the production of the disease in question, and by a vitiated atmosphere I mean one that is overheated or highly charged with impure gases or particles of suspended matter. I allude particularly to this latter condition—the presence of an abundance of suspended matter in the air both in and out of doors. As before mentioned, it may be demonstrated that dust enters the larynx and trachea, consequently the naso-pharyngeal membrane must receive a greater quantity, unless the person breathe through the mouth altogether, which is very rarely the case. The air of all large cities, near the thoroughfares, is loaded with dust of a very filthy nature, which cannot but prove irritating to any delicate surface with which it comes in contact; and although some mucous membranes seemingly stand the contact of dust for a long time without receiving any permanent injury, yet I believe every acute catarrh which these develop is prolonged by this irritant, particularly in the resolving stage, when the secretion gets scanty and the membrane dry. But in those having a delicate cuticle and thin epithelial covering, the constant inhalation of dust particles may cause

chronic inflammation without the occurrence of acute attacks. That the inhalation of dust will cause chronic catarrh of the superior air-passages in animals, I have proved to my entire satisfaction, by confining them in an atmosphere loaded with suspended matter for a length of time,* and the air which these animals were forced to breathe contained no more dust than I frequently see in the air in certain parts of the business portions of this city. The out-door air is by no means the only source from whence the dust we inhale comes; but in houses heated by furnaces, as most houses in the city are, the hot air coming from the register is frequently very highly charged with minute particles of matter, and patients affected with catarrh notice themselves the difference between a room heated by hot air and one warmed by other means. Whether furnaces may be so regulated as to carry no dust into the apartments they heat, I do not know; but I am certain that in many instances they generate a great deal of very fine dust, which certainly penetrates farther into the air-tubes than coarser matter; and I think, also, the finer the particles the more harm they do, in proportion to the quantity present and the nature of which they are composed, for they adhere more firmly to the membrane and mix more readily with the secretion. I find that the dust which escapes from the registers, which I have tested several times, has a very faint acid reaction, while the dust taken from out of doors, as found lodged in the doorways and window-sills, is perfectly neutral.

If it be objected to my views regarding the influence of the matter inhaled in causing chronic catarrh, on the ground that conductors on railroad trains, commercial travellers, and others of like callings, who are constantly exposed to an atmosphere of suspended matter, do not sustain any injury to the air-passages, I would state that the dust inhaled by these people is comparatively clean and of a different nature altogether from that which is present in the atmosphere of a large city, or which comes into a room from the furnace; and further, it is a mistake to suppose that the individuals above alluded to do not suffer to a greater or less extent, although some seem to escape entirely. Naso-pharyngeal catarrh is extremely prevalent among conductors on the city horse-cars, and during the spring and early winter months, when the streets are dry and the amount of dust dragged after the cars excessive, they are always made worse. Earth has been extensively used of late as a dressing for foul sores and abraded surfaces, and injections of muddy water are said to be of great service in leucorrhœa and gleet; but no one would think of making a poultice of the scrapings of the streets of New York, nor of washing out the vagina with a solution of the same. The particles of dust suspended in the air, and which we inhale at every breath, are derived both from organic and inorganic matter, and let me ask is it too much to suppose that the organic particles carry the germs of putrefaction and decomposition, and that they induce this process in other organic bodies with which they become mixed, under favorable circumstances, as the retained secretions of the different mucous membranes?

Alluding to a foul stomach as a cause of disease of the superior air-passages, this I know has been recognized before; but I scarcely think sufficient importance has ever been attached to it. We all know that the diagnostic symptom of a deranged stomach is a coated tongue, and this coating of the tongue is nothing

* The writer will take pleasure in giving a full history of these experiments, together with that of some others now under way, at his earliest convenience.

more than cast-off epithelium and an abundant secretion from the mucous glands of the organ, due to the contact of acid irritating gases from the stomach that act equally upon the other mucous membranes with which they come in contact, and, if this condition is constant, give rise to an obstinate form of catarrh, which can never be cured so long as our attention is directed to it alone, and the condition of the stomach ignored. Functional derangement of the stomach, I think, may be the sole cause of a laryngeal or pharyngeal catarrh, and that in persons of temperate habits who neither drink nor smoke at all, and it certainly is a very important factor where other causes are brought to bear. If any proof on this subject were wanted, we would have it in the fact that where the state of the stomach is corrected, the catarrh of the pharynx or larynx, as the case may be, improves, and further, that it frequently happens patients while under treatment for chronic inflammation of the mucous membranes alluded to become dyspeptic, suffer from acid eructations, and vomit after eating, when it almost invariably follows that their catarrh gets worse unless the condition of the stomach is immediately attended to.

Coming to constriction of the nasal passages, there are two reasons why such a condition should favor disease of the mucous membrane behind it: First, owing to the hindrance to the free discharge of the secretions of the part; and second, owing to the rarefaction of the air, which must occur to a greater or less extent on inspiration, which by lessening the normal pressure tends to allow of dilatation of the vessels, cause stasis, and produce exudation upon the free surface of the membrane. These remarks, of course, apply more particularly to the part immediately behind the stricture; but if the narrowing be considerable the pharynx and larynx are affected indirectly in another way, by the patient breathing through the mouth, which, particularly in cold weather, will favor the production of catarrh of these parts. These constrictions occur frequently at or near the anterior nares, and then consist for the most part in a deviation of the septum; obstructions further back are due generally to polypoid growths. In most cases of nasal catarrh there is a more or less swelling of the mucous membrane covering the inferior turbinated bones; but this is due to or is a part of the disease, and not a cause of it; still it has something to do, as already shown, in producing disease of the parts immediately behind it. Deviations of the septum, if looked for, will be found to be exceedingly common, and, in my experience, the septum is generally turned to the right side. They are not all of sufficient extent to give rise to symptoms, and may even be extreme without creating trouble where other causes are not also brought to bear; but if chronic catarrh is once developed, it will be aggravated by this condition, and a cure of the disease will be a difficult matter until the narrowing is dilated or removed.

Dr. J. Solis Cohen, of Philadelphia, in his book on diseases of the throat, mentions, among other causes, the alternate taking of hot and cold food and drink at meals. I attach great weight to this practice as a cause of disease of the parts in question, and instead of placing it at the end of the list of causes, as Dr. Cohen does, I would mention it first. I think, however, that the eating and drinking of hot things, and then rushing immediately into the open air, in cold weather, is more injurious than alternately bringing cold and warm substances in contact with the parts. The taking of solids and fluids very hot, even if not followed by cold draughts or the inspiration of cold air, is to be denounced in the strongest terms.

Another cause of disease of the mucous membranes, recognized by some authors, is the existence of a constitutional disease, which in some may show itself as an eczema or psoriasis, while in others it affects the mucous surfaces. I believe this theory to be correct, for it not infrequently happens that a catarrh develops upon the disappearance of an eczema of the scalp or skin, and as we see chronic eczema of different parts of the derma, persisting for months sometimes, and even for years, in spite of all treatment, there is no reason why the mucous membranes should not be affected in the same way. Supposing the predisposition to exist in a given case, the mucous membrane of the superior air-passages would be more likely to suffer than any other, on account of its exposed position.

I did not propose to enter into all the causes of chronic catarrh of the superior respiratory tract, but simply to mention these several, which I think are important, and merit more attention in the prophylactic treatment of the disease than they have generally received.

In the treatment of chronic inflammation of the air-passages, I would suggest the removal of the patient as far as possible from a vitiated atmosphere, remembering that by this term I also frequently include the air of apartments heated by hot air. This will certainly add to his comfort, if it does not hasten his cure. The state of the stomach should always be inquired into, and a thorough examination for constriction or obstruction of the nares made. If any narrowing of these parts is found to exist, it should be relieved at once, before any further treatment is commenced. For the purpose of dilating the nasal passages, I have used the lamina digitata, and with very good success; but if the membrane covering the inferior turbinated bones is thickened and swelled, incisions should be made through it down to the bone; the application of caustics affords only temporary relief, and if frequently made, does more harm than good, but after the incisions are made, and the hemorrhage stopped, the point of a stick of nitrate of silver, or a bit of sponge dipped in a saturated solution of the same, may be run through them. The hemorrhage after incisions here will be considerable, for the parts are exceedingly vascular. I have known persons faint during the bleeding, but the sight of the blood might have had something to do with that. Owing to the excessive hemorrhage, only one side should be operated on at the same visit. In the treatment of chronic catarrh we may recognize two principal forms of the disease; in the one, the secretion is scanty and the membrane dry and irritable, in the other, the secretion is more abundant, the membrane flaccid, more or less swollen, and not so sensitive to irritants inhaled with the air, because in a measure protected by the secretion. In most cases of long duration the former condition will be found to exist, and soothing applications, with such as tend to promote secretion, as a mucilage of gum-arabic or flaxseed, containing chlorate of potash, will be proper for awhile, and afterward weak stimulating solutions answer best, but they must be frequently and faithfully used for a long time. If there is hypertrophy, with loss of sensibility, the applications must be stronger. In many of these cases there is an extensive loss of epithelium, and the coating formed by the mucilage protects the part from the air, and whatever irritants it may be charged with. Where there is considerable secretion, astringents are to be used from the first, applied of any strength, according to the peculiarities of the case, as sulphate of copper or zinc, from gr. $\frac{1}{2}$ to gr. xx. of the former, and from gr. ij. to lx. of the latter, or gr. i. to gr. xx. of the nitrate of silver to the oz. of water. Balsam of co-

paiba, 3i.-3ij, to the oz. of mucilage, is a favorite remedy with me, given to the patient to use himself several times daily; this is also of great service where the secretion is offensive, or where it is retained and decomposes. Cansties are only required when there is something to be destroyed; for the peculiar, jelly-like, puffy elevations, which not infrequently appear, and which are due to cell proliferation, strong solutions of zinc or copper are superior to the nitrate of silver, but they must be used oftener. For healing catarrhal ulcers quickly there is nothing like the nitrate of silver, but it should only be applied to the ulcerated surface. Before any remedial application is made to a mucous membrane it should be washed off thoroughly with tepid water by means of a syringe, and the manner of making the application is of the utmost importance. I will here call attention to some instruments which I have devised* for carrying the caustic and stronger astringent solutions, by means of which I think the posterior nares, larynx, and trachea may be medicated as thoroughly as the pharynx or fauces.

brush wet in a strong solution of nitrate of silver. In the treatment of naso-pharyngeal catarrh the condition of the pharyngeal surface of the soft palate should be looked to, and it will generally be found diseased; the cure of the pharyngitis will be greatly hastened by treating the soft palate also, for at every swallow the two surfaces come in contact. In applying the weaker solutions to the pharynx and nares, Thudicum's nasal douche is an excellent apparatus; but I am afraid of it, for I am sure it frequently does harm to the internal ear, notwithstanding all that has been said to the contrary. Next to the douche, the ordinary syringe will be found the most convenient instrument for applying the weaker solutions to all parts, if it is properly made and of the proper curve. In those cases of pharyngitis where there are enlarged varicose veins, I have frequently cut across them in several places, and seemingly with benefit in some instances. If there are enlarged follicles or thickening of the membrane, the compound tincture of iodine diluted, according to the sensibility of the part, has proved in

FIG. A. represents a laryngeal spray-syringe. FIG. B. a posterior nares spray-syringe; *a*, receptacle for the solution used; *b*, tube which conveys the solution. The only difference between the two instruments is that one is smaller than the other, and curved upward instead of downward.

The end of the nozzle of the larger syringe, with the aid of the laryngeal mirror, may be carried over the epiglottis to just above the vocal cords or even between them, and at the moment of inspiration, as the cords are seen to separate, a shower of spray thrown out. The curved extremity of the smaller syringe being introduced behind the soft palate, and the piston driven home, the spray comes in contact with the whole superior pharyngeal surface, and enters the posterior nares; if the patient can be taught to expire forcibly through the nose at the proper moment, the effect is all that can be desired. I think these instruments possess some advantage over others that are in common use, especially for medicating the cavity of the larynx and trachea, for the probang, or brush, is not readily introduced far down, even by skillful hands, and it always causes severe spasm; moreover, it does not touch the whole of the mucous surface, but impinges against the anterior or posterior or lateral wall. With the ordinary spray tubes there is no doubt but that the larynx and trachea may be medicated quite thoroughly, but in doing this all the parts above are sprayed at the same time, and as the solutions used in these cases are strong, the pain and spasm produced is severe—sufficient in many instances, particularly in phthisical patients, to make the exhausted and debilitated sufferer refuse to submit to further treatment. Ulcerations, if above the vocal cords, should always be touched with a sponge or

my hands of more service than any other remedy. I think that many of the ulcerations and abrasions which occur in bad cases of nasal catarrh are due to violent attempts at clearing the passages; the swelled membrane obstructs respiration, and imparts the sensation of accumulated secretion, which the patient tries to force out by frequent energetic attempts at blowing the nose. If true hypertrophy exists, it is incurable; but there are many cases of apparent hypertrophy with thickening, due to infiltration of the submucous tissue, which come under observation and recover entirely. A few suggestions only are here offered, as it is not the object of this paper to consider fully the matter of treatment.

Regarding the aid to be derived from examinations of the larynx in making the diagnosis of phthisis, I would state that as a rule the mucous membrane of that organ is pale red here and there in circumscribed spots, which are raised above the surface and here and there presenting small yellow discolorations, especially on the post surface of the epiglottis. It is true the membrane may be congested and reddened throughout its whole extent, but if in suspected incipient phthisis we find the appearance above described, it is entitled to great weight in confirming our diagnosis. Ulceration of the membrane corresponding to the insertion of the vocal cords on the posterior surface of the larynx is considered by some authors as characteristic of phthisis, but this does not generally occur until we have already recognized the disease of the lung by auscultation and percussion. In laryngitis or

* On the principle of Richardson's Atomizer.

pharyngitis due to a foul stomach, the membrane is more generally congested than in phthisis, and there are apt to be enlarged follicles; at the point where the tongue presses against the pharynx in swallowing there will be a patch or two of a spongy, velvety, or gelatinous appearance, raised above the membrane, and due, as already mentioned, to the proliferation of epithelial cells beneath the surface layer. This condition, however, may occur from other causes. Varicose veins of the pharynx are frequent in those addicted to the use of *spirited* liquors and condiments, and also in those who habitually take food and drink very hot.

Regarding the extreme constriction of the glottis, which may gradually take place without causing death by suffocation, I allude to it not merely as a curious fact, but to call attention to the truth that the patient's life is in danger from other causes than apnoea when this condition exists, and to urge an attempt *always* at the prompt relief of the obstruction to the respiration. These constrictions of the larynx occur mostly in syphilis and phthisis; they are far more common, however, in the latter-mentioned disease. I feel certain many consumptives die from exhaustion due to the loss of sleep and the over-exertion consequent upon difficult respiration. The dyspnoea is the indirect cause of their death, and it is frequently due to swelling and circumscribed oedema of the glottis, which might in a great many cases be reduced by local treatment. In connection with this subject I may also mention the feasibility of relieving the cough and vomiting which are due to an ulcerated larynx, in phthisis, by local treatment. It is indeed too true that many of these cases go on from bad to worse, in spite of all that can be done for them; but, on the other hand, I am sure I have frequently not only removed the dyspnoea, but also the dysphagia, and to some extent the cough, by local medication and scarification, and by this means prolonged life for many months. I have great faith in local applications in phthisis: not that I expect to cure the disease, or even heal or remove permanently the ulcer and oedema to which my treatment is directed, for they will appear again and again, but I prevent the patient dying from exhaustion by enabling him to take rest and nourishment.

Alluding to the absorption of moisture from the atmosphere by diseased membranes, it need scarcely be explained that this takes place to a greater degree in the mucous membranes of the air-passages than anywhere else, a greater quantity of air coming in contact with these parts owing to the act of respiration; and again it will easily be seen that the nearer the external orifices the diseased part is situated, the greater still will be the amount of moisture presented for absorption, for the deeper the damp air penetrates into the lung the dryer it becomes, being robbed of its moisture as it passes along.*

The influence of the moisture is very manifest in those suffering from naso-pharyngeal and laryngeal catarrh, and to a less degree in persons with chronic bronchitis and phthisis. I think it is important to bear this in mind in the treatment of all catarrhal affections, particularly when we are about to recommend a change of climate. There may be some few cases where the membrane is so dry and irritable that they absolutely require a humid atmosphere, but as a general rule the reverse is the case; and I am sure that persons with the diseases already mentioned suffer more during

July and August, when there is a great deal of moisture in the air, than during the coldest weather in winter, when the air is dryer—that is so far as the symptoms relating to the chronic disease is concerned, and not referring to the distress or discomfort produced by acute attacks. If a bad case of laryngitis, for example, be examined on a dry, bracing day, and again on a damp, humid one, after having been exposed to the out-door air for some time, the appearance of the membrane at the two examinations will be very different. In the latter case the membrane will be much more swollen and tumefied, the secretion increased, and the vessels more distended and tortuous, and if there be active cell-formation at certain points, giving rise to jelly-like elevations, or warty-looking vegetations, these will be very prominent, and stick out as spongy, puffy masses of twice the size they appear after inhaling a dry atmosphere. In naso-pharyngeal catarrh the swelling of the membrane covering the turbinated bones is markedly increased on damp days, and the patient will generally tell you that he feels something behind the soft palate which he in vain tries to hawk down and spit out. This is due to the excessive swelling of the epithelial cells from absorption of moisture, a certain degree of prominence of the membrane due to cell proliferation having existed before.

Referring again to treatment, it may be truthfully stated, I think, that too much is as bad, or worse, than none at all; for most applications are in themselves irritants, and do good only by removing or correcting some already existing condition of greater activity or permanence; and it requires as much judgment to know when to stop as what to use, or where to use it.

ACUTE ARTICULAR RHEUMATISM.

REMARKS UPON A CASE,

By J. M. DA COSTA, M.D.,

Visiting Physician to Pennsylvania Hospital, Philadelphia.

(Phonographically recorded for THE MEDICAL RECORD.)

Miss D—, et. 19 years. This patient has been in the hospital only a few days, and has the appearance of a healthy female. Her father has had rheumatism, but at the present time is in good health. The patient herself has always been healthy until the present attack, which came on about three weeks ago. Upon admission, although presenting the appearance of a strong, healthy girl, she was so crippled with rheumatic swelling of the joints of the feet, and suffered such pain upon moving them, that it was necessary to bring her to the hospital on the most comfortable conveyance that could be obtained. When admitted, her temperature was 103°, respiration 22, and pulse 87. We now find her feet very much swollen and very painful, particularly the right foot and leg. But the trouble is not confined to the lower extremities, for she has swelling of the left shoulder and left elbow-joint.

The patient was at once placed upon the treatment usually adopted in my wards, which consists in the administration of bromide of ammonium in twenty-grain doses every three hours. The painful joints were wrapped in dry cotton, and given perfect rest. The diet was regulated. These are the only points which

* The converse statement, however, is true of dry air: the deeper it enters into the air-tubes the more moisture it contains.

need be mentioned in connection with the treatment of the case, except that in all such cases it is customary to administer an occasional laxative, in order to prevent anything like constipation, and further, to promote a healthy performance of the secretory functions of organs immediately connected with the alimentary track. Under this treatment the patient has improved, and to day, the fourth day since her admission, her temperature is 100°, respiration 20, and pulse 80; and she expresses herself as feeling very much more comfortable than at the time of admission.

There is still considerable pain upon motion, as you can readily perceive when I attempt to move the left shoulder. Some of the smaller joints have also become involved.

Listening to the heart, we find an extremely faint murmur with the first sound; the second sound is normal. The skin is acting moderately well, and there is entire absence of those acid perspirations which are common in rheumatism.

The urine has a S. G. of 1024, is acid, but not excessively so, and contains no albumen. This completes the record of the case up to the present date.

I will now, gentlemen, direct your attention to some of the facts connected with this case, which are exceptional, or at least worthy of special notice. In the first place, it is to be noticed that this patient has a skin which is not acting in the way in which the skin is supposed to act in a case of acute rheumatism; namely, there is no profuse perspiration, and the perspiration is not highly acid.

In the second place, you will perceive that, associated with this comparative absence of acid perspiration, is a urine which is not excessively acid. These are peculiarities of this case. But, you may ask, do I wish to have the idea entertained that it is wholly exceptional? Do I, in other words, wish to teach that the existence of great acidity of the urine and very acid sweats are a constant phenomena of this disease? I answer, No. At the same time, however, I believe that this entire question of excessive acidity, acid sweats, etc., has been overstated. I feel convinced that there are a large number of cases in which the skin does not yield these excessive acid perspirations, and in which the amount of acid in the urine is not what you might suppose from reading books is to be expected. In other words, the so-called acid theory of rheumatism which assumes that there is an extreme acid condition of the system, and that such acid must be eliminated, fails to satisfy me as applying to all cases, and fails to convince me that it is the real and only solution of the phenomena of acute articular rheumatism. Again, there is a point of interest in this case connected with the heart.

Here is a patient with a faint endocardial murmur. This is very common, and the more expert you become in physical diagnosis the more constantly you will find such a murmur in cases of acute rheumatism. Even in cases which apparently are not very marked, a slight alteration of the first sound of the heart, a slight prolongation, or assuming a murmurish kind of sound, or even a faint murmur, is of very frequent occurrence. There is, in those cases in which the leading symptoms are not marked, a slight endocardial swelling of exactly the same nature, but in a modified form, of that which takes place in the lining membrane of the joints. This amount of endocardial swelling, however, will disappear under treatment, and pass away with the rheumatic inflammation. It is not sufficient to give rise to the lesions which we perceive when the rheumatic trouble is in itself marked, or associated with

marked signs of endocarditis, such as a distinctive murmur, disturbances in respiration, etc., which usually mark endocardial complication. If you choose, it may be regarded as a slight amount of endocarditis, or rheumatic swelling of the endocardium, and this will be present in a vast majority of cases, but is not sufficient to give rise to the typical signs of endocarditis.

Thirdly—with regard to the treatment—this patient has received bromide of ammonium, and no other internal remedy. The case is uncomplicated, therefore simple bromide of ammonium has met all the indications.

The results which I have obtained with bromide of ammonium in the treatment of this affection have been very satisfactory. I have now had the remedy on trial for more than a year, and I have come to favor its use from the fact that it relieves the pain, acts generally upon the skin, keeps up the action of the kidneys, and, as I think, lessens materially the tendency to internal inflammations. I am further pleased with the remedy, for the reason that the cases which I have treated with it have seemed to have a shorter duration than cases treated according to other plans, and quite as short as cases treated according to the ordinary alkaline plan. The advantage which it possesses over the alkaline treatment is that the recoveries are good recoveries; there is no pallor and anemia, general distress, alteration of blood and tissues, which the long-continued administration of alkalies will cause. For these reasons I am in the habit of using the bromide of ammonium in the treatment of this class of cases. It is sometimes associated with acetate of potash, when internal complications render it desirable to have the influence of a somewhat more active diuretic.

As soon as the acute symptoms have disappeared, the remedy is followed by the administration of quinine in fair doses, which has, as I believe, the power to lessen the tendency to the occurrence of relapses.

EXCISION OF A PORTION OF THE SPLEEN —RECOVERY.

By H. C. MARKHAM, M.D.,

WINTHROP, IA.

The novel character of the following case, surgically and otherwise, may seem to give it a "sensational" tinge: if so the circumstances themselves are responsible, instead of any desire on the part of the writer to give it such an aspect.

At the instance of, and accompanied by the sheriff of the county, I visited an Indian of the Winnebago tribe, who in an altercation with a white desperado had received, as was supposed, fatal injuries. The object of my visit was to enable me to appear in court as a witness against the supposed murderer, more than to attempt any professional assistance. Arriving at the small Indian encampment, we found the object of our visit lying upon the ground in his wigwam, attended by a genuine "Indian doctor." Examination revealed no less than seven incised wounds upon the trunk and extremities; some of these wounds were six inches in length, but none had severed any important vessel. Owing to the peculiar and effective treatment of the "medicine man," these wounds were doing well. Curiosity induced me to observe the method of treating these huge wounds, and so well was it repaid that it may be pardonable to describe it. The native surgeon obliged an aged squaw to carefully lick the sur-

faces of the cuts, after which—using his mouth as a syringe—he injected them with a wash of a dark color, the value of which the fine condition of the wounds well attested. Native skill, however, was baffled by one of the wounds, the principal feature of which induces this report. This wound penetrated the cavity of the abdomen, and was situated immediately over the region of the spleen. Through this wound the desperate struggles of the Indian with his enemy had forced the spleen to the extent of three-fourths its volume, the extreme projecting portion or border, from constriction at the wound and the extreme heat of the season, had already become sphacelated, about thirty-six hours having elapsed since the infliction of the wound. This wound, owing to its grave character, had been left to itself, the “doctor” by grave signs confessing his inability to treat it. To enlarge the wound and return the organ in the condition then existing, was out of the question, to leave it was, in my belief, equally unwarrantable—to remove it presented little better hope other than would arise from the scientific interest involved in the result. This interest impelled me to take charge of this “section” of the case, being satisfied that the other wounds were in safe hands and did not seriously imperil life. After preparing ligatures, with a common bistoury the spleen was removed by making a section nearly on a plane with the surface of the abdomen. In spite of the constriction the hemorrhage was appalling, but with the assistance of my friend, the sheriff, I succeeded in applying ligatures sufficient to arrest it. The pulse was absent, and nothing but an early fatal issue seemed possible. Whiskey was given freely and cold water dressings used, with instructions to continue them. I saw no more of the case at that time, and was surprised some weeks after to learn that the party arrested for the killing had been released. About one year from the date of my medico-legal visit, an Indian came into my office smiling, and, drawing aside his blanket, exhibited the cicatrix of a wound that was at once recognized. His only statement was “Indian heap no run.” Accepting the usual theory of physiologists, and in view of the fact that his spleen was then in my possession, his laconic expression required no verification.

Although the entire organ was not removed it cannot be doubted that the portion remaining was wholly useless. The case determines the question as to the vital nature of the organ, and compels the admission that it throws much light upon an interesting physiological problem. A point of minor interest rests in the illustration it furnishes of the remarkable power of resistance to injury in this race, and contrasting with that of the “pale face” whose habits of life are at such divergence with these children of nature.

MODE OF DISCOVERING WHETHER RED WINES ARE ARTIFICIALLY COLORED OR NOT.—M. de Cherville, in one of his clever agricultural notes in *Le Temps*, gives the following useful hints for deciding the above:—“Pour into a glass a small quantity of the liquid which you wish to test, and dissolve a bit of potash in it. If no sediment forms, and if the wine assumes a greenish hue, it has not been artificially colored; if a violet sediment forms, the wine has been colored by elder or mulberries; if the sediment is red, it has been colored with beet-root or Pernambuco wood; if violet-red, with logwood; if yellow, with phytolac berries; if violet-blue, with privet berries, and if pale violet, with sunflower.”

Progress of Medical Science.

DYSPEPSIA.—DR. LEVEN (*Lyon Medical*, No. 7, 1874) read recently in the Academy of Medicine a paper on the physiological pathology of the stomach, and particularly concerning dyspepsia. According to Leven the stomach has only the secondary part to play in digestion—it reduces, by means of its movements, and the juices secreted, the volume of the aliments, breaks them up, and facilitates their entry into the intestines; thus, its function is that of the triturating machine.

The injection of nitrogenous substances does not augment the secretion of gastric juice, but produces a great amount of watery fluid due to exosmosis from the capillaries of the mucous membrane. According to this author, dyspepsia is an affection of the stomach characterized by an aqueous secretion, which retards digestion and injures it. The hypersecretion is in some way commenced by the organ to get rid of foreign bodies, over which it has little power and which are expelled in a quantity of fluid. Perhaps in all cases of dyspepsia the predominant symptom is hypersecretion of fluid; and treatment should be directed against this. But the classic remedies, such as quinine, carbon, pepsin, etc., are usually inefficacious. Doubtless these often give relief, but rarely cure. For this reason Dr. Leven has abandoned these and makes use of the following treatment, which in many cases has cured even the most inveterate dyspepsia. He advises his patients to take small doses of neutral salts, or others attacked with difficulty by the stomach, sulphate of soda, phosphate of soda, phosphate of lime, chloride of sodium, or bromide of potassium. He never gives doses larger than from four to eight grains in the day of such remedies, and soon notices an improvement in the symptoms of dyspepsia; the swelling of the stomach diminishes, the secretion is less exaggerated, and the disease is gradually cured. Besides this, a diet easily digested is recommended.

REMOVAL OF A TUMOR FROM THE BLADDER.—Professor Billroth has recently performed another singular and daring operation, which is described by a correspondent to the *Irish Hosp. Gaz.*, of July 15, viz., the removal of a tumor from the urinary bladder of a boy twelve years of age. Until ten months before the operation the boy had been very healthy, but began then to complain of pain in passing urine. The pain was not very severe, and was located in the glans penis and the region of the bladder. The urine soon became cloudy, and the desire to void it came so suddenly that the boy would not have time to reach the urinal. The case was supposed to be one of calculus, and was sent to Billroth for an operation. No calculus could be detected; but on examination made after the bowels had been thoroughly emptied, a tumor in the region of the bladder could be distinctly felt through the abdominal walls. It could also be felt by examination per rectum, and was slightly painful on pressure. Its consistence was very much like that of a fibroma, and it seemed to spring from the bladder. Further examination showed that the walls of the bladder were greatly hypertrophied; the sound, however, came in contact with no hard body within the viscera. When the fever following the last examination had abated, the following operation was made. Lateral lithotomy was first performed, with the intention, if the tumor proved to be adherent to the bladder, to make the high operation and remove the growth. When the finger was passed into t

bladder through the opening in the perineum, a tumor the size of an apple was felt to be growing from the posterior wall, but its pedicle could not be found. The high operation, over the symphysis pubis, was at once performed, some difficulty being experienced in making an opening into the bladder, owing to the danger of opening the peritoneum, in consequence of the contracted state of the organ. The tumor grew with a short and tolerably broad pedicle from the posterior wall of the bladder, and very high up. Notwithstanding an enlargement which was made of the upper wound, the opening still proved too small for the passage of the tumor, and an effort was made to break up the latter with the fingers. At first only small portions of the rather soft tumor were detached, but finally the whole of it was torn from its pedicle, and by compressing its centre it was extracted through the upper wound. The portion of the bladder to which the pedicle was attached was then drawn through the aperture; the pedicle was dissected off, to do which effectually required so deep a dissection as to imperil again the continuity of the peritoneum. Two small arteries were recurved, and the ligatures carried out through the perineal wound. After the operation the patient continued relatively well, having but slight fever. The wounds, at the time of writing, looked remarkably well, notwithstanding their contusion during the operation. Microscopic examination showed the tumor to be a pure myoma.

REST IN PULMONARY PHTHISIS.—Dr. John McCrea, of the Belfast dispensary, writes to *The Lancet*, of July 18, saying that recent writings relative to the necessity for carefully selecting the cases to be treated by this method according to the amount of lung involved, is likely to prevent as general a use of the measure as its importance and safety would warrant. In a large number of cases at the above dispensary he has found nothing equal to it in efficiency and general applicability. Indeed, he knows of no stage of the disease in which it has done harm, and in nearly all cases the patients have desired a reapplication. His method differs somewhat from the one recommended by Drs. Berkart and Dolbail, and, in brief, is as follows:—For application to the upper part of the chest emplastrum rotundum spread upon swan's-down and cut into strips three-quarters of an inch wide and extending across the cloth. The first strip runs up the back in the space between the spine and the scapula on the affected side, and being drawn tight and applied slowly and carefully, is carried over the shoulder and down the front of the chest. The second strip, which is applied horizontally, commences at the spine, crosses the first strip, passes under the axilla and on towards the sternum; forcible expiration being maintained by the patient during the attachment of both strips. Other strips are to be applied in a similar manner until a sufficiently firm grasp is had of the chest, when the large rectangular strip of plaster is applied to the scapular interspace, extending down to the last dorsal spine, and another squarish piece to the front between the clavicles and mammae, serving to keep the ends from curling up. The whole is then well rubbed over to ensure its adhesion. This dressing will ordinarily require changing only once a fortnight.

CURE OF IN-GROWING TOE-NAIL.—Dr. Ozanam (*L'Abeille Méd.*, July 6) regards the surgical operation at present commonly resorted to for the relief of this affection as needlessly cruel. The tearing out of the nail, or portions of it, leaves the toe in a tender condi-

tion for a long time, sometimes permanently. The plan which Dr. O. suggests as a substitute is as follows. A nick is made in the centre of the edge of the nail, extending in to its attachment. Then the upper surface of the nail is scraped along the middle line until it is thinned nearly down to the quick. A small piece of sheet-rubber is afterwards inserted on either side of the nail with the aid of a spatula, so as to form a sort of gutter around the edge, and to separate it from the adjoining flesh.

Dr. O. lays great stress upon this part of the treatment, and in particular upon the employment of rubber. Lead, he remarks, is too hard, charpie too soft and yielding, while the elasticity of the rubber on the one hand, and its comparative softness on the other, serve to keep up a constant but gentle pressure on the inflamed tissues without giving undue pain. Thus, with the elastic pressing up the outer edges of the nail and the thinness of its centre allowing a certain amount of yielding, it gradually becomes flatter, and its edges cease pressing upon the adjoining flesh. Should fungous granulations exist about the in-growing edges of the nail, it will be proper to apply some astringent, and the best for this purpose is powdered nitrate of lead, which reduces the fungosities and rapidly arrests suppuration. After the condition of the nail is once remedied, it is necessary to keep the central portion scraped thin for some months, until it becomes flatter and assumes a more normal form.

ACIDIBLE AND INAUDIBLE SOUNDS.—The phenomenon of color-blindness is a familiar fact; but an analogous phenomenon, which might be called pitch-deafness, though not uncommon, is not so generally known. By *pitch-deafness* is meant insensibility to certain sound-vibrations. Prof. Donaldson, of the University of Edinburgh, used to illustrate the different grades of sensibility to sound by a very simple experiment, namely, by sounding a set of small organ-pipes of great acuteness of tone. The gravest note would be sounded first, and this would be heard by the entire class. Soon some one would remark, "There, 'tis silent," whereas all the rest, perhaps, would distinctly hear the shrill piping continued. As the tone rose, one after another of the students would lose sensation of the acute sounds, until, finally they became inaudible to all.

There is reason for supposing that persons whose ear is sensible to very acute sounds are least able to hear very grave notes, and *vice versa*. Probably the hearing capacity of the human ear ranges over no more than 12 octaves. The gravest note audible to the human ear is supposed to represent about 15 vibrations per second, and the sharpest 48,000 per second.

The auditory range of animals is doubtless very different from that of man; they hear sounds which are insensible to us, and *vice versa*. Many persons are insensible to the scream of the bat—it is too acute. But to the bat itself that sound must be in all cases perfectly sensible. If, then, we suppose the bat to have an auditory range of 12 octaves, and its scream or cry to stand midway in that range, the animal would hear tones some six octaves higher than those audible to the human ear—two and a half million vibrations per second.

Scoresby and other Arctic voyagers and whale-hunters have observed that whales have some means of communicating with one another at great distances. It is probable that the animals bellow in a tone too grave for the human ear, but quite within the range of the cetacean ear.—*Pop. Science Monthly*.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, September 15, 1874.

THE RIGHTS OF INDEPENDENT CRITICISM AND THE SUIT FOR LIBEL AGAINST THE MEDICAL RECORD.

THE attention of the readers of THE MEDICAL RECORD is called to the appeal of Dr. W. A. Hammond, which we have extracted from the last number of the *Psychological and Medico-Legal Journal*, Sept. 1, 1874, and which follows this editorial. The matters under discussion refer so directly to the editor of this journal, and so imperatively demand a personal explanation, that I am compelled to waive my usual custom and address my readers in the first person. I do not shrink from such responsibility, for as editor of THE RECORD, and as a member of the medical profession, I am always willing to have all my public or private professional acts criticised by my peers, and always ready to stand before the bar of professional opinion and give an account of myself.

It will be remembered that in the issue of the MEDICAL RECORD for August 1 there appeared an editorial on hydrophobia, in which Dr. Hammond received a share of criticism. Shortly after the publication of the editorial Dr. Hammond came to the office of THE RECORD and complained that he had not received justice at my hands. After a conversation with Mr. Wood, the publisher, and at his suggestion, Dr. Hammond addressed me by note, stating his grievances, and thus began a correspondence which is published in full in Dr. Hammond's Journal, and which I reproduce.

As far as my letters to him are concerned, and the circumstances attending them, the truth is told by Dr. Hammond, and personally I am under obligations to him, not only for his statement of facts, but for the

presentation of his side of the argument, which presentation I have been anxious that he should make from the beginning. It will be seen from Dr. Hammond's own showing that I took the usual course to do him justice, and that in my letter from Barrytown I gave my reasons for so doing. In my reply to his first letter I maintained that "all the statements made in the said article were based upon what I believed to be facts," and if he convinced me that I was in the wrong "no one would be more willing to acknowledge it." There was no other way, in my opinion, to give him entire satisfaction than to open the columns of THE RECORD for any reply he might choose to make. By this means he could come before the same audience as myself and have every opportunity to present his side of the argument. The advantage of this proposition was, that in case he could not convince me that my facts were without foundation, which I imagined was quite likely, he could, nevertheless, take the additional chance of a verdict in his favor from the professional public. The mere examination of his specimens by me would not affect the question one iota, as nothing had been said tending to prove that he did not see what he described. The criticism as to microscopical appearances was upon his conclusions only, and as such it must stand upon its merits. I fail to see by what train of argument Dr. Hammond justifies himself in stating that I impugn his good faith, that I intimate that he made no microscopical examination at all, or that I make it appear that I believe he "wilfully and falsely" described appearances which did not exist. The only way to explain such conclusions on his part is to allow the possibility at times of imagination getting the better of reason even in the best regulated minds. That I do charge him with unethical conduct is true, and this charge is principally based upon the manner in which he allowed himself, as a professional man, to be paraded before the public in the columns of the *New York Tribune*.

After having written to Dr. Hammond explaining my reasons for inviting him to reply through the columns of THE RECORD, I expected an answer giving his reasons for objecting to such a course. This I thought would be a matter of civility on his part. No such answer came, however, and consequently my correspondence with him ceased. Next came his letter to Mr. Wood, which in my opinion—(Dr. H. concedes the right I have to an opinion)—was threatening in its tone; then followed the admirable answer from Mr. Wood; and last of all, a suit for libel was commenced against THE RECORD.

Although this resort to law could not alter the position I had taken, I nevertheless regretted Dr. Hammond's course, on account of my friend Mr. Wood, who had so nobly stood by me during the whole misunderstanding. I then concluded, in order to set myself right in the matter before the profession, to publish the whole correspondence, and then volun-

teer such a statement as would answer the possible charge that the editorial was not founded on facts. To this end I wrote to Drs. C. P. Russel and Arnold, and called upon Dr. Knox, who had performed the autopsy in the Entwistle case. After I received answers to these letters, and was ready to proceed with my statement, Dr. Hammond's journal appeared, anticipating me in my publication. I merely mention this latter circumstance to explain why no reference was made in these letters to Dr. Hammond's charges.

That portion of the editorial particularly obnoxious to Dr. Hammond is the following: "It was scarcely fair in Dr. H. to appropriate all of interest in the McCormick brain, as we understand he had likewise done at the Entwistle post-mortem, before the arrival of the curator of Bellevue made it necessary for him to deliver up two or three thin slices. In the latter case, Dr. H. discovered no extraordinary lesions."

He claims that these assertions are not founded on fact. I beg leave to differ with him on that point. At the same time I do this. I admit the truth of the statements contained in the letters which he publishes from Drs. Hadden and Arnold.

I shall take the portion of editorial alluded to as a text for a few remarks bearing upon the questions at issue. I shall try to be particular in establishing my premises. The celebrated philologist, Geo. Crabb, thus defines the verb "to appropriate": "It is to take to one's self either with or without right. It is a matter of convenience. It springs from a selfish concern for ourselves, and a total unconcern for others." I accept this definition of Mr. Crabb, and propose to justify its use in accordance with the facts which I shall present.

Next in logical order I submit some correspondence the most of which antedated the September number of the *Journal of Psychology*.

I wrote the following letter to my friend Dr. Russell:

"OFFICE OF THE MEDICAL RECORD, N. Y., Sept. 7, 1874.

"DEAR DOCTOR:—You will recollect that in a conversation with you some time since concerning the cases of McCormick and Entwistle, you related to me certain circumstances of which you were an eye-witness. The statement made in THE MEDICAL RECORD of August 1st relating to the post-mortems of the said McCormick and Entwistle in regard to the disposition of the specimens, etc., were based upon your observation. Dr. Hammond objects to the editorial, and maintains that it was not based upon facts. I have written to him two or more letters denying his assertions, assuring him, however, that I was willing to be corrected, and tendering him the columns of THE RECORD for any reply he chose to make. He has persistently refused this offer, and in the end has sued THE RECORD for libel. Now, in order to set myself right before the profession, I propose to publish the whole correspondence. The question of fact which must be settled has special reference to his action at the post-mortems in question. Please answer me as soon as possible, that I may be able to prepare what

is necessary to be said for the forthcoming number of THE RECORD.

"Sincerely your friend,

"GEO. F. SHRADY.

"DR. CHAS. P. RUSSELL."

To this I received the following reply:

"NEW YORK, 54 W. NINTH ST.,

"September 8th, 1874.

"DEAR DOCTOR:—In answer to your note requesting me to state, in writing, whether facts within my knowledge, previously given in conversation to you, warrant the particular language which you employed in your editorial of August 1st, to wit: 'It was scarcely fair in Dr. Hammond to appropriate,' etc., I will state the circumstance which came under my observation, as I was present, by invitation, on both occasions.

"The McCormick autopsy was made principally by the deputy coroner, Dr. Leo, who removed the brain, with its appendages intact, as far as possible, and placed them in Dr. Hammond's hands. The latter gentleman, with a knife, cut off the pons varolii, medulla oblongata, and a small segment of the upper cord, and placed them in bottles which he had provided. No one, within my hearing, was offered the slightest piece of these sections. Large slices of brain-substance were certainly 'lying around loose' in sufficient quantities to have supplied each person liberally; there was no objection to any one's helping himself, and I presume some did so.

"The subsequent one upon Entwistle was somewhat different in its character. Dr. Hammond appeared at Bellevue a few hours after Entwistle's death; and notwithstanding he was informed that the coroner expected to officiate at the post-mortem, he persuaded Dr. Knox to make it two hours in advance of the coroner's arrival. Dr. Hammond was unconnected with the hospital, yet he assumed charge of the autopsy, and directed how it was to be done. He himself cut off the similar portions to those dissected by him from McCormick's brain, bottled them up in flasks brought by him for the purpose, and put them in his pocket.

"The post-mortem having been virtually concluded, Dr. Hammond was about leaving, when he unexpectedly met Dr. Arnold near the door, to whom he offered the specimens in his possession. But that he had 'appropriated' the specimens mentioned, *i.e.*, had secured them entire, in order to use them for his own personal examination, was sufficiently palpable to me. Having myself been, some sixteen years since, house-surgeon of Bellevue Hospital, and being not unfamiliar with its rules, I was the more surprised that a gentleman unconnected with the institution should have been permitted to exercise therein what appeared to be self-constituted authority.

"Yours very truly,

"CHAS. P. RUSSELL.

"DR. GEO. F. SHRADY."

Desiring to follow out my chain of facts still further, I wrote to Dr. Arnold as follows:

"NEW YORK, September 8th, 1874.

"DEAR DR.:—I beg leave to call your attention to some statements made in an editorial of THE MEDICAL RECORD, August 1st, in reference to the post-mortem examination in the Entwistle case. I believe those statements to be founded on facts. If they are not, I shall be happy to be so informed. You can aid me very much in arriving at the truth, by answering the following questions:

"Is it customary or proper for any gentleman unconnected with Bellevue Hospital, and not a coroner, to take any active part in post-mortem examinations held in that institution? Did you invite Dr. Hammond, directly or indirectly, to make any examination of the body of Entwistle? In the absence of the coroner was it not proper for any one who desired to make any such examination to ask your permission so to do?"

"Did Dr. Hammond have the medulla oblongata or any other portion of Entwistle's body in his possession, and in a bottle, before you arrived?"

"The only reasons for asking you questions in this manner is to avoid the writing of a lengthy letter. I will ask of you as a special personal favor to answer the questions at your earliest convenience.

"Sincerely yours,

"GEO. F. SHRADY.

"DR. J. W. S. ARNOLD."

The following was Dr. Arnold's reply:

"NEW YORK, September 10th, 1874.

"DR. GEO. F. SHRADY,

"MY DEAR SIR:—Your letter of the 8th inst. is at hand, and with reference to your questions I would state:

"It is not customary for any gentleman not connected with the Bellevue Hospital, and not a coroner, to take any active part in post-mortems held in said institution.

"I did not invite Dr. Hammond to make any examination of the body of Entwistle, either directly or indirectly.

"In the absence of the coroner, it was proper to ask the permission of the attending curator to make such examination.

"Dr. Hammond, immediately upon arrival, handed me a bottle containing the medulla oblongata of Entwistle.

"Very sincerely yours,

"J. W. S. ARNOLD."

After the appearance of the *Psychological and Medico-Legal Journal* for September, not having sufficient time to write to and receive an answer from the coroner in charge of the Entwistle case, I called on that gentleman, and obtained from him the following:

"NEW YORK, Sept. 10, 1874.

"I hereby certify that I at no time gave authority to Dr. William A. Hammond to hold a post-mortem in the Entwistle case, nor to any one else, but found on my arrival at the Morgue that the post-mortem had already been held. I further certify that the post-mortem in this case was held without any authority from my Deputy, Doctor Wm. Shine.

"HENRY WOLTMAN,

"Coroner."

Next in my line of argument, I quote from Dr. Hammond's letter to Dr. Arnold: "The facts as I understand them are, that you were absent when the post-mortem was begun; that it was said you would not be present; that Dr. Knox, who made the post-mortem, authorized me to take the medulla oblongata, etc."

Next comes the following item of correspondence which took place after the appearance of Dr. Hammond's journal:

"NEW YORK, Sept. 10, 1874.

"DR. A. W. KNOX.

"MY DEAR SIR:—Wishing to learn all the facts bearing upon circumstances attending the post-mortem of Entwistle, I take the liberty of asking you the

following question: Did you authorize Dr. Hammond to take the medulla oblongata from the said Entwistle's body, or did you in any way give him authority to conduct any part of the autopsical examination?"

"Very truly yours,

"GEO. F. SHRADY.

"DR. KNOX, Bellevue Hospital, N. Y."

Dr. Knox wrote me the following reply:

"BELLEVUE HOSPITAL, Sept. 11th, 1874.

"DR. GEO. F. SHRADY.

"DEAR SIR:—In reply to your note of the 16th inst., I would state that I not only did not 'authorize' Dr. Hammond (by any word or act, so far as I am aware) to take the medulla oblongata from Entwistle's body, or to conduct the autopsical examination, but further, that I had no power to 'authorize' him or any one else in the matter.

"Very truly yours,

"A. W. KNOX."

Asking my readers to bear in mind the definition of the verb "appropriate," I am ready to draw the conclusions.

I admit that Dr. Hammond had a right to conduct the autopsy of McCormick, and I have never denied it; neither have I denied that he had a right to the specimens, but I claim that "it was scarcely fair to appropriate all of interest in McCormick's brain." I mean to be understood as saying that Dr. H., as a matter of professional courtesy, should have offered some portions of the medulla or pons varolii to some of the medical gentlemen present—and especially to such as he knew were interested in the study of nervous diseases. This it appears he did not do, according to Dr. Russell's statement. The pieces of brain "lying around loose," were in my opinion of no special pathological interest in connection with the case.

In regard to the Entwistle post-mortem, I think I have substantiated my assertions so far as the matter of appropriation is concerned. I believe I have proved that Dr. Hammond conducted his portion of the post-mortem without any authority whatsoever, and that he did so in the belief that the curator would not be present. Still bearing in mind the definition of the verb "appropriate," I ask what is the conviction which forces itself upon any one's mind acquainted with the facts of the case? If Dr. H. knew or believed Dr. Arnold would not be present, how can I explain the fact that he came prepared to take specimens from the dead-house—specimens which unquestionably belonged to the hospital? Here I must again refer to the definition of the verb "appropriate." Again, if it was not necessary for him (Dr. H.) to deliver up these specimens on the arrival of the curator, why did he (Dr. H.) do so?

I do not wish to misinterpret Dr. Hammond's motives in this matter, and am free to say that, in his enthusiasm over the case, he forgot, for a time at least, the extent of his privileges as a visitor, and the usual professional courtesies which obtain on such occasions. Such actions, in my opinion, render him liable to criticism; and in my function as medical journalist, I claim, in the name of the profession, the right—recogn-

nized throughout the civilized world, wherever the independence of the press is fostered—to express an opinion. Dr. Hammond does not deny me this right, provided I have the facts upon which to base such an opinion. I have now presented him with these, and I hope he is satisfied.

Having said thus much, in justice to him and to myself, I frankly acknowledge that the facts of the case will not bear me out in the literal interpretation of the statement that he delivered up only “two or three thin slices;” I take pleasure in saying that he delivered up *all* the Entwistle specimens in his possession, and that Dr. Arnold has the medulla in question in his keeping as curator.

The statement, “in the latter case, Dr. H. discovered no extraordinary lesions,” is, I believe, true. If Dr. Hammond has found any extraordinary lesions I have yet to hear of them.

I am exceedingly sorry that Dr. Hammond should have seen fit to sue *THE RECORD* for libel under the circumstances, but if the case comes into court I shall hope for a vindication of the rights of independent criticism. That the editorial is “evidently dictated,” as Dr. Hammond expresses it, “by ‘envy, hatred and malice, and all uncharitableness,’” I emphatically deny. I have no ill-feeling whatever towards him, for personally we are entire strangers to each other; neither have we ever had any misunderstanding during our official intercourse while I was a member of the medical staff of the army and he Surgeon-General. Convinced that Dr. Hammond deserved to be criticised in the matter, I acted accordingly. From this point of view, I do not regret my action, and shall deem it my duty to repeat it whenever Dr. Hammond, or any other gentleman, gives me occasion, at the same time taking the usual care that my statements are “based on facts.” I have presented these facts, and am glad that Dr. H. has given me an opportunity so to do, and not treated me as he has done my friend “the *Ishmaelite* of the *Philadelphia Medical Times*,” whose editorial he dismisses with the argument, “in mercy I stay my pen.”

His charge that I offered my services to the New York *Tribune*, to give an account of the meeting of the American Medical Association, is perfectly true. I did this solely in the interest of the profession, that it might be fairly represented to the world, and without any other expectation of reward than a consciousness of performing what I considered a privileged duty. My offer was gladly accepted, and I would have fulfilled my promise if I had not been afterwards informed that by some mistake different arrangements had been made previous to my calling. I am as much surprised at Dr. Hammond for bringing up this matter as part of his argument, as I am at the violation of the ordinary courtesies of journalism on the part of the *Tribune* in furnishing him with the information.

GEO. F. SHRADY.

AN APPEAL TO THE MEDICAL PROFESSION.

By WILLIAM A. HAMMOND, M.D.

(From the Psychological and Medico-Legal Journal, New York, September 1, 1874.)

THE MEDICAL RECORD, of this city, issued on the 1st of August last, contained an editorial article on hydrophobia, which appeared to have been written for the express purpose of disparaging me in the estimation of my professional brethren and of the public. It was an unprovoked attack, and, as the following correspondence, and the preceding article in the present number of this journal, quoted from the *New York Medical Journal*, show, was not based on facts.

Since my residence in New York (now ten years), I have studiously endeavored to avoid disagreements and controversies of all kinds, and if I have not been altogether successful in this direction, I have at least been able to abstain from troubling the profession, and the public generally, with my private quarrels. I suppose every man who attains to any degree of eminence in the medical or any other profession has his enemies. I am quite sure I have as few as any of my colleagues.

But the attack of *THE RECORD* was so public, and so entirely without proper cause, that I was bound, in justice to myself and the many eminent medical friends who knew the truth in the matter at issue, to call the responsible perpetrators to account. In the article on the Scientific Results of the post-mortem examination instituted on the remains of McCormick, I have replied at length to the gratuitous attack of a coroner's jury; in the present communication I shall not have much to say in addition to submitting the correspondence.

Immediately on reading the editorial in *THE RECORD*, I wrote the following letter to Mr. Wood, the publisher:

“43 WEST 54TH STREET,
“NEW YORK, Aug. 1st, 1874.

“MY DEAR MR. WOOD:—The last number of *THE MEDICAL RECORD* contains an editorial article on hydrophobia, which is so eminently unjust to me, and is so evidently dictated by ‘envy, hatred and malice, and all uncharitableness,’ that I am constrained to request you to give it your attention, and to disavow what I am quite sure you did not see before publication.

“For any difference of opinion with me, I have no complaint to make. The writer is, of course, as fully entitled to his own views as I am to mine; but in this article he has gone beyond the pale of decency, and has descended to scurrilous and libellous language, altogether unbecoming a respectable and scientific journal, such as I have always understood *THE RECORD* to be.

“He impugns my good faith, questions my ability to make histological examinations, and accuses me of improper and unethical conduct. He even intimates that I made no microscopical examinations at all, or that I wilfully and falsely described appearances which did not exist. He also perverts the meaning of the coroner's verdict.

“Now, as I have said, I am very willing that the writer shall differ with me as much and as often as he pleases; but I cannot consent to allow such assertions as I have specified to pass unnoticed, and I therefore respectfully request that you will direct a proper re-

traction and disavowal to be made in the next number of THE MEDICAL RECORD.

"Yours sincerely,

"WILLIAM A. HAMMOND.

"WILLIAM WOOD, Esq., 27 Great Jones Street."

In order to save time, I took this letter in person to Mr. Wood. He read it in my presence, and informed me that he had nothing whatever to do with the editing of THE RECORD; that by the terms of his contract with Dr. Shrady, the latter had absolute control of the journal so far as the matter for publication was concerned, and asked me to write to Dr. Shrady, on the subject of my communication, as he was sure Dr. S. would be very glad to rectify erroneous statements, and acknowledge any injustice he might have committed. Yielding to his representations, I wrote the following letter to Dr. Shrady:

"NEW YORK, Aug. 3d, 1874.

"DEAR SIR:—I have written to Mr. Wood, calling his attention to the article on hydrophobia in the last issue of THE RECORD. I now write to you with the same object.

"Either you believe it to be true in its allegations direct and indirect, or you do not believe it. In the former case it is, I conceive, your duty to take the means which I now offer you of correcting your views; if, on the contrary, you do not believe it, you ought to disavow it at once.

"I have confidence enough in your sense of justice to believe that you will do what is right in the matter.

"Yours sincerely,

"WILLIAM A. HAMMOND.

"DR. GEO. F. SHRADY."

I sent this note to Mr. Wood's place of business, as he had informed me that Dr. Shrady would be in town on the 5th, and that it would be handed to him on his arrival. It seems, however, that Mr. Wood was mistaken, for Dr. S. did not, as appears from the following communication to me, arrive in the city till the 11th:

"NEW YORK, Aug. 11, 1874.

"DEAR DOCTOR:—Yours of the 3d inst. has just been received. My absence from town until the present has prevented an earlier reply.

"I have carefully reconsidered the article to which you call my attention, and while I am sorry that anything has been written to cause you any annoyance, I am compelled to say, in justice to myself, that all the statements made in the said article were based upon what I believed to be facts. As I have not been able to change my views, I cannot disavow anything written in the said editorial. If I am wrong, I am perfectly willing to be set right, and for that purpose open the columns of THE RECORD for a reply, which reply I shall publish with pleasure.

"My only desire is to get at the truth, and I am willing and ready to do anything in my power to that end. If you convince me that I am in the wrong, no one will be more willing to acknowledge it.

"Respectfully yours,

"GEO. F. SHRADY."

The reader's attention is particularly called to the last paragraph of this letter. I thought Dr. Shrady's expressions fair and honorable, and I took him at his word by immediately writing him the following note:

"NEW YORK, Aug. 12th, 1874.

"DEAR SIR:—I have received your note of the 11th inst.

"It is not for me to defend myself in the columns of THE RECORD from its unjust and unprovoked attack. It is your place to correct and do justice.

"I do not question your sincerity when you state that you are anxious to get at the truth, and if wrong, to make proper acknowledgment.

"I shall therefore be happy to see you at my residence to-morrow evening to show you some of the microscopical preparations, and to offer you other evidence that your editorial was not in reality based on facts.

"Yours sincerely,

"WILLIAM A. HAMMOND.

"DR. GEO. F. SHRADY."

I mailed this note to Dr. Shrady, to the office of THE RECORD, Messrs. Wood's place of business, and then calling to mind that I had not asked whether or not the appointment would suit as to time, I wrote another note requesting Dr. S. to inform me on this point. This note I took myself to the office of THE RECORD, and was informed that Dr. Shrady had left town the day before. It was therefore impossible to get a retraction in the forthcoming number of THE RECORD, to be issued on the 15th of August.

I expressed my disappointment in strong terms to Mr. Wood the following day, when I went to his place of business for the purpose of conversing with him on the subject. I told him what I had written to Dr. Shrady, and he, in my presence, wrote to Dr. S., requesting him, as he said, to come to the city as soon as possible, and to accept my invitation. Mr. Wood said he had no doubt that Dr. S. would take advantage of the opportunity I offered him. Instead, however, of seeing Dr. S., I received, a day or two afterwards, the following remarkable communication:

"BARTTOWN, Aug. 13th, 1874.

"DEAR SIR:—Your two notes of the 12th inst. were promptly forwarded, but they came too late to be answered within the time you expected they might have been. I hasten to say this, in order to correct an impression that you may have formed, that any neglect to acknowledge your courtesy was unfounded. I now assure you that I am obliged to you for the invitation, but for the present I wish to be excused from accepting it. I differ with you so entirely as to the manner in which the questions at issue should be settled, that I am either forced to take this stand, or to place myself in what would, in my opinion, be a false position to the readers of THE RECORD. The editorial in question was a public criticism, was made in an official way, and the reply, as I view it, should be made through the same channel. The readers of a journal have some rights in this matter which an editor has no business to ignore. If you have any objections to make to the article, it strikes me you should view it in the light of a public challenge to give your side of the argument.

"If in a private conference you convince me that I have done wrong, I am bound to give my reasons *publicly* for changing my views—in other words, I am forced to be a spokesman for you, or worse than that, an interviewer.

"This I think is altogether unnecessary, as you are abundantly able to speak for yourself, and can present your own views a great deal better than I can. Again, if you cannot succeed in convincing me at the private interview, you deny yourself, conditionally at least, any opportunity of presenting your views at all.

"If you choose to alter your decision in the matter, you shall obtain every courtesy from THE RECORD.

"Your reference to the attack as an 'unjust and unprovoked one' gives me the impression that you may consider that there is a personal element in the case. If you have any suspicion of this sort, I can assure you that it is altogether unfounded, and that the article was written with the sole intention of vindicating the right of independent criticism.

"Respectfully yours,

"GEO. F. SHRADY.

"DR. W. A. HAMMOND."

I think it will be apparent to every intelligent and unprejudiced reader that Dr. Shradý was more anxious to avoid investigation and the possible obligation of a retraction than anything else, and that the "false position" of which he was so afraid could never come from efforts to get at the truth, and if wrong to make suitable acknowledgment, which he expressed himself so ready to do in his first letter.

As to my defending myself in the columns of *THE RECORD*, that is not my business. He and his publishers have done the wrong, and it is his and their place to retract and apologize. If A calls B a scoundrel and B demands an apology, it would scarcely be adequate satisfaction for A to say to B, "I cannot apologize or even take measures to convince myself that I am wrong, but I will allow you to come to my office and to say to the people who heard me call you a scoundrel, that you are not one."

Dr. S. says: "If in a private conference you convince me that I have done wrong, I am bound to give my reason *publicly* for changing my views."

Yes, that is exactly it. Just as publicly as he uttered the slander, and that is exactly what I demand and will insist upon.

Of course I could have no further correspondence with Dr. Shradý on the subject, but still in the continued effort to avoid the last resort I wrote as follows to Mr. Wood:

"NEW YORK, Aug. 22d, 1874.

"DEAR SIR:—Contrary to the expectations you expressed to me at our last interview, Dr. Shradý has declined my offer to allow him to inspect for himself the microscopical specimens obtained in the McCormick case, and to examine the other evidence which would have convinced him that his editorial of August 1st was based on false premises. Comment on such (to say the least of it) short-sighted and disingenuous conduct is entirely unnecessary at this time. It speaks for itself.

"Dr. Shradý offers to publish any communication I may send him, and is kind enough to express the opinion that I am abundantly able to speak for myself. It was not for me that I desired Dr. Shradý to speak, but for himself. I am able, as he and you will eventually find, to speak for myself, but I prefer to do it through another channel than *THE MEDICAL RECORD*.

"I am sorry my efforts to obtain a recantation and apology have failed, and I regret it the more because at our last meeting you seemed to be convinced that injustice had been committed, although you expressed yourself as being unable to rectify the wrong without Dr. Shradý's aid. As this has been refused in the only way it was possible for me to accept it, nothing remains but an appeal to an authority which both you and I are obliged to respect.

"Your obedient servant,

"WILLIAM A. HAMMOND."

To this letter I received the following answer:—

"NEW YORK, Aug. 24th, 1874.

"DEAR SIR:—Your favor of the 22d inst. is received. From it we perceive that you misunderstood

our remarks at the interview referred to. We stated not that we were unable to rectify the wrong without Dr. Shradý's aid, but that the matter lay *entirely* in Dr. Shradý's hands, and that by our contract with him, as editor of *THE RECORD*, we had no power to direct his management of the journal, he being its published and responsible head; we further said that if the facts of the case were as you represented, it *seemed* as if an injustice had been done you, but we did not and would not, even if the circumstances were known to us upon which the editorial was based, presume to judge upon subjects so entirely professional. We shall be sorry if this difficulty between yourself and *THE MEDICAL RECORD* cannot be amicably settled by the proper parties, and in a satisfactory way, but do not desire to be considered, from anything we may have said, as wishing to avoid any right responsibility which may attach to us as its publishers.

"Dr. Shradý will be in town to-morrow or next day, and will, we presume, look further into the matter.

"Sincerely yours,

"WILLIAM WOOD & Co.

"WILLIAM A. HAMMOND, M.D., New York City."

This letter was dated the 24th. I waited till the 31st, and having no intimation that Dr. Shradý was looking further into the matter, have begun proceedings against Messrs. William Wood & Co., the publishers of *THE MEDICAL RECORD*, for libel. I am sorry to be obliged to take this course. Mr. Wood has in his personal relations with me in this matter been frank, kind, and considerate, and I have no other than friendly feelings towards him. I appreciate his position, but I can see a way for him to right himself and me, which, as a man, a gentleman, and above all in this connection, a member of a religious society whose main principle is peace, I think he ought to take. As for myself, I am determined, if the law of the State of New York admits of it, to get redress for the gross outrage which, under the name of "independent criticism," has been perpetrated.

One thing only remains to be considered, and that is my defence against the false innuendoes and assertions of *THE RECORD*. Most of them are sufficiently answered in the paper published in the *New York Medical Journal* of this date, and reprinted in the present number of the *Psychological and Medico-Legal Journal*, and to which this writing is an appendix. Two other charges—the worst made against me directly—are met and settled by the following correspondence with Dr. Hadden, McCormick's physician, and Prof. Arnold, the Curator of Bellevue Hospital:

"NEW YORK, Aug. 15th, 1874.

"DEAR DOCTOR:—In an editorial published in *THE MEDICAL RECORD* of August 1st it is said:

"It was scarcely fair in Dr. H. [Hammond] to appropriate all of interest in McCormick's brain," etc.

"As you requested me to make the autopsy and the microscopical examination, I would be glad to have you state whether or not in your opinion my action was improper in any respect.

"Yours sincerely,

"WILLIAM A. HAMMOND.

"DR. ALEXANDER HADDEN, 155 E. 51st Street, New York."

"NEW YORK, Aug. 18th, 1874.

"DEAR DOCTOR:—When I received the consent of the friends of McCormick to hold a post-mortem examination of his body, I placed the matter in your hands for the two obvious reasons: 1st, that you had been the consulting physician in the case; and, 2d, that you were a specialist in diseases of the nervous

system. This was before the coroner was notified. The statement that you took all the specimens of interest in the case is not true; none were denied the privilege of taking what specimens they wished, and some did. That you took all the specimens that became of interest would be true.

"Yours truly,

"ALEXANDER HADDEN, M.D.,

"155 E. 54th Street.

"WILLIAM A. HAMMOND, M.D., West 54th Street."

"NEW YORK, Aug. 15th, 1874.

"MY DEAR DR. ARNOLD:—In an editorial published in THE MEDICAL RECORD of August 1st, it is stated:

"It was scarcely fair in Dr. H. to appropriate all of interest in McCormick's brain, as we understand he had likewise done at the Entwistle post-mortem before the arrival of the Curator of Bellevue made it necessary for him to deliver up two or three thin slices."

"Will you be kind enough to tell me whether or not the foregoing extract is correct in statement?

"The facts as I understand them are, that you were absent when the post-mortem was begun; that it was said you would not be present; that Dr. Knox, who made the post-mortem, authorized me to take the medulla oblongata; that on your arrival I at once without hesitation offered the whole of it to you; that you said you only wanted part; that I insisted on your taking the whole, and that I took nothing whatever except a few slices from the cortical substance of the brain, which I did with your sanction.

"Yours sincerely,

"WILLIAM A. HAMMOND."

"MILFORD, PA., Aug. 18th.

"Prof. W. A. HAMMOND.

"MY DEAR DOCTOR:—Your note of 15th has been forwarded just now. The matter is very simple indeed. I was a little late the day of the post-mortem of Entwistle, and as soon as I arrived you handed me the vial containing the medulla oblongata, and I gave you some pieces of the brain myself which had been removed before my arrival. The rest of the post-mortem was made under my immediate supervision. The case, as stated in the extract from THE RECORD (which as yet I have not seen, being in the country), is not true at all. Trusting my delay in replying has been no inconvenience,

"I am very sincerely yours,

"J. W. S. ARNOLD."

The remarks of THE RECORD relative to the publications in the *New York Tribune* are answered in the article immediately preceding the present; but it will probably scarcely be believed that the editor of THE RECORD, who affects such righteous indignation at the publication of medical matters in secular journals, was himself an applicant for the position of medical correspondent of the *New York Tribune*, to report for that paper the proceedings of the Detroit meeting of the American Medical Association!

I think I can now leave the members of the medical profession who may read what I have said and brought forward relative to the attacks of a few members of a coroner's jury and THE MEDICAL RECORD to form their own opinions.

As to the Ishmaelite of the *Philadelphia Medical Times*, who has presumed to dabble in the matter, he is being so heartily punished by our Western brethren for his slanders on them, that in mercy I stay my pen.

WILLIAM A. HAMMOND.

NEW YORK, Sept. 1st, 1874.

Reviews and Notices of Books.

CYCLOPEDIA OF THE PRACTICE OF MEDICINE. Vol. I. Acute Infectious Diseases. Part 1. Typhoid Fever, Prof. Liebermeister; Typhus and Relapsing Fevers, Cholera, Prof. Liebert; The Plague, Prof. Liebermeister; Yellow Fever, Dr. Haensch; Dysentery, Prof. Heubner; Diphtheria, Dr. Qertel. German edition edited by Dr. VON ZIEMSEN. Wm. Wood & Co., New York.

THROUGH the kindness of the American editor we have had the privilege of looking over some of the advance-sheets of this magnificent work, and have thus got a foretaste of the rich treat in store for the medical world. Liebermeister's introduction to the subject of acute infectious diseases, to which the first volume is devoted, and his article on Typhoid Fever, are masterly efforts. The subjects, in their various phases, have been ably and thoroughly digested, and cannot fail to merit profound attention. The author's style is easy, simple, and colloquial, and he manages to intersperse such an array of interesting facts through the pages that he holds the attention of the reader during the discussion of each important topic. His final conclusions are stated with clearness and precision, so that there can be no doubt as to his individual views on the subject.

The chief value of a book of this kind lies in its completeness. The entire range of medicine is, at present, so large that our every-day text-books fail to grasp the entire matter; indeed, it is impossible to condense it into a single volume of ordinary size. This present cyclopædia aims to exhaust the subject, practically, by furnishing all that is really valuable within the domain of practical medicine.

To accomplish a task of such magnitude, it was necessary to employ a large number of collaborators, giving each of the different subdivisions of the work to men who had devoted special attention to the topics included under them, and whose experience and well-known position would give the requisite authority to their views. By reference to the list of authors, it will be seen that this has been very happily done, and the names of Professors Liebermeister, Lebert, Rindfleisch, Wagner, Schroeder, Thomas, and others, well known as able writers and clinical teachers, assure us that we may expect that their work will be thorough and exact in every particular, and contain the practical views which are called for by the profession at large. There is another advantage, too, connected with such a large corps of workers, that is, we may expect the completion of the whole edition within a reasonable period of time; and, there is little doubt, if the present rate of publication is sustained on the other side of the water, the whole work may be completed much earlier than was at first proposed.

It seems to be perfectly proper that German writers should assume the responsibility of this undertaking. During the last ten years, the Germans have been the foremost of all nations in the field of medical investigation, and they have made real progress by long and careful experimental studies that have shed important light on both the etiology and pathology of disease. We and other nations have been content rather to stand by and approve or disapprove of their views, according as the results they have published have agreed with or varied from our own experiences. The labors of Virchow, Cohnheim, Recklinghausen, Stricker, and others have been masterpieces for the

rest of the world, and the position they hold is proved by the number of students that have collected about them, and the enduring character of their teachings and writings. No students of medicine have brought more erudition to their work, or have compiled statistics or classified results with more care and exactness.

We have special need of a book of this kind at the present time. There are, it is true, an abundance of books on the practice of medicine. We have Flint, that has never been surpassed as a text-book for students, and a book of ready reference for practitioners. The force of its logic, its simple and practical teachings, have left it without a rival in the field. But we need a more complete book. Among the more recent books we have Aitken, and may soon have the completed edition of Reynolds, but they neither of them correspond to our present wants. Aitken is justly regarded as unsatisfactory; for while the description of diseases is tolerably complete, it is not sufficiently so as a book of reference for practitioners, nor does it emphasize the facts with sufficient force to be useful for students. Reynolds is far more exhaustive, and, appearing under the form of a collection of monographs, each writer lays special stress on the views that his experience has led him to adopt; more decided reliance may, therefore, be put upon the opinions expressed by each one. Yet this book will probably not exceed 4,000 pages, if the plan originally proposed be adhered to, and four volumes only are issued. Ziemssen, on the other hand, will contain at least 10,000 pages, or two and a half times the number in Reynolds, and we may fairly expect that the additional 6,000 pages will contain a corresponding increase in valuable material. It may be proper to add here, that two new features will be introduced. The nomenclature of diseases and the system of weights and measures will correspond with our American usages as far as possible, but when the decimal system is employed the American equivalent will be annexed. The bibliography of the subjects will be added for purposes of reference, and we may further add, that there will be a goodly number of illustrations. Such a book, complete in itself, is needed by every practitioner. He frequently meets with cases where a disease assumes a novel type, developing symptoms that have not previously been noticed in the text-books, or a rare form of disease not usually described breaks out in his locality. He feels that he wants advice such as he might obtain from a consultant, whose large experience in public hospitals or other institutions would have given him the opportunity of seeing disease under the most varying phases. Such advice is not within the reach of all; indeed, only those that are fortunate enough to live within a limited distance of the great centres can expect to obtain the benefit of such assistance. For these practitioners, and they are in the great majority, a complete handbook of medicine will be really valuable, and in fact indispensable, supplying them, as it will, with the aid they want in the hour of their need.

By referring to the list of articles we find a large number that have never before been treated in a book on the practice of medicine. Special volumes, too, are devoted to diseases of the skin, nervous diseases and diseases of the female genital organs, subjects which usually appear in independent treatises. Public hygiene also receives a large share of attention; indeed it is interwoven through a large number of the articles. The latest phases of the doctrines of etiology and pathology in diseases will also be ably discussed, if we are to judge by the way in which Liebermeister

supports his views of a *contagium vivum*, and we presume that the same spirit will animate the rest of the work.

The American translation appears to be satisfactory so far as we have seen it. An effort has been made to free it from German phrases and cumbersome expressions of all kinds, so that it reads in many places with elegance, and generally with smoothness. It is to be hoped the rest of the work will be finished in an equally acceptable manner. There have been so many bad translations foisted upon us, that we should not be ready to accept any but the best work. The list of translators includes many familiar names already known to us by their contributions in the line of original investigations, and they are a guarantee, in some sort, of the character of this work. Translation is not an easy task, though it may seem so to many; for it is one thing to be able to get a fair idea of the sense from a hasty perusal of the text, and quite another thing to render it in a good readable shape. The one involves a very moderate amount of acquaintance with the language, the other an appreciation of its refinements that can only be gained by a long course of study or the familiarity resulting from speaking it or hearing it spoken frequently. The task of translating has been divided among about fifty gentlemen in various parts of this country, a fact which in itself argues well for the character of the education, as well as for the enthusiasm of our medical men; for it is extremely doubtful whether a similar number of men could be found elsewhere who would be willing and able to undertake it.

This edition is under the supervision of Dr. A. H. Buck, well known to the profession as the American editor of Stricker's Histology, and a frequent contributor in certain branches of medical literature: his name assures us that the revision will be thorough and exact.

We are glad to see that the type is entirely new, and of large size, so that the text is clear and legible. The paper, also, is of excellent quality. The profession of this country and of England are under no small obligation to the enterprising publishers who have had the boldness to undertake a work of such magnitude, involving as it must so large an investment of capital. We trust, as we confidently expect, that they may be amply repaid. We have just heard that a firm in France have made arrangements for translating and publishing the work, and that it will appear shortly in the French language.

THE PHYSIOLOGY OF MAN, designed to represent the Existing State of Physiological Science as applied to the functions of the human body. By AUSTIN FLINT, JR., M.D., Prof. Physiology and Pathological Anatomy in the Bellevue Hospital Medical College, New York, etc., etc. Vol. v., Special Senses; Generation. New York: D. Appleton & Co. 1874.

This volume is the fifth, and the completing one, of a series commenced in 1866. When the first volume, on Blood, Circulation, and Respiration appeared, eight years ago, it was a surprise to the profession of this country, as much on account of its exhaustive treatment of the subjects, as the promise at that time given that it would require four other volumes of equal size to complete the work. Notwithstanding the magnitude of the undertaking one volume after the other made its appearance at regular intervals, each one a surprise in itself; and the fifth, which is now upon our table, is equal if not superior to any of its predecessors.

Prof. Flint, Jr., has proved himself eminently

qualified for the work so creditably performed. A teacher of this branch for many years in one of the largest medical schools of the country, he has had facilities for the practical study of this department of science second to none, and this, coupled with a love for his branch which amounts to enthusiasm, he has spared neither time nor labor to give us the best series of text-books to be found anywhere. Not only has he labored faithfully to prove positions taken by others in the various departments of physiological study, but he has given the profession many original views which are of great value as contributions to science. Notably in this connection are to be mentioned his proof that the *besoin de respirer*, or sense of the want of air, is due to the want of oxygen in the general system; his discovery of the condition which he termed cholesthermia, the demonstration that sugar was produced in the liver during life, and his investigations on the physiological effects of severe and protracted muscular exercise, with special reference to its influence upon the excretion of nitrogen. These described have been given to us in the first four volumes, and the author states that he has found no reason to modify his opinions with regard to them.

The present volume takes up the consideration of the special senses. He devotes chapter i. to the special sense of touch, giving its general and then its special characters, comprising the variations in tactile sensibility in different parts, the appreciation of temperature, etc. The next chapter is devoted to olfaction, which is interesting and instructive, giving in a general way the physiological anatomy of the olfactory apparatus, and preparing the reader to appreciate the details of chapters vii., viii., and ix.

Chapters iii., iv., v., and vi. are devoted to the physiological anatomy of the optic nerves, eyeball, and its different tunics and humors; the laws of refraction, dispersion, etc.; the movements of the iris, accommodation, etc.; and binocular vision.

The topographical anatomy of the ear, the physics of sound and the uses of different parts of the auditory apparatus are discussions of singular merit, but more especially the latter, which presents us with the best account of the mechanism of this apparatus in detail, which we have ever read. In this connection we would refer particularly to the admirable description of the organ of Corti, illustrated by two very fine engravings. Gustation forms the subject of chapter x. All the apparatus connected with this function is quite minutely described; its relations with the sense of smell, with facial paralysis, and paralysis of the tongue.

The sense of taste is believed to be located in the dorsum of the tongue, to which portion of the organ the ultimate filaments of the glosso-pharyngeal and chorda tympani are distributed.

The remaining nine chapters are devoted to generation and the development of the embryo. The organs of generation are described, and their respective functions explained, after which the ovulation is discussed, then fecundation, and finally the development of the new being from the segmentation of the vitellus up to its entrance in the world. In regard to the entrance of the spermatozoid into the uterus, our author places a great deal of confidence in the observations of Dr. Beck, of Indiana, who noticed an orgasm in a patient while under treatment for uterine disease. During the orgasm, Dr. Beck states, "the os opened to the extent of fully an inch, made five or six successive gasps, drawing the external os into the cervix each time powerfully, and at the same time becoming quite soft to the touch." It is unfortunate, however, that the fe-

male was not in a strictly physiologically sexual condition at the time, having been a sufferer from uterine disease for more than eight years. The observation of Litzmann, which the author quotes, is, however, more to the point. Alluding to the statement by Després, that a fluid secreted by glands in the cervix, which is ejaculated during the orgasm and facilitates the entrance of spermatozooids, our author says: "Assuming that the views just stated be correct, we can readily understand how the neck can be erected and hardened during the orgasm, extruding an alkaline mucus, that the semen is ejaculated forcibly toward the uterus, and becomes mixed with the mucus, and that the sudden relaxation of the cervix and opening of the os may exert a force of aspiration and thus draw in the fecundating elements. Certain it is that spermatozooids may be found in the mucus of the cervix a very short time after coitus." This may be a remarkable explanation of the fecundating act on health, but is, as our author intimates, inadequate to explain fecundation in those cases where there is no female orgasm, insufficient penetration, and like impediments. Beyond this, however, in the present state of our science we cannot go for an explanation.

Once in the cervical mucus, the spermatozooids pass through the uterus in a manner not exactly known, and thence through the Fallopian tubes, where they fecundate the ovum either at the entrance of said tubes or in the dilated portion near the ovary. The escape of the ovum and its entrance into the Fallopian tube is described in a very satisfactory and clear manner, and must, we think, in view of any better explanation, be accepted:

"If we take into account the situation of the ovaries and the relations of the Fallopian tubes, we can understand how an ovum may pass into the tube without invoking the aid of muscular action. Let us suppose, for example, that a Graafian follicle be ruptured when the fimbriated extremity of the tube is not applied to the surface of the ovary. One of the fimbriae, longer than the others, is attached to the outer angle of the ovary, and presents a little furrow or gutter, leading to the opening of the tube. This furrow is lined by ciliated epithelium, as indeed is the mucous membrane of all the fimbriae, the movements of which produce a current in the direction of the opening which we might suppose would be sufficient to carry a little globule, only $\frac{1}{100}$ of an inch in diameter, into the tube. At the same time, there is probably, as has been suggested by Becker, a constant flow of liquid over the ovarian surface, directed by the ciliary current toward the tube; and when the liquid of the ruptured follicle is discharged, this with the ovum takes the same course."

In regard to the difference between the corpus luteum of menstruation and that of pregnancy, the accuracy of the investigations of Prof. John C. Dalton, of this city, are very deservedly complimented and endorsed.

The period at which conception is most likely to occur is still an open question, although the greatest weight of evidence leans towards the time immediately succeeding menstruation. Far from this being absolute, however, our author states that there is abundance of proof that the spermatozooids may be lively and liable to impregnation during the whole or any part of the period between the menstrual epochs. The development of the embryo, as we have before intimated, is traced from the first change in the ovum up to the period of birth, and is an admirable, comprehensive, interesting, and intelligent account of this wonderful process. This portion as well as many

others of the work is suitably illustrated with excellent engravings, and although very few are original, those that are given show great discrimination and taste on behalf of the writer. This remark applies particularly to the superb woodcuts which are taken from Dalton's "Physiology," and which tend so much to elucidate the early stages of the growth of the embryo.

In conclusion, we would reiterate the statement that this work takes a well-merited rank with its predecessors in the series, and they as a whole form the most complete and trustworthy work on physiology to be found in any language.

Reports of Hospitals.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, June 24, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

EXSECTION OF THE HEAD OF THE HUMERUS.

DR. SAYRE presented the upper extremity of the humerus of a man aged 32. The patient was of robust constitution, of healthy parents, and no hereditary taint. He was admitted into Bellevue Hospital last November, suffering from inflammation of the right shoulder-joint. No cause was assigned for the trouble except violent muscular exertion. The arm was stiff from muscular contraction and intensely painful. Finally an abscess appeared on the inner and anterior portion of the arm, opening and discharging a large quantity of pus. No dead bone could be detected on probing. Following this, another abscess formed on the inner side of the arm, an inch and a half higher, and this likewise opened. Both abscesses discharged freely. Although no dead bone could be detected, Dr. Sayre concluded that the joint was involved, principally for the reason that the abscesses discharged a peculiar gelatiniform material, and the disease was of such a long duration. He made an explorative incision through the posterior part of the deltoid muscle. The head of the bone was found to be carious, with its cartilage of incrustation destroyed. The section was made through the anatomical neck, but the bone having been found diseased at that point, another slice was removed. The surface of the glenoid cavity was eroded and was scraped off by the elevator. The entire wound, with the exception of the most dependent portion, healed by first intention.

MYXOMA AND ENCHONDROMA OF THE THIGH.

DR. SAYRE presented a second specimen, which was a tumor of the femur. The patient was a male aged twenty-one, who had been brought into Bellevue a week before the meeting of the Society. Two years ago while carrying, in company with others, a heavy bar of iron on a railroad, his foot was caught in the track and he suffered a violent wrench, which gave him the sensation of something having given way on the inside and back part of the knee-joint. In the course of a week or so after, continuing to walk around as usual, he noticed a hard round swelling the size of a bird's egg growing from the inner condyle. This tumor grew gradually for six weeks, at the end of which time it was the size of a lemon. About this time he took some violent exercise in running, which increased the activity of the growth of the tumor, at the same time causing it to become inflamed. He continued, how-

ever, at his work for a year more, and at the time of his admission to hospital the growth measured around the knee twenty-seven inches. It had the form of an irregular knob, was whitish at the base, and red on the summit, while pressure on the surface gave the sensation of the crackling of an egg shell.

The fluctuation at some points was quite distinct. The point of a hypodermic syringe was introduced into the most prominent portion of the tumor, but no fluid could be drawn out. On removing the beak, however, a straw-colored gelatiniform mucus exuded in great quantity from the opening made. This discharge kept up during the remainder of the day and night, and Dr. Hunt was compelled to arrest it the day following. The tumor, from the loss of the fluid, diminished an inch in circumference.

The thigh was amputated very near its middle, June 24th. On laying open the tumor it was found to be made up of sharp spicula of bone. The growth seemed to spring from the periosteum at the inner condyle of the femur, that membrane stretching itself over the tumor. The spaces of the tumor were filled with the gelatiniform tissue before alluded to. On sawing through the longitudinal axis of the bone and tumor, the medullary canal at the upper portion and just below the section was found to be the seat of enchondroma. The tibia did not seem to be involved in the tumor, but at its lower portion was the seat of a roundish enchondromatous mass springing from the spine of the bone. In conclusion, Dr. Sayre remarked that had he made the amputation lower down, he would have gone through healthy osseous tissue, and the enchondroma alluded to would have been overlooked.

DR. JANEWAY examined the growths microscopically and pronounced them of a mixed variety, partly myxomatous and partly enchondromatous.

INCARCERATED HERNIA. *

DR. E. MASON exhibited a specimen of hernia occurring in a patient of Charity Hospital. A female, sixty years of age, was admitted with phlegmonous erysipelas of the leg and foot, which resulted in ulceration of the dorsum of the latter two months afterwards. May 26th, she was seized with great pain in the abdomen, attended with nausea and vomiting. At this date, she called the attention of the house-surgeon to two tumors in the groin. These were made out to be oblique inguinal herniae. One on the right side was readily reducible, and had, as she stated, existed seven years; the other, on the left side, the size of an English walnut, was not reducible at that time, and has existed eighteen months. An attempt was made to reduce the latter tumor, but failed, and ice was applied, and was allowed to remain on all night. In the morning, all the unpleasant symptoms, pain, nausea, and vomiting had been relieved, and in addition she had a movement of the bowels. The tumor was then regarded as incarcerated hernia, although not strangulated.

THREE SPECIMENS OF GLIOMA RETINÆ.

DR. H. KNAPP presented three eyeballs affected with encephaloid cancer, and made, in substance, the following remarks:

Two of the specimens, the first to be described and the third, I owe to the kindness of Dr. E. WILLIAMS, of Cincinnati; the second is derived from my own practice. The first specimen was taken on Feb. 21, 1874, from a rather delicate sallow girl of 12 years. A week before, one of her playmates discovered a peculiar, shining reflection from her pupil, and on covering her other eye the patient noticed that the one was blind. Glioma was diagnosed, the eye enu-

cleated, and kindly sent to me for examination. A meridional section showed the whole retina detached and corrugated, passing as a straight chord from the optic nerve towards the crystalline lens, where it expanded laterally and connected with the posterior portion of the pars nonplicata corporis ciliaris. The outer (parietal) surface of the corrugated retina was uneven, and at its anterior and transverse parts markedly nodular. The section surface was in some places granular, in others finely striped, generally white, with some black spots. Under the microscope the whole retina was found to consist of the well-known small round cells lying closely together in a granular or striated matrix. The nodules in the anterior part showed the typical glioma structure. Their greatest development could be traced to the pars ciliaris retine, and it seems that the growth originated in that locality. The black spots contained the same kind of cells as the other portions, and, in addition, a great many small round, or irregular pigmented cells, as well as dispersed granules of pigment. This condition appeared to be the result of hemorrhage.

The case has some unusual features: 1. The extensive pigment of patches. 2. the greatest development, and probable origin of the growth, in the anterior, *i.e.*, ciliary portion of the retina. 3. The somewhat advanced age (12 years) of the patient; glioma of the retina being usually observed in children under 8 years of age. The prognosis is rather favorable, as all the other structures of the eye, the optic nerve included, were unaffected, as furthermore there was a moderate amount of fibrillary substance between the cells, showing a less vigorous tendency to proliferation than is commonly witnessed in encephaloid cancer. The age of the patient is probably another favorable condition concerning the probability of a permanent recovery.

The *second specimen* presents the ordinary conditions of glioma retine. The whole posterior space of the globe, from the optic nerve to the posterior capsule of the lens, is filled with a soft, white, exceedingly vascular, brain-like substance. The retina is not to be traced; the optic nerve, choroid, ciliary body, and the other structures of the eye, are unaffected. I removed the specimen, a few days ago, from a child, *æt.* two years, of pale and sallow complexion, who, in all probability, will soon die from the generalization of the malignant retinal tumor. Three weeks before its removal, the blind eye had become painful, injected, hard, and somewhat enlarged. The pupil was wide, immovable, and through it a dull yellowish substance, filling the vitreous chamber, was seen.

The *third specimen* was taken from a well-developed and intelligent boy of about 4½ years of age. About two years previously a white spot had first been noticed in the pupil, which gradually enlarged and destroyed the vision. The physician called it cataract, and the sight had been totally abolished about a year. Five weeks previous to the operation the eye began to protrude and was painful. The patient also suffered a good deal with pain in the bowels. At the time of the operation the eyeball was displaced before the eyelids, which contracted behind it. The cornea had sloughed away, and from the interior of the globes protruded a dark, reddish-brown, soft substance which easily bled. The eyeball was enucleated by Dr. E. Williams in March, 1874. The optic nerve, being enlarged, was removed as near the optic foramen as was practicable. Its proximal (cerebral) end, being still large and lardaceous, left no doubt that the disease had extended into the cranial cavity. The child recovered from the operation in a few days, and

though no symptoms of secondary tumors could at the time be detected, yet death must soon follow. The eyeball has about double the normal size, and has the shape of a goblet. The sclerotic in the ciliary region is thinned and studded with bosses such as we see in hydrophthalmic eyes. The whole eye is filled with encephaloid substance. The thickened optic nerve shows a degeneration by the same morbid elements which are dispersed through its connective tissue and bundles of the nervous fibres, a small part of which are preserved. There are some episcleral tumors around the optic nerve, but not in connection with it. On careful dissection the place is found in which they communicate with the intra-ocular growth. In this place, which has about a line in diameter, the sclerotic is thinned and softened, yielding readily to the probe, but offering still so much resistance as to show that the fibrous tissue is not wholly destroyed by the pseudoplasm, but pierced and macerated.

These three specimens, Mr. President, present three different stages of encephaloid cancer of the eye: in the first the disease is still limited to the retina, and no symptoms of inflammation or irritation annoy the patient; in the second the globe is filled with the pseudoplasm, is hard, painful, and inflamed (glaucomatous stage); in the third the globe is perforated, mostly in the cornea, the sclerotic is bulging, and the growth extends into the orbit and the brain. In this stage the majority of the patients die. The fourth stage, the formation of metastatic tumors, is very readily met with.

MULTIPLE EMBOLISM, WITH HEMORRHAGIC INFARCTION OF THE PIA MATER, LUNGS, KIDNEYS, AND SPLEEN; GANGRENOUS DEGENERATION OF THE LATTER.

DR. SATTERTHWAITE presented the heart, kidneys, and spleen, with portions of the brain and meninges, and also portions of the lungs, removed from a gentleman who died suddenly on the twenty-second of June. The patient had been chiefly under homeopathic treatment, but during the latter stages of his illness had called in two well-known practitioners in regular standing. He was seen but three times by these gentlemen. At their suggestion Dr. Satterthwaite performed the autopsy. A complete history of the case could not be obtained, for obvious reasons, but the main facts were as follows:

About the middle of April, the patient was taken sick with some form of fever, which lasted four or five days, confining him to his room. After recovery from this attack, but before leaving the house, the patient thought he caught cold, and feeling decidedly unwell, took to his bed and never left it. During the first two or three weeks the temperature never exceeded 100° F., and varied between that and 98° F. The rapidity of the pulse was noted at this time. It was so marked, that when he sat up, it would reach 140-150, and on one occasion even rose to 165. During the last two weeks of his life, it varied between 120-150 and, the temperature between 102° and 105° F. At an early period a diagnosis of endocarditis, with aortic obstructions, was made out. The respiration was never embarrassed except on assuming the upright posture. It is said that there was no impairment of sensibility or motion, nor did the patient suffer any pain except on a single occasion when his chest was examined, some two and a half weeks before death. His physician was assisting him to turn over on his left side, when he called out suddenly, "You have killed me," at the same time placing his hand over the region of the spleen, and groaning with pain. He recovered from

this paroxysm, and never again alluded to pain at that point. Latterly he lost a great deal of flesh, and became so weak that examinations of the chest were made with difficulty. It was added that percussion of the internal viscera failed to detect any abnormal variations in their size.

The urine was examined, but neither albumen nor casts were present. There was no retention until within the last twenty-four hours of life. Consciousness was clear up to the end, though it was apparent that for a long time previously he showed indifference to what passed about him.

On making the autopsy, the dura mater was found a little adherent, and a few flakes of fibrine showed themselves on the surface of the pia mater. This membrane was somewhat thickened, and showed over the convexity of the brain small whitish points surrounded by areas of extravasated blood. These whitish points varied in size from the head of a pin upwards, and were found on microscopic examination to be formed by small collections of a fibrinous material; they were in the calibre of the minute vessels of the pia. The thickening was not due to recent inflammation, as shown by the microscopic examination. The vessels at the base of the brain were free from atheroma and were empty. No emboli were found in any vessels of the brain, nor was there an undue amount of fluid there.

The heart was found hypertrophied, especially the left ventricle. In the aortic orifice there were calcareous concretions and several vegetations. The stenosis here was so great as barely to allow the first joint of the little finger to pass. The aorta itself was somewhat atheromatous. The kidneys were enlarged, and showed hemorrhagic infarctions of dark and light colors. The capsules were not adherent except in a few places. The cortex was marked with the peculiar stellate distribution of the minute vessels often seen in nephritis. The testes were generally contracted, and there was an increased amount of intertubular tissue, such as is observed in intestinal nephritis.

The spleen was found enormously enlarged, measuring about nine inches in length. About one-third of its substance had undergone gangrenous degeneration, while the remainder of it was marked by hemorrhagic infarctions of various ages, some of deep-red color and others of a dirty-brown or yellow, with commencing cheesy degeneration. The capsule was still perfect, and when open discharged from a pint to a pint and a half of a dirty grumous fluid, having an offensive odor. In the lower lobes of both right and left lungs were hemorrhagic infarctions of large size. The liver contained none, but was fatty. These specimens were referred to as exhibiting the lesions that may occur in a case of multiple embolism.

The originators of the mischief were the vegetations at the aortic orifice. Smaller and larger portions of these bodies were swept away by the blood-current and driven onward until they became impacted in blood-vessels too small to admit their passage; venous stasis and extravasation then followed, giving rise to the so-called hemorrhagic infarctions. Owing to the small size of the bronchial arteries and the large size of the infarctions in the lungs, it seemed probable that the latter were produced by thrombi from the spleen, which, taken up and carried into the right side of the heart, entered the lungs by the pulmonary artery. The degeneration of the spleen was due to the breaking down of one or more large infarctions, for they were found to be continuous with the gangrenous sac.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from August 19, 1874, to September 4, 1874.

SMITH, A. K., Surgeon.—Granted leave of absence for 30 days, on Surgeon's certificate of disability. S. O. 135, Department of the Missouri, August 26, 1874.

WRIGHT, J. P., Surgeon.—Relieved from duty at Fort Hays, Kansas, and assigned to duty as Chief Medical Officer, District of New Mexico, Santa Fe. N. M. S. O. 132, Department of the Missouri, August 22, 1874.

MONROE, F. LE B., Assistant Surgeon.—Granted leave of absence for one month, provided he furnishes a suitable substitute during his absence. S. O. 139, Department of the South, August 29, 1874.

STEINMETZ, WM. R., Assistant Surgeon.—Assigned to temporary duty at Fort Melleny, Md. S. O. 183, A. G. O., August 21, 1874.

Medical Items and News.

SIR WM. GULL, OF LONDON.—That Sir Wm. Gull does not owe his success in life to adventitious aids is evident enough. He was the son of a poor farmer—a laborer who tilled a small plot of ground, the property of Guy's Hospital. He attracted the attention of the Treasurer of the Hospital as a bright lad, and was given a place as bottle-washer in the drug-room of the hospital. He was given the opportunity also to have some instruction, entered as student, graduated with honor, became house-physician, assistant physician to the hospital, physician, and lastly consulting physician, his present place. These facts are well known, yet he is created Baronet, and welcomed into their ranks by the most exclusive aristocracy on the globe. He is no common man, whatever may be said of him, who can carve out such a career for himself, and from a charity lad become the foremost physician of the greatest city of our modern civilization. Gull is said to be so closely occupied that patients have to make engagement days in advance of the time."—London correspondent of *The Clinic*.

DR. WASHINGTON ATLEE has been elected President of the Pennsylvania State Medical Society for the ensuing year.

A LOST CASE.—A physician in Vienna, Wis., who recently sued a man for services rendered in the treatment of his son for fracture of the thigh bone, lost his case. The local paper says that after the plaintiff had proven his case and rested, counsel for the defendant moved for a nonsuit, under chapter 95, laws of 1867, which in effect provides that no person practising physic and surgery shall be allowed to collect fees for services rendered unless he is a graduate of some medical college, or is a member of the State or some county medical society. The lawyer claimed that the plaintiff's duty was to prove he was a graduate, or was a member of one of the societies mentioned, and inasmuch as he had not done so, the defendant was entitled to a nonsuit. The motion was sharply resisted by the counsel for the plaintiff, but the defence sustained the theory by authorities, and the Justice dismissed the case.

Medical Department of Life Insurance.

THE INFLUENCE OF MALARIA ON LONGEVITY.

By J. R. BLACK, M.D.,

NEWARK, OHIO.

THERE are two grand sources of disease essentially distinct in their origin, to wit, the one in which man is himself the causative agent, and the other in which nature is supposed to be the *fons et origo*. Of the latter, malaria, as a fruitful source of disease, is considered as occupying by far the most prominent place, and as such deserves thoughtful consideration. That which is a source of disease becomes also by natural sequence a source of untimely death, of defective constitutions, and of structural faults in some organs of the body.

When, however, an attempt is made to gauge its power in these respects, and especially the influence it exercises in the development of secondary diseases, or as a complication of others, and the part it thereby plays in the curtailment of life, the intricate complexity of the problem becomes discouragingly apparent. In fact, the formation of a strictly accurate estimate of the influence of any single cause of disease and of untimely death is, from the nature of the case, impossible. Individuals exhibit almost every possible shade of constitutional defect, of special taints in blood, affecting and modifying in innumerable ways the impress of an external deleterious agent, and thus present almost every grade of yielding or of resisting power. Then, there are scores of transient modifying influences for or against the action of a morbid cause, which are often capable of turning the scale toward health, or toward aggravation and death. The knowledge, therefore, of the power of malaria over life for evil can only be approximative, approaching accuracy in proportion to the breadth of information, the opportunities for extended comparison, and the care and judgment with which deductions are drawn. Even in estimating the direct effects of malaria we should be led into error did we fail to note the remarkable influence of acclimatization in its preservative power over healthy life.

Deport a hundred Germans, a hundred New Englanders, among a like number of the indigenes of a malarious region, and the exemption and susceptibility to its influence would be strikingly apparent. New elements of the problem would also be manifest. The Germans as a whole would resist the malarious influence better than the New Englanders, though some of the former would suffer from periodic fevers to an intense degree. The solution of the cause of these differences is not difficult to the careful observer. The superior constitution of the German, his simple, regular, and primitive way of living, enable him to resist any untoward external condition better than the more tender and luxurious New Englander; but some of the former, on account of their uncleanly habits, and their careless way of crowding a large family into small unventilated apartments, lay themselves especially liable to inveterate attacks of malarious fever.

Whatever may be the opinion as to the essential nature of malaria, it is an agent or condition that acts with redoubled force when aided by some causes which deprave the purity of the blood, and the health of the body. Additional illustrations of this are frequent. Persons who have spent an average lifetime in a ma-

larious region without once exhibiting any of its visible effects, are almost sure to suffer from some periodic fever, should their health be undermined by any other cause.

Not only does the influence of malaria hasten the appearance of a gathering morbid process, but it complicates its action when in full operation, and it lingers and prolongs systematic disorders after the main acute disease has disappeared. It is a question whether malaria, by hastening the appearance of some latent cumulative disorders, does not sometimes render them more mild, or abort them altogether. For example, the consciousness of not being quite as well as usual often precedes for a long time the onset of some protracted and dangerous disease. The lowering of the health tone which thereby exists gives, in a malarious region, that supposed emanation a power over the system which otherwise it could not possess—developing, it may be, an attack of remittent fever, which so changes and renovates the blood that the sense of the original and slight impairment of the health is forever removed. This fever being one of the least destructive to life, eliminating in its course large quantities of biliary matter, cutaneous and intestinal excretions, is it not highly probable that it may in this way carry out of the body other elements of some forming disorder? At the least, those who have had much to do with this disease cannot fail to be impressed that it sometimes seems to right up the health in a very satisfactory manner. On the other hand, it is true that the effects of remittent fever, when very severe, are often quite the reverse; giving a severe shock to the vitality of the system, and bringing on some chronic derangement which, though not of itself dangerous, serves as a favoring condition for the development of some other disease of a more fatal character.

The action of malaria on the system being influenced by inherited and acquired peculiarities, and modifying in its turn, usually for evil, the course of other diseases, or following them up with a long train of evils, and sometimes seeming to act as a therapeutic eliminator of occult morbid conditions, and to the exclusion of some other diseases (of which more anon), these considerations though stated in general terms make plain what an intricate problem it is to ascertain with tolerable certainty the exact influence of this mystic agent on longevity. As an etiological cause it may very properly be considered as an addition in certain localities to all the causes of disease existing elsewhere, for it does not seem to displace any one of them, whatever may be thought of its modifying power in any other respect. Were we in possession of vital statistics recorded with the special view of ascertaining what the influence of this superadded cause of disease is upon health, as in a few contiguous non-malarious, and a few malarious counties, a very accurate estimate of its power over life might be made. But as nothing of the kind has been attempted, the solution of the problem is attended with peculiar difficulties, and will account for the line of research I have been compelled to adopt.

It would be unnecessary in this connection to dwell upon the vexed question of the origin of intermittent and remittent fevers did not the conception of their causation largely influence the mind in the formation of its conclusions, as to the effects. To one who has his mind made up that these fevers are due to a gaseous poison, or to certain disease-producing germs, the conception of evil effects, and of their persistence, would be much more likely to prevail, than to one who regards their production as due simply to certain endemic climatic conditions. In other words, he who believes that the atmosphere of certain places is charged with

a substance highly and constantly inimical to life, will be more likely to regard it as very unfavorable to longevity, than he who believes that there is no such substance, but that the alleged effects are solely due to the local variations of a perfectly natural force, which only disturbs for the time the healthy play of the functions. In the former case, there is supposed to be, as in the inhibitor of alcohol, or the eater of opium, an unnatural material in the body, producing abnormal results, as in the so-called malarial cachexia, and which under no circumstances can be supposed to affect life other than in a detrimental manner, even when those subject to it are apparently in good health. With a poison of this kind in the systems of all the inhabitants of a malarious region there may be supposed to be a suspension, but not an immunity to its influence. Like the influence of all other poisons the untoward effects will be shown sometime in life, and in a manner highly unfavorable to health and longevity. The enormous influence of a free use of alcoholic drinks in shortening the expectation of life is well known, and why not also malaria, which is the alleged cause of so much disease? From this point of view it must be acknowledged that the prospects of long life in a malarious region are decidedly dark; there being supposed to be a more or less constant inhibition of a poison as constantly inimical to health and life.

On the other hand, if the cause of these fevers consists in certain local climatic conditions to which there is not constitutional adaptation, and to which the strength of the body sometimes affords insufficient resistance, the unfavorable influence upon life would more likely be regarded to be nearly as transient as the operation of the conditions. It would then be like an irregular, but great variability of climate, affecting the weakly and the unadapted only for the time in a manner unfavorable to longevity. When fairly over the transient effects, the subjects of one kind of climatic variation, like those of another, may be supposed to have nearly as good chances of prolonged life as those differently circumstanced. At the most, the evil effects would only be when the vital force of the body was lowered by some cause, rendering it subject to exterior changes, above which it rose when in a normal condition.

Proof of the exact influence of malaria on the duration of life being unattainable, it necessarily arises that the opinions thereon will be very much influenced by what is supposed to be the nature of its cause; whether it is an entity or a condition. As the object here is first of all the promotion of truth; and second, to aid in the formation of a correct opinion on the subject involved in the title, I shall be compelled to state in as brief terms as possible what seems to be the true nature of the malaria which is usually assumed to be the cause of periodic fevers.

While not questioning the accuracy of the observation that the decomposition of large quantities of vegetal or animal matter on a limited space is productive of disease, I do question that such decomposition has a definite relation in time, in quantity and in invariability of sequence to the prevalence of periodic fevers. And, at the onset I may be allowed to claim a desire to avoid a narrow special pleading statement of facts and observations, which, while accounting in a satisfactory manner for the prevalence of fever in one region, wholly fails when applied to another. The tacit ignoring of the facts pertaining to one region not in harmony with the preconceived notions, and the undue prominence given to those which do, is worse than the mere zeal of a partisan: it is disloyalty to science and to truth.

Assuming that the specific cause of periodic fevers arises from some product of vegetal decomposition, the effect ought to exhibit an invariable relation to the cause—no adequate counteracting influence being shown. Those well acquainted with all the recorded facts on this subject know that there is no such invariability of relation. In the Mississippi Valley the greatest annual prevalence of fever corresponds with the maturation, not with the destruction of vegetal matter. The greatest destruction is during the winter and spring months, or when the entire outcrop of the previous season disappears. Comparing the amount of summer growth and decomposition in Brazil with that of the foot-hills of California, the difference well high expresses the greatest possible extreme of these processes. In the latter locality from May till November of each year the drouth is so extreme that the grass of winter preserves all the properties of sweet, nutritious hay; while in Brazil the abounding moisture, tropical sun, and luxuriant vegetation present conditions extremely favorable to a rapid decomposition, as well as to a profuse growth of every kind of vegetal matter; yet periodic fevers are quite rare in Brazil, while along the foot-hills of California they are extremely rife. The most obstinate intermittents I ever met with occurred in that part of the Golden State. A number of persons whose names I can recall, who emigrated to California from the fertile plains of Ohio, like myself, became subject for the first time to intermittent fever of a very persistent form—in some instances producing great enlargement of the spleen. Blodget, in his *Climatology of the United States*, in noticing this statement of mine, which first appeared in the *New York Journal of Medicine and the Collateral Sciences*, March, 1854, doubted the accuracy of the diagnosis on account of the fact that all the conditions favorable for the generation of malaria are absent to an extraordinary degree. The air of that region does seem to indicate an unusual absence of the conditions which favor septicity, or of atmospheric agents destructive to organic structures. A quarter of fresh beef is preserved for use by simply hanging it on the limb of a tree; there it desiccates, but never putrefies. The statistics of the United States Army, as well as the published statements of many other later writers, abundantly vindicate the accuracy of the diagnosis referred to. At every military post of that State, away from the coast, periodic fevers, according to the army returns, constitute the main disease. Camp Far West was so insalubrious in this respect that it had to be abandoned.

Ferguson records of the British army in Spain during the Peninsular war, while encamped on the barren and sandy plains of that country, that the troops suffered to an unusual degree from periodic fevers. Difficult as the presence of so much fever was to account for on the malarious hypothesis, it is not more so than to account for its absence in the most fertile portions of the Sandwich Islands. Here, there is no need to search for water nor for vegetal matter as in that of which Ferguson wrote; both abound, with a tropical sun and yet no malaria, if the absence of periodic fevers be accepted as evidence. Other examples equally conclusive of the absence to an almost total degree of the assumed cause, and the presence to a virulent degree of the assumed effect, and of the abundant presence of the assumed cause, and the almost complete absence of the effect, might be narrated, but these must suffice for the present purpose. They are quite sufficient to satisfy an unbiased mind that when the range of our mental vision is extended beyond the limits of a county or State, the theory

which may serve to account for the presence or absence of intermittent fever in one locality may wholly fail to do so in another; and that when such is the case, when there is no invariability in the succession of an assumed antecedent to an assumed consequent, their occasional conjunction must be regarded not as causative but accidental.

A theory of the cause of periodic fevers, to be worthy of credence, requires to be competent for the explanation of the phenomena everywhere—in Ohio, in South America, or in Africa; as well as to account for all counteracting and modifying circumstances. Such a theory—one that seems to meet all the requirements of logical sequence, not simply here or there, but in all countries—is laid down at length in the *Transactions of the American Medical Association* for 1864. Continued observation since that time, in a region where this type of fever annually prevails, has only served to establish to my mind its claims as the true one; and the same opinion has been expressed to me by a score of leading medical gentlemen in this and other States, whose judgment and opportunities for its verification are entitled to the highest respect. This theory is as follows: *With a mean summer heat of 60° and upwards, the greater the regular diurnal oscillations of temperature, the greater, ceteris paribus, is the prevalence of periodic fevers, and with the rise of the mean is the increase of susceptibility to fluctuations, or the smaller comparatively the regular oscillations requisite to produce the morbid phenomena, and the more intense their character.*

A condition which has a marked influence on the operation of this law of production is the prevailing degree of atmospheric humidity. When this is great, the characteristic effects of diurnal fluctuations of temperature are in accordance with what familiar observation has taught of other vicissitudes, much more likely to arise, as well as to present a much graver character.

A collection of statistics, gathered mainly from the meteorological and sick reports of the United States Army for 1839-54, and 1855-59, in every section of the Union, is added in the *Transactions* above referred to, to prove the uniformity of the relation of the alternations between the temperature of day and night, when great, to the prevalence of periodic fevers. Without going into details suffice it to say, that no exception to the law has come under my notice; and that when the modifying influences above referred to are kept in mind, the relation of the cause to the effect is, as all real causes, are perfectly uniform.

Those in the habit of noting the vicissitudes of atmospheric heat, are well aware that they are of two kinds; the irregular sweeping changes of the weather, and the regular, from surface diurnal absorption and nocturnal radiation. The one is more or less general, the other local. The character of the soil, the altitude, the humidity and immobility of the atmosphere, and the cloudiness of the sky, influence to a remarkable degree these local fluctuations of the thermometer, and with which we have here alone to do. They are also well known to be, nearly everywhere in the northern hemisphere, much greater during the autumnal months than during any other portion of the year. They are also greater in low than in high localities, over a loose organic soil than over a dry clayey surface. The plain, having the heaviest dews and the most severe untimely frosts, attests in a general way the correctness of these observations.

A very wet cloudy summer season by hindering diurnal absorption and nocturnal radiation reduces local oscillations to a minimum, and the relation of

such a season to salubrity, at least so far as periodic fever is concerned, is well known to the resident physicians of the so-called malarious districts.

The rural physician, in his midnight rides, during the summer season, is made aware of the great influence of local conditions in depressing the temperature. In the low damp valleys the atmosphere is very chilling, on the adjacent hills it is much warmer and dryer, while under the foliage of a lofty forest the nocturnal warmth reaches its maximum, and is peculiarly grateful. I have found by experiment that on still nights the depression of the temperature of the air decreases about 8° to an altitude of fifteen feet. The bearing of these differences on the production of periodic fevers is obvious. Such fevers, other things being equal, are always more prevalent in valleys than on the adjacent hills, and persons whose night quarters are on the lower floor of a house are more likely to suffer than those in the rooms above.

The foliage of trees has been supposed, from the protection it affords to the invasion of fever, to absorb malaria. The theory of regular diurnal oscillations explains this protection on a more rational mode than by a double hypothesis, or the supposed absorption of a supposed existence. A dense foliage equalizes the temperature of the day and night, hindering absorption during the one, and radiation during the other. A little observation of the thermometer at sunrise in such a place, or the mere fact of the absence of dew, will soon convince any one of the equalizing power of an overshadowing foliage. The following facts were related to me by an intelligent pioneer of the Muskingum Valley. One of his neighbors, a Mr. B., from some whim preserved the indigenous trees over an area of an acre or more around his dwelling. It was a matter of common talk, that while all his neighbors suffered annually to a greater or less degree from autumnal fevers, Mr. B. and his family escaped. By and by he was gathered to his fathers, and his sons, desirous of having their home look more like those of the neighborhood, cut down all the primitive forest trees, and planted some low evergreens in their place. From that time the exemption of the family from autumnal fevers ceased.

A considerable body of water diminishes the diurnal oscillations of temperature on the adjacent lands to a marked degree. Water absorbs and radiates heat much more slowly than land; hence it acts as an equalizer of the local atmospheric temperature, and in this way preserves the inhabitants favorably located to feel its influence against great diurnal vicissitudes. Writers on malaria uniformly mention the fact that a river often seems to serve as an effectual barrier to the passage of malaria, and that on the worst fever-generating coasts to anchor a vessel a few hundred yards from the shore protects the occupants of the vessel from a febrile invasion.

On the Sandwich Islands and over a large portion of Brazil, the regular diurnal fluctuations of heat very seldom exceed 10°, and the mean only about 5°, consequently periodic fevers are quite rare. On the other hand, in the interior of California, the diurnal fluctuations often reach 40°, with a high mean temperature, and were it not for the extreme aridity the periodic fevers which result would be of extraordinary virulence. As it is, such fevers are remarkably prevalent and obstinate, a prevalence so difficult to account for on the malarious hypothesis that some writers have attributed them to the alkalinity of the soil.

At this place, on yesterday, the 1st day of July, the thermometer from nocturnal radiation stood at 6 A.M. at 56°, and at 3 P.M. at 89°. This is no unusual fluctuation.

tuation, and it only remains to add that periodic fever is the prevailing disease.

On this theory can readily be explained the danger of exposure to night air, and of sleeping apartments near the ground; of the greater prevalence of such fevers during the autumnal months; of the strictly local action in some places of the cause; of the protection afforded by water, the foliage of trees; why compactly built cities in the midst of a malarious region afford comparative immunity; why exposure to night air and morning fogs favor the development of ague, and why certain precautions in bracing the system and protecting it by appropriate clothing secure to an eminent degree exemption, in even the most noted of the malarious districts. Dr. Jones, the President of the Ohio State Medical Society, at its session in June last, in an address, related that a young physician, surprised at the hale, hearty appearance of an old physician of the Maumee Valley, the inhabitants of which are known to be much subject to periodic fevers, inquired by what means he succeeded in keeping himself in such an admirable state of health, "Oh!" said he, "a flannel shirt did it all."

Whenever great nocturnal depressions of temperature regularly prevail there is an alternate activity and excitement of the cutaneous functions, and then of a sluggish, depressed action—with corresponding irregularities in the action of the liver, kidneys, and intestinal secretions. An attack of ague is only an intensified repetition of these phenomena, so rapid in occurrence, and so severe in degree as to constitute disease. First, the alternate excitement and depression becoming too great for physiological resistance, it becomes morbid—just as delirium ebriusum is liable to become delirium tremens; then secondary effects ensue from such extreme irregularity of function, denoting that the functions of all the digestive organs have become seriously impaired. The periodical repetition of a great irregularity of function from a like cause is often seen under other circumstances, as in periodical hemicrania or sun pain. This is a winter or early spring disease even more distinctively than ague is an autumnal disease. The cause, though similar, is different, its application being local and artificial. During intensely cold weather the brow is exposed to a very low temperature, while during the night it is sometimes exposed to temperature artificially high. Continual repetition of this will often beget brow or local ague, precisely as a general repetition of severe alternations often begets general or systematic ague.

It is obvious that, if this doctrine be accepted as true, it must affect very materially the conceptions of the chances of an ultimate recovery from the direct morbid effects, as well as of the more remote sequelæ. There is, according to this theory, no continued impregnation of the system by a poison, only a temporary disturbance of healthy function by the excessive alternations of a normal force. The anæmia, the disordered functional action of the liver, the enlargement of the spleen, the irregular and debilitated digestion, are only consequences of an exterior disturbing force; not of a saturating, lurking poison. There is only a functional derangement to correct, and the removal of the depraved secretions which thereby ensue from the body as the main condition for the complete establishment of health.

It is well known that the sudden exposure of the body to a low temperature is attended with dangerous consequences, in the main, in proportion as it is previously exhausted by a high heat. This is pointedly true in the case of exposure to diurnal oscillations. In Ohio, where the mean of summer heat rises only

to about 70°—the effects of such alternations are less serious than where the summer mean rises to 80°, as in Florida. A rise of 10° of the mean heat is more than equal in effects to that of an addition of 10° to the mean of the diurnal oscillations. Especially is this true of the unacclimated; the effects are then so intense that they not unfrequently prove immediately fatal. Accordingly, other things being equal, as the mean heat rises so does the fatality of intermittent and remittent fevers increase. In a general way, this is very clearly shown by the mortality from these fevers in the following States, as reckoned from the last United States census, of deaths from all causes:

State.	Percentage of deaths from Intermittent and Remittent Fevers.
Alabama.....	7.0
Arkansas.....	7.0
California.....	1.0
Florida.....	9.4
Georgia.....	5.1
Kentucky.....	3.0
Louisiana.....	5.7
Minnesota.....	0.4
Missouri.....	3.8
Mississippi.....	6.8
Wisconsin.....	0.5
Ohio.....	1.2
Pennsylvania.....	0.9
Michigan.....	2.2
Indiana.....	2.3
Illinois.....	2.6
Kansas.....	5.2

While this table is undoubtedly approximately correct as to the loss of life immediately arising from periodic fevers in the several States as a whole, it colors the loss too highly in some regions, and too faintly in others. Over all the southeast part of Ohio, from near the centre of the State, periodic fevers are quite rare, while over the northwest part they are decidedly prevalent. At this place, which is just within the so-called malarious region, and at Toledo, —the only places of which I have reliable statistics,—the percentage of deaths from periodic fevers is nearly two per cent.

The number of deaths from these fevers, while correctly indicating their severity, by no means correctly indicates the degree of their prevalence. It is well known that some epidemics of scarlet fever, diphtheria, dysentery, etc., are very fatal,—and others, as justly entitled to the term epidemic, are very rarely so. Just so is it with those endemic fevers. In one locality they are quite fatal, while in another, the cases, though quite as numerous, are rarely fatal. Other things being equal, the higher the mean summer heat the more fatal will attacks of periodical fever be likely to prove. Moreover, experience has amply shown that in localities where the mean range of summer heat is only about 70°, adaptation to the environment is possible—but when, as in India, or in the West Indies, it ranges about 80° and upwards, such a thing as acclimation never occurs. (Aitken.)

In Indiana, all over the valley of the Wabash, autumnal fevers prevail to a greater extent than in any other portion of the State. In California, the coast region is comparatively exempt, while on the Sacramento and American valleys they are very prevalent (*vide* Medical Statistics United States Army 1839–54, and 1855–60; also Dr. Hatch in *N. Y. Jour-*

nal of Medicine and Collateral Sciences, July, 1854). In Illinois, periodical fevers prevail with considerable uniformity all over the State. Their grade, however, is decidedly more severe in the southern portion, and their prevalence if anything somewhat greater. In Kansas, according to Dr. Beeman (*Transactions Ohio State Med. Society*, 1870), the greatest prevalence of periodic fever is in the southeast of the State. In accordance with the table above given, he records, from personal observation, that intermittent and remittent fevers are more rife and severe there than in any portion of Ohio. But he is at a loss to account for it, as "the natural drainage of the country is among the best in the world: there are no swamps or marshes; the streams have deep, narrow channels and rapid torrents, they seldom overflow their banks; nearly all the streams have rocky bottoms; there is no stagnant water; the atmosphere is in constant and much of the time violent motion. It surely is not produced by undrained marshes, for there are none in the country. But a comparatively small part of the vegetation that grows upon the prairies is destroyed in the ordinary mode of decomposition, by far the greater portion being consumed by fire" (page 73). He then endeavors to show that the prevalence of these fevers is due to the enormous quantity of carbonic acid liberated by prairie fires—forgetting apparently the dissipating power of the strong winds, to say nothing of the atmospheric commotion produced by the fire itself. The real explanation may be found in the fact that at Fort Scott, a military post of that section, the mean diurnal oscillations for summer months, from observations made as late as 7 A.M. for the night, and 2 P.M. for the day, is 20°; the mean heat of same period being 72°.

In reference to deaths directly due to periodic fevers age has an important influence. According to the United States census, thirty-four per cent. of those dying by these fevers are under five years of age, and sixty-two per cent. under twenty years. Dr. Jones, of Toledo, writes that nearly fifty per cent. of those dying at that place of intermittent and remittent fevers are under their fifth year. Among adults the proclivity to periodic fevers does not seem to be much influenced by age. The prevailing opinion, however, seems to be, that, if anything, susceptibility decreases with advancing years.

Taking into account the early age at which the greater number die from the direct effects of the fevers in question, the influence of malaria on the duration of adult life must be estimated at a very low rate. And this corresponds with the answers received on this head from experienced practitioners in the so-called malarious districts. Dr. Patton, of the Wabash Valley, Indiana, a region famed for its periodic fevers, says, "Malaria does not shorten the duration of life to any great extent." Dr. Cutting, of the same region, says, "I think as a rule malaria shortens life but little." Dr. Russel, of Mount Vernon, Ohio, an old and highly reputable gentleman, says, "Intermittent and remittent fevers influence the duration of life very little." Dr. David Prince, of Illinois, says, "Without knowing the statistics I have the impression that we have as many old people in proportion to the population as in any other part of the world." Dr. Beach, of Madison County, Ohio, says, "Have no doubt that the average duration of life is materially lessened by this cause, but to what extent can form no definite opinion." Dr. Fitch, of Logansport, Indiana, reports, "that including all ages from infancy, the average duration of life is lessened by periodic fevers in the years when it most prevails." Dr. Jones, of Toledo,

says, "That climatic influences exercise a vast influence upon longevity all over the world, must be conceded, and more in America than in Europe, though if there was no so-called malarial disease in this country, I believe there would be nearly as many deaths, as the causes of malaria are the causes of nearly all diseases arising from the so-called 'colds.'"

A little more than a quarter of a century ago, many medical men held the opinion that the prevalence of malarial disease was antagonistic to that of phthisis. Time and a more enlarged observation has shown this opinion not only to be without foundation, but, on the contrary, that the deterioration of health wrought by this agency rather favors, if anything, the development of the disease. The statistics of deaths from consumption in this place for four years show a mortality of 18 per cent. to the deaths from all the causes, one per cent. higher than for the State at large.

Personal observation in the treatment of disease for a number of years in a locality where periodic fevers are quite rare, and then in a region where they constitute the prevailing disease, has convinced me that the influence of these diseases is prophylactic to that of some others of a more fatal character. In particular have I observed the infrequency of typhoid fever on the level plains of this State—a disease which constitutes the bane and the dread of the residents of the hilly region of Eastern Ohio. The same thing has been noted and expressed to me in many instances by non-professional persons who have removed from the latter to the former. In this place, with a population of about ten thousand, the mortuary returns for the past two years show but one death from typhoid fever; and the only case I have seen within the same period inside of the corporate limits was that of a young man who came here sick with the disease from Wheeling, Virginia. Dr. Patton and Dr. Fitch, of the Wabash Valley, report that typhoid fever is not a prevalent disease in their region, and that it may be the malarial poison antagonizes that of typhoid fever. On the other hand, it is but fair to say that other medical gentlemen of repute do not think periodic fevers exercise any prophylactic influence over the prevalence of typhoid; though, so far as my knowledge extends, they have not attempted a comparison with any region where the former does not prevail.

For obvious reasons, a comparison of the relative prevalence of typhoid in the so-called malarious and non-malarious regions, should not extend to compactly built cities; as it is well known that such civic conditions exclude periodic fevers, and serve to disseminate the typhoid miasm through numerous sewers.

Periodic fevers exercise a well-known influence in the development of some remote chronic disorders, and thus act in a manner more or less unfavorable to the prolongation of life. The effects upon the health very clearly indicate the organs upon which the weight of the derangement falls. These are the organs instrumental in the elaboration of blood. The liver, stomach, spleen and intestinal canal suffer the most; exhibiting, first, marked functional derangements which, if long continued, are likely to result in serious structural changes. Frequent attacks of extreme digestive languor; of a liver and intestinal canal acting with extreme irregularity,—now apparently entirely torpid for days together, then ejecting excretory matters with acute activity,—are very sure to result in the production of anemia, of jaundice, of debility, and more remotely of enlarged spleen and liver, or of hepatic abscess or dropsy, and more rarely of Bright's disease. Sympathetic functional derangements of the heart are also very common, such as pal-

pitiation and an interference with its normal rhythm, yet in persons of fair constitution, and not far advanced in life, nearly all these derangements are remarkably amenable to treatment. Take albuminuria as an example; it is not one of the common sequelæ of periodic fevers, yet the few fully-developed cases I have seen were of this origin, and all recovered.

The result is likely to be very different in those broken down by intemperance, or by other forms of dissipation, or in those very feebly constituted or well advanced in years. It is, however, uncommon to see in this region any of these diseases in old persons, as the sequelæ of periodic fevers, perhaps for the reason that the most of those well advanced in years have gone through the process of acclimatization. In the great majority of instances this is accomplished during the first few years of residence. After repeated attacks the health is usually fully restored, and another seizure may not occur during a residence of forty years.

Personal observation, and the evidence furnished by a very limited collection of statistics, has convinced me that of the causes of deaths arising from the more remote effects of periodic fevers, dropsy furnishes the largest number. The oft-repeated and severe alternation of function to which the liver is subject, and the anæmia arising from this and correlated conditions, favor to an eminent degree the development of ascites. In this place it causes three per cent. of the deaths; and this, too, almost exclusively among adults.

Deaths from uncomplicated diarrhœa in this region, except among children, is of very infrequent occurrence. I am unable to call to mind a single instance of it, except in those who had contracted the disease in the army during the late war of the rebellion.

It is the opinion of some, and I think on good grounds, that periodic influences sometimes affect unfavorably the course of other diseases. Take pneumonia as an example; when this complication exists to a considerable degree, there is a greater tendency than usual to sudden congestions during the inception as well as during the progress of the disease. Pneumonitis, under such circumstances, becomes peculiarly dangerous to life, and no doubt adds to its fatality, but to what extent it is not possible, in the absence of needful data for comparison, to say. A well-marked complication of this kind is not, however, so far as my observation extends, of frequent occurrence. When it does happen, it is usually only in those who have recently suffered by an attack of periodical fever, and who have not fully recovered from its effects.

From all this it appears that the weight of testimony is altogether against the view of malaria, throughout this region, at least, affecting the prolongation of life unfavorably to any great extent; and, moreover, the statistics bearing upon this unfavorable influence show that it is more potent during infancy than any other period of life.

In reference to the influence of the sequelæ of periodic fevers upon longevity, their importance, though decided, should not be overrated. Their hurtful tendencies upon organic life, when severe, prolonged and oft-repeated, are unquestionable. Yet, even then, with youth, correct habits, and judicious treatment, every apparent vestige of these effects will vanish, and the subject never afterwards exhibit a trace of them in a long life, not even in the mode of dying. The result will be likely to prove different in those of frail constitution, past middle life, or in those predisposed to pulmonary consumption. Recuperative power is then lacking, and the prostrating effects

may be apparent for years. The signs by which this state of the system is denoted are important: a pale, dingy-colored face, thin or flabby flesh, tongue paler than natural and never wholly free from coating, abdomen usually tumid, urine charged with bile, appetite capricious, and the action of the bowels irregular. Such results, arising from prolonged attacks of periodical fever, are, however, comparatively rare or exceptional in this region. When they do occur, and under the conditions above specified, a life-risk should be deemed hazardous.

Aside from these effects, as the result of long-continued and profound functional derangement, the so-called malarial influence does not seem to exercise any pernicious influence upon life. The supposition that there may be in it an occult power in bringing on other diseases of a dangerous character, either of the lungs, liver, or bowels, without manifesting or ever having manifested itself in its characteristic way, viz., by a well marked periodicity of the morbid symptoms, does not appear to rest upon any other than hypothetical considerations. On the hypothesis that the so-called malaria is a poison, an entity, not a condition, it may be supposed to play a part in nearly all the diseases of the Mississippi Valley. Of the truth or falsity of this assumption there is a test which may well be termed an *experimentum crucis*. On all forms of malarial influence, or more properly on all kinds of periodical disorders, the administration of quinine acts in the happiest manner in the removal of the morbid symptoms. When its therapeutical influence is not decided, or when its proper and timely administration does not immediately arrest a disorder, save in cases of exceptional severity, it may be safely affirmed that the cause is not malarious. The production of a perceptible toning effect is not sufficient evidence of that condition, for this may be seen in the enfeebling stage of any disease everywhere. There must be an immediate and remarkable impression on the violence, if not a total arrest, of the malady for which it is given. The narration in a few words of two typical instances may make the distinction plainer. A wholesale merchant, of fair constitution, though pale and liable to glandular irritation of the fauces, was suddenly taken with sore-throat and a large glandular swelling under the left ear. The swelling of the sub-maxillary glands was great, and after endeavoring to dissipate it two or three times with iodine, with apparent success, the enlargement would obstinately reappear, and on each reappearance looked worse than ever; so that supuration at last seemed inevitable. With this view poultices were ordered, resolution again occurred, and recovery seemed as complete as it had been two or three times before, but again the swelling returned. The friends attributed the reappearance to exposure, but I at last discovered that the intumescence made its appearance at regular intervals on every third day. Quinine was immediately prescribed, and the disease disappeared as if by magic, permanently. A middle-aged man, who had frequently suffered with ague, was taken during the winter season with a decided chill. He immediately procured quinine, thinking it an ague, and as soon as he felt a little better took twelve grains in appropriate doses. On the day succeeding he was worse than ever. Examination revealed his ailment to be organic, which was promptly removed by appropriate treatment of another kind. There is scarcely a week in which I do not meet with similar cases, some one who has been taking quinine for days on his own responsibility, thinking he has an ague, without benefit, nay with injury.

In this way experience reiteratingly inculcates that unless a disease manifests periodicity, the so-called malaria in the system has no more to do with its existence in the Mississippi Valley than with the existence of a like disease on the Grampian Hills.

In attributing so little importance to malaria upon longevity, there may appear to those not practically familiar with all the facts in the case, a staggering inconsistency. How is it that a form of disorder can be so common as to be termed the prevailing disease, and yet not prove highly inimical to life? To my mind there can be but one answer to the question, and that is—not that there is any antagonism of the cause of periodic fevers to other diseases, but that the eliminative struggles of nature in an attack of this fever result in correcting some latent derangement and expelling some latent product from the body, which, if not thus got rid of, would continue to augment and at last culminate in some form of disease far more dangerous to life.

MORTALITY AT SEA IN 1873.*

THE return relative to the deaths of seamen in the British Merchant Service during the year 1873 has just been issued. It applies to the 292,239 seamen in British registered ships of the United Kingdom, exclusive of river steamers, so far as their deaths take place out of the United Kingdom, so that it does not include passengers nor masters, nor those who are landed at home in a dying state or return from sea. Therefore, as regards disease, this return does not enable any reliable comparison to be made with the mortality in any other section of the population. This will be evident when we state that whereas the death-rate from disease under medical care in the Royal Navy in 1872 was 6.05 per 1000, that registered in the mercantile marine out of the United Kingdom, without medical aid, is only 8.41 per 1000; the fact being that under the continuous service system in the Queen's service sick and dying men are, on arrival in England, discharged to the naval hospitals and their deaths included in the mortality returns. We have, then, no hesitation in affirming that the death-rate from disease amongst merchant seamen is probably double that which appears on the face of these returns. We must also raise our voice against the delusion that any reliance can be placed upon the forty subdivisions of diseases under which these fatalities are grouped, so long as the diagnosis is in each case determined by the mate or the master of the ship, without any subsequent medical inquiry into the symptoms and treatment on which that determination is based. The fact of death is only known at all because the Board of Trade, with commendable care, administers to the wages and clothes of deceased seamen; and the Board is concerned alone with the fact, not with the cause of death. It is a pity that the return does not confine itself to fact, as the guesses made by mates and masters about the disease are utterly illusory.

No such observation obtains as to the violent death-rate, as mortality from accidents is not so largely affected by its ultimation occurring within the United Kingdom, and so being excluded from the return. We may fairly assume that most of the deaths by accident, being of a sudden character, are likely to result on the high seas where the occurrence takes place, and will therefore appear in this return. As no medical inquiry ascertains the cause of such deaths as are

supposed to result from disease, so no legal investigation by coroner or otherwise follows upon suspicious or sudden deaths at sea. During twenty years no person has been put on his trial for causing a death at sea otherwise than by red-handed murder. But if murder may be inquired into and punished, why not manslaughter, negligence, carelessness, and other preventable causes? Mark the effect of the absence of all inquiry in deaths by violence in 1873—a year when a Royal Commission was sitting, the Board of Trade being badgered on all sides, and Mr. Plimsoll appealing to popular indignation. In that year 1000 more seamen were drowned than in the preceding one, though 1481 less men were employed; 17.58 merchant seamen per 1000 were killed or drowned for every landsman per 1000 in the home population killed by accident, or for every 24 men-of-war's men per 1000. For every merchant seaman who died by disease out of the United Kingdom two others were drowned. Had the death-rate per 1000 of the Royal Navy in 1872 obtained in the mercantile marine last year, 2231 men drowned by shipwreck, 794 of those who were washed overboard or otherwise drowned, and 75 of those who were killed by other accidents, out of a total "accidental" death-list of 3554, would have been now alive. Instead of a total mortality of 5393 men, or 26.67 per 1000, we should have had only 1717 deaths, or 8.5 per 1000, and this notwithstanding that the former rate does not include mortality after arrival and discharge in the United Kingdom, whilst the latter does include it.

With whatever this violent death-rate be compared, it shows a vast waste of human life. That a great deal of this vital waste is quite beyond the natural risks of the sea, and is easily preventable, seems, in the absence of any legal inquiry, to be a reasonable conjecture. Before anything can be done to stop this vast accession of drownings, a coroner must inquire, in each individual case, according to the old sea law, "whoe killed him, and unto whom the ship did belong." In the face of the following table, may we not ask, "Is there not a cause" for such inquiry?

MORTALITY OF THE BRITISH MERCHANT SERVICE OUT OF THE UNITED KINGDOM.

Supposed Cause of Death. (292,239 men employed.)	As it was in 1873.		As it would have been if same ratio as Royal Navy in 1872.

"THE MEDICAL RECORD is disposed to find fault with the Southern Life Insurance Convention at Bath Alum, for only partially adopting the report of the Committee on Medical Blanks and Examiners. Under the caption of "Half-way Measures," it complains of failure to improve the opportunity for the accomplish-

* From "The Lancet" of May, 1874.

* Including deaths in the United Kingdom.

† Including gun exercise and action.

ment of the more important reforms in the medical department which are so clearly indicated in the report. It arraigns the members of the convention, because, as it asserts, "it was voted not to lay the axe to the root of the present unsafe and demoralizing system of appointing examiners, but simply to surround it by one or two additional safeguards. The falling of the old tree might stir up a rebellious spirit among the agents of the old régime, and the officers of the various companies hardly cared to face this disturbance in the camp."

As it was purposely to face such "disturbances," and all other disturbing elements, that the gentlemen composing the convention assembled together, such an allegation or such an intimation of want of pluck is altogether unfair and unjust. The assemblage was convened rather for preliminary consultation, having in view a permanent organization, and for deliberate and well considered action, not for hasty measures at the outset, and certainly not for "half-way" measures in the end. The action complained of was merely temporary, no one concerned having an idea that anything beyond partial acceptance of the report was desirable or practicable in the absence of the fuller and more extended facts and particulars which, it was expected, would be furnished in the future. Besides, there were but two medical representatives in attendance, and it was but fair to the non-represented companies that their voice should be heard before the final adjustment of such delicate and all-important questions. The first three sections of the report were not, in effect, or in point of fact, rejected; they were simply postponed for further report, and for more intelligent action than the members at the start were prepared to bestow.

It is also complained that the committee did not "improve the opportunity at their command to present to the convention for study, amendment, and eventual adoption, a uniform list of questions for the medical examiner to answer," the *Record* adding the remark, which nobody will deny, that "it is a source of considerable annoyance to a physician who examines for several companies to fill in correctly so many different forms of blanks, and, on the other hand, there is no good reason why the companies should not all make use of the same style of blank." This is so palpably true that the members of the convention interchanged their blanks for future comparison, and with a view to that eventual assimilation and uniformity which is so desirable. If the *Record*, or if any medical authority will indicate, in advance of their action, a form of blank so manifestly clear, simple, comprehensive, and beyond criticism that all can promptly agree upon it, that action will be materially hastened. In northern and western companies the best forms of questioning by the examiner have found imitators and copyists, but no general movement, even in the Chamber of Life Insurance, has yet been made for the adoption of a common, uniform list of questions.—*Baltimore Underwriter*.

Miscellaneous.

"DIRECTIONS FOR THE EXAMINATION OF URINE."—Prof. Austin Flint, jr., of this city, has recently published an excellent little pamphlet entitled "Directions for the Examination of Urine of Applicants for Life-Insurance." Although the book was written expressly for those who make examinations for life-insurance companies it is one that very many practitioners

will be glad to keep upon their office table. It contains in a nutshell all that is essential to a proper knowledge of these chemical manipulations.

While we can hardly agree with those who advocate the practice of examining the urine of every applicant for life-insurance, we certainly think that the companies would avoid not a few bad risks were they to insist upon such an examination in the case of all applicants who have reached their fiftieth, or perhaps even their forty-fifth year.

If we are correctly informed, it has been for some time past the custom with one of the New England life insurance companies to require an examination of the urine in quite a large proportion of the applicants for policies. It would be very interesting to know how successful they have been in carrying out the plan, and what have been the real difficulties in the way of its accomplishment.

INCREASE OF INSANITY IN ENGLAND.—In a very interesting paper on this subject, T. Harrington Tuke, the President of the Psychological Association, makes the following statements: In the recent report of the Commissioners of Lunacy, tending to show that a great wave of insanity is slowly advancing, various reasons have been suggested to explain this increase, among which the following are worthy of mention:

It has been assumed that the congregation of large bodies of workmen in towns and cities, the confinement arising from the nature of their toil, and the restriction of their space have given us a degenerate population, subject to mental disease. But this is not altogether so. Such causes would induce idiocy in children and diminish the average duration of human life, but would not necessarily induce insanity in men of mature years. Moreover, it is by no means certain that the inhabitants of the crowded city are more prone to mental disorders than the inhabitants of agricultural districts.

The emigration of the adult population, which has been steadily increasing during the last half century, may also have had some influence upon these returns, but it cannot be a great one. If emigration takes to other and kindred shores some of the finest of our peasantry, the best of our workmen, it also fortunately tempts the unstable, the enthusiastic, the adventurous, the disappointed who, perhaps, remaining here, fretful and despairing, would have swollen the number of insane.

The hypothesis has been advanced that the progress of civilization and the spread of education among the masses have, with a greater activity of brain, produced a corresponding increase of nervous exhaustion and disease. This is a melancholy theory; it would unsettle our belief in the onward progress of mankind; it would shake the very foundation of our faith. Such a theory receives no support from statistics. If intellectual training and mental exertion were causes of insanity, then it should be more frequent in those ranks in which, during the last half century, the mental powers have been so much more cultivated and exercised. The statistics of lunacy show, on the contrary, that the increase of insanity has been amongst the poorer classes only. This increase has been notably great during the last two years. I fear the explanation is to be found in higher wages, and the consequent means of undue indulgence. But there is another aspect to this view. It may be that the inexorable laws of supply and demand, while giving more than due wages to some of the working class, plunge others into dire distress, which in time saps their strength, both physically and mentally, and ultimately makes them denizens of the madhouse.—*Baltimore Underwriter*.

Original Lectures.

FISTULA IN ANO.

A CLINICAL LECTURE

BY ERSKINE MASON, M.D.,

ASSISTANT PROF. SURGERY IN THE UNIVERSITY COLLEGE AT CHARITY HOSPITAL.

TO-DAY, gentlemen, I shall call your attention to another variety of rectal disease, associated with hemorrhoids, viz.: *fistula* and *fissure* of the anus. First we will say a few words in reference to *fistula* in ano, and then we shall examine and operate upon this patient before you, who has for some time suffered from a variety of this disease; and afterwards you will be shown two other patients who, though the subjects of *fistula*, will enable me to demonstrate to you the other varieties of this condition. You will find that among the diseases of the rectum, *fistula* is one that is exceedingly frequent; and you may see it both in the young infant and the old man, but observed oftener in the male than the female. The earliest age which it has occurred to me to observe this affection was in a child eighteen months old, and in whom it had been known to have existed for six months. It was an example of what I shall presently describe to you as a complete *fistula*, half an inch in length, and situated posteriorly towards the coccyx. I have often seen it in this hospital in very old men, but their ages I am unable to give you. With respect to its frequency, it has been said by a recent writer, to be the most common of rectal diseases which are observed in the adult; and the data for this statement is taken from the case-books of a hospital specially devoted to the treatment of rectal diseases. In general practice, however, I take it that you will see and hear more of hemorrhoids than the one which we shall study to-day. In considering *fistulas* we have also to speak of abscesses, for the *fistula* may be said to be but the result of abscess. Now, what are the exciting causes of this trouble? They may result from what we are obliged, through ignorance, to call "taking cold." Thus a person, as a result of sitting down upon a cold or damp stone while overheated, has an inflammation set up in the anular tissue immediately around the verge of the anus, or else in the locality which you know as the ischio-rectal fossa, and as a consequence of this, its termination may be abscess and *fistula*. Should you chance to see this trouble in its earlier stage, you would only notice the tissues in these localities, perhaps a little indurated or brawny, and painful to the touch, or else you might observe the parts presenting the appearance of a boil; which, after the discharge of pus, will often leave behind a permanent fistulous track, unless relieved by art. The reason of these fistulous tracks being so loath to heal of themselves, I think is often chiefly due to the mobility of the tissue in this neighborhood, though where there is a communication with the bowels, the presence of fecal matter is alone sufficient to keep the parts from healing. Another exciting cause is a traumatic one, viz.: the wounding of the mucous membrane of the bowels, either from fish-bones or some other hard substance that has been swallowed with the food, and as a proof of this, these bodies have been found in the abscesses that have formed outside the bowel. The most frequent cause I believe to be the passage of hardened feces, especially in those who are the subjects of internal hemorrhoids, and have to strain violently at stool. In proof of this I think you

will often find that the internal orifice of these *fistulas* is often situated just at the upper part of the base of a hemorrhoidal tissue (and may indeed be caused even by one of these pendulous tissues), and, again, the mucous membrane, just in this situation, is often very much thinned by constant tension exerted by these tissues, which often present a considerable obstruction to the free movement of the bowels. The lacerated wounds thus made in the internal coats, set up a cellulitis which passes into the suppurative stage, and hence abscess and *fistula* result.

Again, the bowels may not be actually wounded, but the passage of these harder masses may be sufficient to set up inflammation in some of the follicles of the intestine, which gives rise to an ulcer which perforates the bowels, and the result is the same as in the former case. This condition is the one which probably takes place in those constitutions which have been vitiated from disease, and hence, perhaps the cause that *fistula* may be so often (if looked for) observed in those who are suffering from phthisis. Let this suffice then for some of the causes.

Now, gentlemen, from some remarks I have just made, I by no means wish you to infer, that every induration or boil that you may see in the neighborhood of the anus is certainly going to give rise to *fistula*. The tendency that way, it is true, is very great, and may indeed so result, in spite of surgical aid, yet, on the other hand, timely treatment, such as warm fomentations to the parts, or when pus is present, free incision, so as to give ready exit to matter, and then rest and attention to the parts, may spare a patient from the unpleasant result of *fistula*.

I said I would show you some varieties of *fistula* to-day. Here, for example, is a man who for some time has had what we term a complete *fistula*, and upon whom we shall presently operate. By the term complete, we mean one that has not only an external opening, but also an opening into the bowels. Thus you see I readily pass this silver probe through the external opening and along the fistulous track for nearly an inch, and on turning the probe you see it has passed out of the anus. Now, very many *fistulae*, which upon first examination may appear to you incomplete, I feel sure, if you use a little care, and do not seek for another opening too high up the bowel, you will find to be really as complete as the one you have just seen. But in the case of this woman now upon the table, I feel sure that this is not the case. Here you perceive a small opening from which flows a drop of pus: taking this same probe I pass it into the opening, and you see it passes up along the side of the bowel, perhaps as far as in the other case. Now introducing the index finger of my left hand into the bowel, I feel the probe distinctly through the coats of the intestine, but after careful examination no communication with the bowel is detected. This, then, is a variety of incomplete *fistula*, and we call it a blind external *fistula*, because it has no internal opening.

While this patient is on the table we shall proceed to operate at once, for fear her courage should fail her at a subsequent time. The operation will consist in first converting this into a complete variety, and I do this by passing a director through the *fistula*, and when it has reached the end of the *fistula* I turn it and thrust it into the bowel, taking care at the same time not to wound my finger which is in the bowel. Now by raising up the end of the probe in my hand I cause its point to pass out of the bowel; if the patient will strain down this manœuvre will be facilitated. Now I pass this sharp-pointed bistoury along the groove of the director, and cut through all the tissues which bridge

over the director, and the fistula is now laid open. After this is done you had better search with the probe to see if perchance there is any fistulous track extending above, that you have not opened up. Should you find one you had better proceed at once to lay it open, else your operation may not prove a radical success. If the edges of the fistula, after laying it open, show a tendency to curve in, it will be beneficial to trim them off with the scissors, else they may offer a serious obstacle to the wound healing from the bottom. The after treatment will consist in placing a small piece of lint in the bottom of the wound, and this will be changed from time to time; and each time as soon as granulations show themselves, which will be in a few days, the size of the lint will be diminished. The method that is pursued by some of packing the wound with a large quantity of lint, I believe, accomplishes no good, and certainly is a source of great annoyance to the patient, giving rise, as it does, to tenesmus and straining to extrude this foreign body. A pad of dry lint and T bandage, such as you saw me use after operating on piles, will afford considerable relief to the pain that follows the first four hours after the operation. The patient will now be placed in bed, and the bowels kept confined for a day or two. After the fistula begins to fill up, you may allow your patient to sit up or lie upon a lounge. If you let them move about the room, union is greatly delayed. In about two weeks, such a fistula as the one just operated on, will, as a rule, have healed. Should at any time the wound appear indolent, you treat it by stimulating applications, as the balsam of Peru, or a mild solution of carbolic acid, or the black wash; the balsam of Peru is the one most frequently used in this hospital. In the majority of cases I do not think any of these will be required. The sooner a fistula heals after the operation the better; should they be sluggish in this respect, you must not only pay attention to the general health of the patient, but examine carefully the fistula, and see that the pus has not burrowed, thus giving rise to other fistulous tracks. If, after your patient has been going about, he complains of pus coming from the bowel in any considerable quantity; examine carefully for such fistulous track that has not healed: if you find it lay it open at once, and keep him quiet till it has thoroughly healed. You will perhaps hear of patients that after having had a fistula cut, have afterwards never fully regained the power over their sphincter, and as a result have suffered more or less from incontinence of pus. Fortunately this is a rare accident, and must probably be due to a careless and rash mode of operating, as in making, unnecessarily, a too free division of the whole sphincter muscle in more than one place at the same time, and perhaps in carrying your incision too far backwards into the surrounding tissues towards the buttock, or else it may be due to improper or entire neglect of after treatment, and this may be as much due to fault on the part of the patient as on that of the surgeon.

From what I have seen I would advise you, should you meet with a case of fistula having two external openings, one on either side of the bowel, not to divide the sphincter freely on both sides at the same time; you had better make two operations if necessary rather than run the risk of destroying or so weakening the sphincter as to leave your patient in a condition worse than before. This fact was very strongly impressed upon my mind by the case of a lady whom, a year ago, I was called to take care of. I found her in a most deplorable condition, having no control over feces or flatus; she had been operated upon five months before for "two fistulae." I found the sphincter had been completely divided on opposite sides, and the in-

cision on both sides carried far outwards towards the buttocks, and the anus gaping wide open. The operator (for I will not call him a surgeon) had left the case without any appropriate treatment, and the result was what I have just stated. By means of paring the edges of one of these large holes, which was the result of his operation, and retaining them together by silver suture, union took place, and she was thus enabled to have great control over her motions, and go about with considerable comfort.

I shall speak further on in reference to other modes of treatment that are practised, besides the one with the knife; at present I wish to refer to some other forms of fistula, while a patient is being placed under ether. There is another form of incomplete fistula, viz., blind internal, because it has no external opening, only an opening communicating with the bowel. I shall not do much more to-day than briefly refer to it, as I have no case of the kind to show you. Without care on your part this fistula may pass undetected. It is not of very frequent occurrence, but when present is a very painful one at times, and the symptoms are often very like those attendant upon fissure (a disease I will at some time show you, and make some remarks about). The opening of this fistula in the bowel is at times very large, thus allowing of ready ingress of fecal matter, which induces its painful train of symptoms, and with the finger in the bowel you may often feel its indurated track. In operating upon these fistulas you have to pass a probe or director, curved so as to enter the opening and pass down the side of the bowel; when its point is felt beneath the skin you cut down upon it with your knife, thus converting it into a complete fistula. The operation is then completed as in the case you have just seen.

These fistulas, if left to themselves, will often become complete, but in so doing, if the process is not rapid, considerable tissue may become undermined in the attempt. From what has already been said you will understand that many of the complete variety you see originally began as an incomplete or blind internal fistula. There is still another form which has been spoken of by some as the horse-shoe fistula. It has but one external opening, and perhaps at first sight appears simply as an ordinary complete fistula; but upon laying it open you will find, by means of the probe, several fistulous tracks starting from this old fistula (if I may so call it), and passing in different directions, so as perhaps to completely encircle the bowels. In these cases, after laying open the main track, these tributaries, so to speak, will have to be opened up before a complete cure will result, and this may be done without cutting the sphincter muscle too extensively, for many of these fistulous tracks pass just beneath the mucous membrane; at least I have found it so. While speaking of laying open these sinuses I must tell you that the profession is divided somewhat upon the question—whether it be essential to lay open a fistulous track which extends beyond the internal opening? If this is not done, I know from experience that a perfect cure may result, and I also know from experience that the reverse of this will at times follow, necessitating a further operation. If the entire length of the fistulous track can with safety be laid open, I believe it the best plan to be pursued. Yet I have seen cases where I have deemed such a proceeding hazardous for fear of hemorrhage that would be difficult to control, so high up the bowel did the sinus extend beyond the internal opening. These cases will have to be dealt with, as each individual case may seem to the surgeon to demand.

No one rule, I think, can be laid down that will apply to all such cases with safety. In seeking for the internal opening of a fistula, where shall we look for it? This very point, let me tell you, has been the subject of considerable investigation and controversy, some contending that it was just within the anus, others that it was an inch or more above the anus. I shall not refer to this matter further than to say that I think you should seek for it about half an inch from the anus, and in the majority of cases it will be found in about that situation, often, indeed, it may be more superficial, and because it may be so superficial it is not to be neglected, but to be operated upon just as well as if it extended two inches up the bowel. In examining if the fistulous track extend higher up than the internal opening, you must hold your probe very lightly, for it will be a very easy matter to run the probe up the surrounding tissues or between the coats of the bowel, thus giving the impression of an extensive fistulous track, where in reality none exists. I will now show you in the person of this woman, who is very much run down from prolonged suppuration, several fistulae, all of which communicate with the rectum. Her history is briefly this. Some months ago she had a large abscess in the ischio-rectal fossa, which, after long suffering, broke externally. At present you will notice a fistulous opening by the side of the anus, and the probe can be passed through this either into the bowel, as you now see, or else, by turning it outwards, it enters the ischio-rectal fossa. On the left side, about the middle of the labia, is another fistulous opening, which leads into the bowel just at the point of opening of the other sinus, and lately another opening has appeared in the left groin, and I doubt not, like all these sinuses, communicate with the ischio-rectal fossa, as the probe passes down through the abductor muscles. The probe passed through the opening by the side of the labia can also be passed downwards and backwards thus, until it is arrested by the tuberosity of the ischium, which is discovered to be increased. All this condition is the result of a neglected abscess in the ischio-rectal space, and from the history she gives is a result of gonorrhoea and a large chancreoid, followed by cellulitis in this immediate vicinity. The abscess in the ischio-rectal fossa has been freely opened and is washed out with carbolic acid lotion. Her general condition, as you see, is very bad, but under stimulants and a better diet than she has been accustomed to, she has greatly improved since she entered the hospital. At present, however, she is in no condition for any further remedial operation. I only present the case to you that you may see some other situations where fistulae communicating with the rectum and this fossa may open, other than I have just spoken of.

The diagnosis of fistula is usually easy, and the method of detecting to which variety it belongs, you have already seen. You must bear in mind that we have fistula in the neighborhood of the anus, which, however, are not rectal, but urinary; these latter, however, are very characteristic; usually they are of a rose color, elevated, with a small depression in the centre, and though they may exude a drop of pus, the discharge is chiefly fluid, and of urinous odor, and the discharge takes place during or just after the act of micturition. The direction which a probe introduced into them will take, together with the general history of the case, should suffice to prevent you from falling into error in your diagnosis. Patients who come to you with fistula will often only complain of hemorrhoids, and give you the symptoms that I have already given you when speaking of that affec-

tion. Indeed, they may only become acquainted with the fact that they are the subject of fistula from your examination. On the other hand, they may give you the symptoms of having suffered from an abscess in this vicinity, and complain of their clothing being soiled from a purulent or fecal discharge, which condition may be more or less constant. In examining a patient with hemorrhoids it is always well to seek carefully whether or no fistula does not also exist, and if you are not careful in those examinations, a small fistula may escape your attention. *Is there any choice as to time of operating?* If you propose to operate at all, the sooner after the discovery of the fistula, I think, the better, except it be just after an abscess has been opened and the parts are inflamed; here we should prefer to delay till the acute symptoms have subsided, and we have only a fistulous track to deal with. Fistulae that are met with in connection with stricture of the bowel, of course you should not think of interfering with before you have relieved the stricture, for before this your operation could confer no benefit upon your patient. In your text-books you will find much in reference to operating upon patients the subject of phthisis. We have not time now but to refer to this point. My own views are that this idea has been carried to an extreme by many. If a patient have some deposit in his lungs, and his general condition be quite fair, and yet suffers from a troublesome fistula, I see no reason why you should withhold relief from him. If he be far advanced in tuberculous disease, you would of course not think of operating for fistula, or for any other cause hazarding an operation. You have now seen two operations by means of the knife, but I must refer to other modes that have been in vogue, and are still in some instances practised. Before enumerating these, I should tell you that you may see cases that get well without any treatment, or at least you will read of them in the books; but this is very, very far from being the rule. Formerly, caustics were freely used for the purpose of destroying fistulae; this now is abandoned, unless we make an exception to the practice used at times of injecting the sinus with stimulating fluids, such as tincture of iodine, nitrate of silver, sulphate of copper, etc. These, though not very reliable, may prove of service in some superficial varieties. The ligature applied, as I now show you, has been often resorted to, and in those who are timid of the knife, or will not lay up for a few days, it can be used with every prospect of success. Its great objections are, that it is not only a more painful method, the ligature having to be tightened from time to time in some cases, the length of time that may elapse before the ligature cuts through, and the uncleanness necessarily attendant upon it. Certainly, of all methods which have been used, the one by the knife is the most satisfactory in every respect, and therefore, when possible, should be the one you select.

TREATMENT OF SPASMODIC ASTHMA.—Dr. Julio J. Lamadrid recommends the combination of chloral hydrate with the bromide of potassium in the treatment of spasmodic asthma. The following is the formula which he employs;

R Chloral hydrat. 3 v.
Potassi bromide. ʒ iiss.
Syr. flor. aurantii,
Aque dest., aa. f. ʒ i. M.

Sig. A teaspoonful in half a wineglass of water every two hours, until sleep is induced or dyspnoea is relieved.—*Phila. Med. Times*, Aug. 29, 1874.

NOTES UPON CASES

PRESENTED AT THE

CLINIQUE FOR DISEASES OF WOMEN,

HELD AT THE COLLEGE OF PHYSICIANS
AND SURGEONS.

By T. GAILLARD THOMAS, M.D.,

PROF. OF OBSTETRICS AND DISEASES OF WOMEN.

PELVIC HÆMATOCELE.

Mrs. S—, æt. 36; been married 10 years, but has never been pregnant.

History.—Menstruation ceased in January, 1873. This was followed by headache, "pains all over the body," and general discomfort.

In March, 1873, she was taken suddenly ill. She suffered at that time "from pains through the whole body." On some days she was able to attend to her avocations, and on others was confined to bed. She gradually grew worse from day to day, and in May, 1873, was taken very suddenly worse while lying in bed. She was suddenly seized with violent pain in the abdomen, and had a sudden sense of prostration and weakness. She continued ill until June, 1873, when she had sufficiently recovered to be able to get out of bed. The pain which suddenly seized her in May was terribly severe, extended over the entire abdomen, but was not accompanied by any discharge from the vagina.

November, 1873, menstruates regularly.

Physical Examination.—Uterus of normal size. Fibrous tumor upon one side. Nothing specially noticeable about the tumor. The tumor has probably been connected with the uterus for a long time, and is the probable cause of the sterility. It is a sufficient cause at least, and we accept it.

The question arises, What has been the probable history of this case viewed pathologically?

It is probable that, from some cause, there was violent ovarian congestion last January. A result of that congestion was an arrest of a flow of blood when there should be a regular hemorrhage. When she was seized last May in the violent manner she describes, she was seen by one of the gentlemen connected with the clinique, who found upon physical examination that there was a large rounded tumor in the pelvis, which had a hard, fibrous feel, and completely surrounded both the uterus and the uterine fibroid we have found to-day.

In July this large mass was being absorbed quite rapidly, and to-day there is no trace of it remaining.

That large rounded mass was in all probability a pelvic hæmatocele.

The necessary examinations were made at that time to render diagnosis positive.

These are the facts which present themselves in connection with this case.

There was a general disordered condition of the ovaries, which continued until rupture of blood-vessels took place, and a large hard tumor was developed, accompanied with great constitutional disturbance. This tumor gradually became absorbed and passed entirely away.

The fibrous tumor remains, and has not in the least been interfered with.

There is one point in this case which is of special interest, and that is, the case illustrates the liability of a

practitioner's being deceived with regard to the effects of remedies in the treatment of uterine fibroids. The condition of this hard fibrous feeling mass in the pelvis was, last May or June, such as might have been easily mistaken for a fibrous tumor of large size. If such a diagnosis had been made by one who believed that iodide or bromide of potassium has the power to diminish the size of uterine fibroids, it would have been claimed that here was an example of reduction in size of a fibroid tumor by the administration of those remedies.

"False facts," says one of the old writers, "are more dangerous even than false theories."

The condition of the patient to-day is simply that which requires supporting treatment.

CASE II.—PELVIC HÆMATOCELE.

Mrs. X—, æt. 23, and the mother of one child.

History.—She was perfectly well until two months ago, when she was taken suddenly sick at the stomach. Nausea has continued from that time until the present without very much diminution. Two weeks ago she became suddenly faint, and remained unconscious for some time. When consciousness was restored, she felt very weak, but was able, within a short time, to walk home, which was only a short distance away. Since then she has lain in the bed some of the time, and other portions of the time has been up and about the room. Has fever occasionally. Pulse and temperature about normal. Has severe pain in both sides and severe backache. These pains are almost continuous.

This completes the history of this case.

Physical Examination.—Patient lying upon the back. Vaginal touch shows cervix uteri thrown forward. Vaginal junction is firmly pressed out by a hard mass, which, at the same time, presses against and closes the rectum. By the aid of conjoined manipulation it is found that this mass fills Douglas's cul-de-sac, is immovable, and is not sensitive to the touch.

The question arises, What is this mass? The history of the case indicates that there was, at a certain time, a sudden loss of blood. Physical examination detects the presence of a smooth mass in the pelvic cavity which, by its mechanical presence, interferes more or less with the viscera of that cavity; and these two facts have led us to the conclusion that it is a pelvic hæmatocele.

Treatment.—In the present case the indications are such as will lead to the administration of quinine, iron, good nourishment, eminently a supporting plan of treatment, and rigidly to insist upon rest.

Here the question may arise, Cannot something beneficial be done for this class of cases by surgical interference and removal of the blood?

One case fell under my observation where the hæmatocele burst, and caused the death of the patient. The question in that case was, Might not the life of the patient have been saved if puncture had been resorted to?

Another case came under my observation, in which the aspirator was used, and the blood removed. At the time of the operation the patient was doing well, but in the light of the other case, some anxiety was felt lest the same termination might take place. The operation was performed and the patient died. The question in the second case was, Might not the life of the patient have been saved, if the operation had been avoided?

These two cases are selected simply as illustrative of the position in which we find ourselves placed relative to the question of surgical interference.

It is to me very often a most perplexing question, and one which I decide with great hesitancy.

If called to see one of these cases at the outset, measures should be adopted to bring about reaction; keep the patient perfectly quiet in bed. Empty the bladder with the catheter, and bowels with enemata if necessary. Soothe with opiates.

After some weeks have elapsed, counter-irritation by means of repeated blisters may be serviceable.

CASE III.—POLYPOID ELONGATION OF THE CERVIX.

Mrs. H—, æt. 30; widow, and the mother of one child.

History.—Perfectly well up to July, 1873. At that time she began to suffer from discharge of blood from the vagina, which has continued almost steadily until the present time (November).

The copious loss of blood is the chief symptom of which this patient complains, and it is for the purpose of obtaining relief from this that she comes here.

A great number of hæmostatics might be administered to this woman, with the view of arresting "uterine hemorrhage," "menorrhagia" or "metrorrhagia," etc.; but, when the results of physical examination are shown you, it will become evident that their administration alone would be a very great departure from a rational method of treatment.

Physical Examination.—I have seen only three cases of this kind.

There is a pendulous mass hanging down in the vagina which is connected with the cervix uteri.

The finger can be swept around the cervix, and there is an evident continuous connection between this pendulous mass and the cervix, except at one portion of its circumference. At that point, there is an opening. Introduction of the sound proves this opening to be the mouth of the uterus, for the instrument can readily be carried on into the cavity of the organ. The condition is one of polypoid elongation of about three-fourths of the cervix, leaving the remaining portion of the cervix and the os nearly in their normal position.

There is, therefore, a long tumor in the vagina; its upper portion consisting of the cervix uteri; its lower portion consisting of a prolongation of about three-fourths of the cervix uteri, and, upon its side, at the junction of the prolongation and the cervix proper, is an opening which is the os uteri. This tumor has never been within the cavity of the uterus, but arose from hypertrophic disease of the cervix.

Treatment.—The mass should be removed at once, for the woman is losing blood very fast in consequence of its presence. The tumor is exceedingly vascular, bleeding upon the slightest touch. It should be removed by means of the galvanic canter if the apparatus were at hand. That would do away with the necessity of taking the precautions for controlling hemorrhage which we feel compelled to take while the tumor is removed by means of the *écraseur*.

To guard against the occurrence of troublesome hemorrhage, the tumor will be drawn down far enough to permit us to cut a narrow groove around the base of the tumor for the reception of a strong ligature.

This ligature will be applied by transfixing the pedicle with a curved needle armed with a double ligature, and then tying each half separately. The ligature, at present, will be tied only sufficiently tight to retain it in the groove. We now have a means at our command which places any hemorrhage that may occur, either at the time of the operation or subsequently, within ready control.

A second girdle is made around the neck of the

tumor, just below the first, for the reception of the chain of the *écraseur*. (The tumor was then removed.)

The greatest care must be exercised in controlling any hemorrhage which may occur from such a stump as this one, for the reason that, after it has been permitted to recede into the pelvic cavity, it would be more difficult to gain access to it for the purpose of applying ligatures to the bleeding vessels. See to it well that all hemorrhage is arrested before releasing the stump from your grasp.

A bat of cotton, wet in a solution consisting of one part Liq. Ferri. Subsulphate and two of glycerine, is now placed against the stump and followed by a moderate tampon of dry cotton.

The ligature, thrown about the pedicle as a safeguard, can be removed within forty-eight hours after the operation if no hemorrhage occurs. If hemorrhage does occur, the ligature can readily be made tighter, placing the hemorrhage under control at once.

CASE IV.—PROCIDENTIA UTERI IN A VIRGIN.

Mrs. C—, æt. 25; married, and the mother of one child sixteen months old.

History.—Has been troubled with her present difficulty eight years altogether. When seventeen years of age, she lifted a heavy weight, a large tub of water, and while lifting it she "felt something give way within her," and has never been well since. Soon after, she could feel her womb come outside of her body. "Every once in a while," since she lifted the tub of water she has felt her womb outside of her body.

Physical Examination.—The uterus is now outside of her body. If the cavity of the organ is measured, without being replaced, it is found to measure, from the external orifice of the os to the fundus, five inches. When the uterus is replaced, and its cavity measured, it is found to measure only three inches. This is an important point; namely, the measurement of a prolapsed uterus should be made only when the organ is within the body. If made when the uterus is outside of the body, the parts are placed upon the stretch in such a manner that the measurement will be much greater than actually exists. Procidentia in the third degree, such as we have here, is exceeding rare in girls at the age at which this patient began to suffer from it.

The case is therefore interesting from the fact that it demonstrates the possibility of an inordinate muscular effort producing displacement of the uterus even in a virgin.

Displacement of the uterus may be produced by anything which increases its weight, such as sub-involution tumors, etc.; anything which produces undue traction from below, such as dragging of a tumor, etc.; anything which removes or enfeebles uterine support, such as ruptured perineum, constantly lying in bed developing mere laxity of fibre and want of tone in the uterine support, etc.; anything which forces the uterus downwards, such as abdominal tumors, violent muscular efforts, etc.

In the present case, it was a violent muscular effort which gave rise to pressure upon the uterus from above, overcoming all its supports, and down it came.

Treatment.—If, in this case, the uterus have been immediately restored to its normal position, it would not have suffered any permanent injury, for all the uterine supports would have had their power restored. As it is, this condition has been present so long that all the ligaments and tissues which assist in maintaining the uterus in its normal position have lost their elasticity, and perhaps, have undergone a hyperplasia

which forbids them ever returning to the performance of their normal function.

The volume of the vagina might be reduced, but the operation would promise but very little. In this case the uterus is so light that something, perhaps, might be accomplished by it.

The only thing which can be recommended with any degree of confidence of relief is the application of a pessary, but that would require a vast amount of patience upon the part of the practitioner, and perhaps equally as much upon the part of the patient.

Original Communications.

SURGICAL CASES.

By GEORGE E. POST, M.D.,

PROFESSOR OF SURGERY IN MEDICAL COLLEGE OF BEIRUT, SYRIA.

CASE I.—*Calculus in urethra removed by a calculus opening.*

A boy, six years old, entered St. John's Hospital in March, 1874, complaining of difficulty in passing urine. On examining with the touch, a tumor of the size of a pea was found just behind the junction of the skin of the penis and scrotum. On passing a catheter No. 4, the instrument was arrested by a gritty calculus, which could not be pushed back into the perineum, nor worked forward toward the meatus. After unsuccessful efforts to withdraw it by the spoon, and by Civiale's urethral process, the scrotum was drawn forcibly forwards in such a way as to bring the centre of the perineum over the stone, over which an incision was then made, and the stone extracted, after which the skin was allowed to return to its original position. A sinus, an inch and a half or two inches long, was thus formed, pointing backwards, and closed in a valvular way, so as to make the passage of urine into it difficult. Little swelling occurred, and but a few drops of urine passed by the wound, which healed entirely within ten days. Had the wound been made anterior to the scrotum, a troublesome fistula would have been the result.

CASES II. and III.—Two children, aged respectively two and seven years, were brought to me with stones impacted in the lacuna behind the meatus externus. In each case, the stones were removed by gradual dilatation without division or incision.

CASE IV.—*Salivary calculi of submaxillary gland.*—A man of about 45 years of age had complained for several years of swelling and tenderness in the region of the left submaxillary gland. On placing one forefinger within the mouth, and the other beneath the jaw, and palpating between them, a hard mass was perceived, and a sensation of grating was distinctly felt. On pressing the gland, pus emerged from Wharton's duct. The gland was then firmly pressed up into the floor of the mouth; and an incision, half an inch in length, made over the hard body, when two calculi, one of the size of a bean, and the other of a pea, were turned out of a cavity in the gland.

CASE V.—*Fistula in perineo.* A man, 25 years of age, was cut for stone 15 years since by a native practitioner, probably by the Italian (median) method. A fistula was left in the perineum large enough to admit a No. 12 sound, and lined with an organized mucous membrane, surrounded by a tube of fibrous tissue, losing itself in the surrounding parts. This tube was not

more than three-quarters of an inch in length, which is less than the usual depth of the membranous portion of the urethra from the surface in a man of that age. This fact was attributable to cicatricial contraction, which I have always observed in such cases to draw the urethra towards the surface, causing it to make an obtuse angle instead of a free curve in the perineum. The anterior portion of the urethra had suffered arrest of development, and would not admit an instrument larger than No. 8. The urine and semen all passed per perineum, thus at once emasculating the man, and making his life miserable. The treatment consisted in removing the fibrous track of the fistula, and restoring and maintaining the calibre of the urethra by the daily passage of bougies. At the end of two months, the fistula would barely admit a probe, and most of the urine and all of the semen passed per urethra. Owing, however, to the abnormal direction of the urethra from the cause alluded to above, a few drops of urine dribbled away at each act of micturition. After ineffectual use of nitrate of silver and the actual cautery, the small fistulous track was removed, and a space half an inch wide on each side of the raphe denuded, and the sides of the perineum drawn to the median line, and fixed by leaden clamps and silver sutures. An additional half-inch of depth was thus given to the perineum. Union of most of the denuded surfaces took place by the first intention, and within a month after the last operation the fistula was finally closed, and the patient was discharged cured.

CASE VI.—*Stricture of urethra treated by external and internal urethrotomy.* The case was one of stricture, which would only admit a capillary bougie, and as I had no tunnelled instruments, and could not get Maisonneuve's or Hott's instrument through the stricture, I incised the urethra as in the median (Italian) operation for stone, reaching the urethra at the junction of the bulbous and membranous portions, which was the posterior limit of the stricture. I then passed a small probe into the stricture from behind forwards, and followed it by a Maisonneuve's urethrotome, and incised the stricture, the length of which was an inch, upon its superior wall. I then passed a No. 12 catheter, from the meatus to the bladder, and left it in position 12 hours. After that I introduced it daily, leaving it a few hours in position, until the seventh day. After that date, I contented myself with introducing it daily, until the perineal wound was healed, and all tendency to contraction had passed away. The patient was discharged cured about a month after the operation.

CASE VII.—*Bilateral lithotomy, followed by fatal colliquative diarrhoea.* Left kidney atrophied, and right kidney hypertrophied. A man about 45 years of age entered St. John's Hospital for stone in the bladder. After the customary test examinations as to irritability of the bladder and tolerance of instruments, etc., and keeping him in the hospital for a week, to become used to the confinement of hospital life, he was chloroformed, and the incision for the bilateral operation made in the usual manner. The great depth of the prostate and the thickness of the inferior wall of the bladder made it easier to complete the incision with a probe-pointed bistoury. A stone of nearly two inches in diameter was extracted with much difficulty, owing to the long, unyielding track of the incision through the infiltrated prostate, and the extraordinary roughness of the stone, which was covered with stalactitic projections, and as hard as flint. The patient rallied well from the operation, and for two days had little reaction. On the fourth day he was suddenly attacked with colliquative diarrhoea, and his

strength gave way almost immediately. On the fifth day hicough commenced, and continued almost without cessation until the time of his death, which took place after twelve days, with symptoms of passive congestion of the lungs. During the whole of this period, he seldom referred to the region of the perineum or bladder, and experienced no symptoms of irritation in his urinary organs. On opening the chest after death, the right lung was found glued to the parietes of the chest by old adhesions, and the whole of the lower half of the lung hepatized. The left lung was somewhat congested, but not hepatized. The other viscera of the chest and abdomen were normal, excepting the urinary apparatus. The bladder was found divided into two compartments by an hour-glass contraction, and the walls of the lower half in which the stone had lodged were thickened to two-thirds of an inch, and the mucous membrane was thickened and plicated, and covered with patches of superficial ulceration, seemingly caused by the irritation of the rough stone. Singularly, the patient had suffered little pain from the presence of the calculus, or the process of exploration. The left ureter was slightly dilated near the bladder, but before crossing the iliac artery, was attenuated to a small fibrous cord, which was with difficulty traced to where the kidney ought to be found. There a hard body of the size of a small almond was found, and enclosed in its fibrous tissue two calculi, one of the size of a white bean, and the other of a pea. No vestige of kidney tissue remained. The right urethra was dilated and sacculated, and resembled the small intestine in diameter and thickness of walls. It proceeded from a kidney twice the natural size, the pelvis and infundibula of which were dilated, and somewhat ulcerated. The kidney tissue proper was not diseased. Some sand was found in the infundibula.

The noteworthy point of this case was the absence of all external signs to show that one kidney was completely useless. Doubtless, in those cases in which the removal of one kidney by a surgical operation is well borne, there must be such an increase of size in the remaining kidney before or soon after the operation, as to enable it to perform the function of its fellow.

CASE VIII.—*Necrosis of the femur involving its upper and outer portion.*

A boy, 12 years of age, reported himself at the hospital of the Syrian Protestant College with a small sinus just below the point of the trochanter major. I incised the skin, and without opening the involucrum, was able to draw out two sequestre from the shaft of the femur, one of which was three inches long, and as thick as a common pen-handle. At a recent meeting of the New York Pathological Society, a sequestrum from the upper third of the femur was presented, and no other case was remembered by the members then present, in which necrosis had occurred in that part of the thigh. The case reported is the only one in which I have met with necrosis in the upper third of the femur, out of perhaps a hundred cases of necrosis on which I have operated during the past six years. Most of the cases occurring in the femur affect its lower third or fourth. I have several cases in my cabinet involving the whole cylinder of the bone, and from one-third to one-half its length.

CASE IX.—*Case of compound comminuted fracture of the ramus of the ischium and pubes without injury of the urethra, or bladder, or rectum.*

A young man working in the sand-stone quarries of Beirut was crushed under a mass of falling stone, dislodged by the caving in of the quarry wall, and a stone driven into the perineum in such a way as to

crush the rami of the ischium and pubes, and divide the internal pudic artery, without lacerating the urethra, or bladder, or rectum. The patient has had severe suppurative fever, and now (the twelfth day from the time of the injury) the wound is granulating well. The cavity left in the perineum would admit a large egg, and has several pouches extending in the direction of the inner face of the tuberosity of the ischium and towards the obturator foramen, and the rough ends of the fractured bone may be felt in the direction of the tuberosity of the ischium and the body of the pubes. About an inch of the bone is lost. Not less than half an inch of the rami are denuded on each side of the hiatus, so that when the dead bones shall have become separated, nearly the whole of the rami will have been lost on the affected side. The acetabulum and the body of the pubes are, however, to all appearance quite sound. The receipt of such an injury without urethral or vesical complications is exceedingly rare.

A CASE OF PERITYPHLITIS. — OPERATION ON EIGHTH DAY.—RECOVERY.

By CHARLES KELSEY, M.D.,

NEW YORK.

LEAH CABARET, age 16, French. The patient, previously in excellent health, was taken on the eve of April 8, 1874, with pain over abdomen and vomiting, lasting all night. Next morning, after an enema, had three good passages from bowels, the vomiting ceased, and pain became localized over right iliac fossa.

April 10. Pain increasing in fossa; great tenderness on pressure; sleeplessness; some fever. A dose of castor oil given by parents was followed by one passage from bowels, in fair quantity.

April 11. No improvement in pain. Physician sent for.

At first examination near the end of the third day of trouble, the patient was found, temperature 101.5, pulse 120, and a hard, painful tumor in right iliac fossa. There was dulness reaching half way from ant. sup. spine to umbilicus, and for about an inch and a half of this distance flatness on percussion. There seemed to be also a slightly greater fulness on the surface over this fossa than on the other side, but no redness or fluctuation.

Persistent questioning failed to reveal that patient had eaten anything liable to become fixed in appendix.

Ord. Sol. Magendie, q. s., to relieve pain.

April 12. Condition unchanged.

April 13. Small, voluntary mucus passage from bowels.

April 14. Pain, tenderness and swelling in fossa continue undiminished, slight increase in area of dulness. Pulse ranges from day to day at about 110, and temperature about 101.5. These are the only symptoms—no vomiting, no chills, no pressure affects firm tumor.

April 16. (Morning of eighth day.) Case seen by Dr. George A. Peters in consultation. At this time the border of tumor, as well as could be felt by deep pressure on abdomen, extended about half way between ant. sup. spine and umbilicus; but for some distance further there was dulness and tenderness. Temperature 110, pulse 110. The tumor had not increased in superficial area for forty-eight hours, and there was no redness or fluctuation.

The diagnosis was confirmed by Dr. Peters, and with his approval and assistance, and that of Dr. Abbe, the operation was performed.

The incision was four and a quarter inches long, beginning at a point one inch above ant. sup. spine, and running parallel with, and an inch above, Poupert's ligament. After cutting through the external oblique, the smallest needle of aspirator was plunged into the tumor, and a few drachms of pus drawn out. The incision was then carried on to transversalis fascia, and a large-sized aspirator needle again used, through which there was an escape of foul gas and pus, without it being necessary to attach the instrument.

Leaving this second needle in as a guide, an incision an inch long was made through the fascia, and two or three ounces of pus escaped.

The cavity of the abscess was carefully explored with the little finger, and the convoluted intestines could easily be felt, apparently covered by the parietal layer of peritoneum separated from the fascia by the collection of pus. But this could not be decided positively; nor could it be found with certainty whether there had been perforation of the appendix or colon, though it was thought by two of us that there was a marked fecal odor about the pus and wound immediately after the abscess was opened.

Wound kept open with lint, and poulticed.

Next day the temperature was normal. Pulse 98; pain greatly relieved; wound discharging well; patient much improved every way.

April 22. One large passage from bowels, assisted by enema.

After this the bowels moved easily and readily every day or two, and by May 8, one month after the beginning of trouble, the wound was almost entirely healed, the patient up and about, and apparently entirely cured.

Progress of Medical Science.

THE LOCAL TREATMENT OF CYSTITIS IN WOMEN.—Dr. Braxton Hicks, in a paper recently read before the south-east branch of the British Med. Association, observes that, in speaking of cystitis, he means the more severe forms, such as that which, among other causes, arises from the effects of prolonged labor, from malignant diseases of the organ, or from paralysis, etc. The only general treatment that may be used with advantage is opium or some other anodyne, and such corrective as may modify an alkaline state of the urine. Supposing it to be alkaline and ammoniacal, it is best to take a gum elastic catheter, which is open at the extremity as well as the sides, and, having oiled it, to pass it gently into the bladder for as short a distance as possible, and withdraw the catheter again just as the bladder is on the point of being emptied, which saves the mucous membrane from flapping down on the ends. Then, with a syringe, throw up through the catheter warm water slightly acidulated with either nitric, hydrochloric, or acetic acid. Vinegar does very well; if nitric or hydrochloric acids are used, about two drops of the strong acid to the ounce of warm water are sufficient. As soon as the patient complains of a desire to micturate, allow it to flow away again. This should be repeated till the bladder seems clear of the phosphates and mucus. About half a pint of acidulated water will generally suffice. Then inject also, through the catheter, about one grain of morphia dissolved in an ounce of water; quickly withdraw the catheter from the urethra, and instruct the patient to retain the injection as long as possible. It is rare that the single application does not give great

relief. This treatment can be repeated twice daily, if the case be very severe. When the urine has not been markedly alkaline, Dr. Hicks simply injects the solution of morphia, or first washes out the bladder with warm water, or warm solution of permanganate of potash. After some days of this treatment, he sometimes employs, instead of the permanganate of potash, a solution of chlorate of potassa, about three or four grains to the ounce, using plenty, drawing it off after a few minutes, according as it gives pain, and then injecting the morphia. Regarding the dose of morphia, he adds that if there be no blood in the urine, and the patient feels no constitutional effects from a grain, he increases it to two grains. If blood appears in the urine, it is a sign of some abrasion, in which case the morphia is more likely to be absorbed; yet he has never seen any unpleasant symptoms from two grains. The more that is used, without affecting the system much, the better, as it acts locally, by subduing the nerve-irritation, and the tenesmus of the bladder, and the crushing of the mucous membrane, produced by the contractions of the muscular coat. As the acute symptoms subside, more astringent washes may be employed, such as two or three grains of tannin, or three or four drops of solution of perchloride of iron in the ounce of warm water, using the morphia solution immediately after. The choice should depend on the amount of pain caused, the object being to produce no more than is necessary. If the urethra be very tender, a bougie or catheter, covered with tannin, made very smooth, and dipped in gum-water, may be introduced. A probe, on which a film of nitrate of silver has been fused, may be tried, or the surface may be mopped out with a piece of cotton dipped in perchloride of iron. In chronic cases a solution of nitrate of silver containing from five to ten grains to the ounce may be injected, followed by the introduction of two grains of morphia in solution. In the acute stages the warm hip-bath and warm sponge to the genitals are not to be omitted, together with perfect rest in bed; the bowels must be kept gently relaxed, and the diet should be simple and light.—*Brit. Med. Jour.*, July 11, 1874.

A NEW THEORY OF THE ORIGIN OF MALARIAL FEVERS.—An article in the last (September) number of the *Nashville Journal of Medicine and Surgery*, by Dr. Duff Child, is entitled *Cyanogen, the Radical of Fever and Ague Poison*. As a specimen of original research the article will doubtless command respect and create no little comment. With regard to the balance of truth and falsity in the views expressed, it is not our province here to decide. The points of weakness are obvious, but in general the argument is well considered and certainly ingenious.

According to Dr. Child, the marsh miasmata are virtually cyanogen or some compound which contains this gas. He believes the cyanogen to be a product of the decomposition of both vegetable and animal matters. This gas is not usually supposed to be produced in the decomposition of these matters. But the writer claims that under certain conditions or at certain stages of the decay this may occur. For his explanation of this point we must refer the reader to the original article. In order to ascertain the presence of cyanogen in malarious localities Dr. Child made the following application of Schönbein's test: Strips of paper which had been saturated with the solution of copper were left overnight in fissures found in the bottom of recently dried-up ponds, near localities where intermittent fever prevailed. The ends of the strips of paper resting in the fissures were found, the morning

after, tinged with blue, "indicating the presence of hydrocyanic acid or some decomposing cyanide." It was noticed also that the strips turned slightly blue while drying in the Doctor's office, which was situated in a malarious district. The writer admits that this test is not conclusive, since by means of other tests he was not able to detect cyanogen in the soil of these regions.

Various authorities are quoted to show that the idea of volatile organic matters in the air being the source of intermittent fever and kindred diseases has been often entertained by others.

The writer endeavors to show a certain correspondence between the symptoms produced by the poisonous compounds of cyanogen, and the symptoms both acute and chronic caused by "marsh poison." But he assumes that the pathogenetic action of these poisons in the state of vapor is not fully known.

With this hypothesis regarding the nature of the malarial origin he proceeds to draw such conclusions as would account for the production and phenomena of the malarious fevers. Supposing a healthy individual to be placed in an atmosphere contaminated with the above poison, it would follow that those organs whose office it is to eliminate such elements from the blood would have an extra labor to perform. They would, moreover, have to remove "the damaged and now hurtful constituents of the blood" which are due to the action of the poison upon the fluid. So long as the emunctories are equal to the increased task imposed upon them, so long will health be preserved. "But suppose, from any cause, the working of any one of the organs mentioned is interfered with, as we know is likely to happen from changes of temperature; or suppose that the amount of work required by all three organs, when at their best, was beyond their power, then would a febrile condition be at once established; in other words, the individual would manifest all the so-called prodromic symptoms of an attack of ague—would be in the initiatory stage of febricula. This would last a longer or shorter time in different individuals or in the same person, according as the functions of the excretory organs were habitually, actively, and thoroughly performed."

But the poison goes on accumulating till these organs can no longer accomplish their task, and exhaustion and a profound depression of the system ensues.

"This stage of depression would be followed by a stage of reaction, shown by a rising thermometer during the chill and fever; and finally would come a sweating stage or crisis, which is but a vigorous effort at the elimination of the accumulated poison." Should this effort result in complete elimination of the poison, an intermission occurs; or in case of but a partial elimination, a remission follows.

Thus he explains the periodicity of malarial fevers. The variations in the length of the intermission, giving rise to the different types of paludal fever, are explained on similar grounds, taking into account the influence of season.

A very ingenious explanation is given of the origin of the anemia, together with the enlargement of the spleen, in long-continued malarious diseases. The writer begins with a quotation from Virchow's "Cellular Pathology," where a change is described as sometimes taking place in the "respiratory substance" of the blood-corpuscles—a kind of paralysis of the blood-cells resulting. Certain poisonous substances are mentioned as capable of effecting this change; for example, arseniuretted and cyanuretted hydrogen may impair the respiratory power of the blood-corpuscles

in the above manner. Accepting this view, he supposes that in an individual exposed to the malarial poison a large number of the red corpuscles are affected as above described. During the stage of depression quantities of these paralyzed corpuscles would accumulate in the spleen, and be then under conditions favorable to their disintegration. The destruction in this way of the red corpuscles would occasion anemia, and the repeated distentions of the spleen would give rise to chronic enlargement or hypertrophy.

With regard to the treatment of malarial diseases the writer naturally suggests a modification of the therapeutics in accordance with his new doctrine. Some agent having an affinity for cyanogen would be indicated. He claims that "mercury in some form is indispensable to the successful treatment of malarious fevers," and he ascribes its beneficial effects to its peculiar affinity for cyanogen. Another metal, also having this affinity, which, it is surmised, might have a similar effect, is palladium, which, however, has never yet been embraced among the materia medica.

The action of quinine, arsenic, etc., is accounted for in supposing that they prevent and cure ague by "rendering the blood, and through it the whole system, proof against the action of the morbid poison."

DIAGNOSIS OF BLOOD-STAINS.—It is claimed by Dr. Joseph G. Richardson that the residuum of a dried blood-clot, left after the action of pure water, is mainly composed of the cell walls or capsules of the red blood-corpuscles. His reasons for affirming the existence of such cell-walls are based upon former investigations of his, made especially with respect to the gigantic blood-disks of the menobranchus. In this case crystals of hæmato-crystalline were seen "to pop out a visible membranous capsule." The possibility of measuring the cell-walls of the globules remaining in an old blood-clot or in blood-stains upon articles of clothing, with sufficient accuracy to discriminate between the blood of man and that of many of the lower animals, is maintained with much positiveness in a recent paper by Dr. Richardson, read before the Biological and Microscopical Section of the Academy of Natural Sciences. The paper is published by recommendation of the Society in the July number of the *American Journal of the Medical Sciences*. Most authorities have held hitherto that the differences observed with the microscope, between the blood-corpuscles of man and those of lower animals, were too insignificant to admit of their diagnosis, or at least to justify their being used as a means of condemning a prisoner charged with murder. But Dr. Richardson asserts that with the aid of high powers of the microscope we may positively distinguish stains caused by human blood from those of the blood of the pig, ox, sheep, horse, goat, cat, and other animals, and this even when the stains are five years old. His assertion is sustained by practical tests of the most convincing character.

A $\frac{1}{2}$ objective was used in his observations, giving with the micrometer eye-piece an amplification of 3,700 diameters. When thus magnified the human red blood-disks appear about one inch and one-eighth in diameter, so that even slight differences in their size can be accurately measured. A series of measurements of human blood-globules in the fresh state showed but a slight difference compared with the same when dried. Thus the average size of the fresh corpuscles was $\frac{3}{32}$ inch in diameter, while that of the dried was $\frac{1}{16}$ of an inch. Moreover, it is shown that the smallest red disks of human blood, as usually

met with, are larger than the largest corpuscles of an ox or sheep. It should be borne in mind that ordinarily in criminal cases the microscopist is called upon to determine, not whether a particular specimen is human as distinguished from all other kinds of blood, but to discriminate simply between the blood-corpuscles of a man and an ox, a man and a horse, or a man and a sheep, and so establish or disprove the defendant's story as to how his clothing or other articles became stained with blood.

In replying to the arguments of opposing authorities, Dr. Richardson remarks: "All these theoretical considerations are of secondary importance in comparison with the positive fact as to whether practically we can or cannot discriminate the stains of human blood from those made by oxen or sheep." Therefore, in order to determine the point beyond cavil, he submitted the matter to a crucial test. His friends, Prof. J. Reese and Dr. S. Weir Mitchell, each prepared three packages of dried blood from an ox, a man, and a sheep. "The two series were simply numbered 1, 2, and 3, and a memorandum preserved by each gentleman, specifying which kind of blood composed each sample." The measurements of the corpuscles which were obtained in these several samples are given in tabular form. The inferences drawn from them are quite obvious, and fully confirm the truth of Dr. Richardson's statements.

To show that the age of the stains does not affect the accuracy of their diagnosis he examined a portion of a stain some five years old, and with a result quite as unmistakable as in the former experiments.

PAROTITIS, WITH TRANSLATION TO BRAIN AND TESTIS.—Dr. S. J. Radcliff reports a case of mumps which is interesting, from the rarity of its complications. The case was that of a young man, 27 years of age, who was attacked first by an ordinary idiopathic parotitis, which appeared to differ from other cases of the disease only in the severity of the symptoms. On the fourth day the right testis became inflamed, and the pain and swelling increased to an extreme degree. On the eighth day inflammation of both parotid and testis began to subside, and convalescence seemed progressing favorably; only the patient was wakeful and inclined to fret. Two days later, symptoms of marked cerebral excitement had developed; there was great restlessness, irritability, and a disposition to talk continually and upon a single subject. The pulse was 110, sharp and unsteady; eyes bright and staring, and pupils contracted. These symptoms continued several days, when decided delirium set in. The delirium was not of a violent character, but there was great mental excitement and evidences of commencing exhaustion. The diagnosis arrived at was that the patient "was laboring under a high state of meningeal excitement or hyperemia, influencing the brain to increased functional activity, due to translation or operation of the materies morbi of the mumps." This condition lasted for upwards of a month. Then the symptoms gradually subsided, and in about three months the patient's faculties were so far restored, that he could partially resume his studies. The recovery was subsequently complete.

In connection with this case, the writer refers very fully to the literature of the subject. Cases of translation to the brain are shown to be exceedingly rare, and have usually terminated fatally. The pathogenesis of the affection remains obscure.—*Phila. Med. Times*, Aug. 15, 1874.

THE ACTION OF MODERN BULLETS ON THE ANIMAL BODY.—Dr. Augustus Küster, of the Augusta Hospi-

tal, has published in the last number of the *Berliner klinische Wochenschrift* an interesting paper on this subject. In a paper read last year before the German Surgical Congress, Prof. W. Busch, of Bonn, called attention to the fact that the Chassepôt bullet, when shot from a short distance into the human body, made a simple aperture of entrance, but that its aperture of exit was larger than a fist, and that there was very extensive fissuring and crushing of the bones. The same phenomenon had been described by Huy and Sarrazin in 1867; but they did not attempt to explain it. Dr. Busch supposed that the ball became melted and broken up by forcible contact with a hard substance, and acted like a mass of shot on the parts lying behind. Dr. Küster, at the time when Dr. Busch's paper was read, had made a similar observation as to the effect of the bullets, but could not adopt Dr. Busch's explanation. He had since made a number of experiments, which, with the courteous sanction of the ministry of war, who placed at his disposal arms, ammunition, and men, and with the assistance of Major Schenck, were carried out at the royal military school in Spandau.

In making the experiments a large target was placed behind the animals, so as to enable the condition of the bullets to be observed after their passage through the body. The distances were five, twenty, one hundred, and eight hundred paces. The arms used were a sporting rifle (muzzle-loader with pointed bullet), the needle-gun, Chassepôt, Mauser, and Henry-Martini rifles; the animals used for experiments were horses and wethers. The latter were first killed by a volley from all the weapons; then shots were discharged at the dead body, and after eight days a further series of experiments were made on the carcass, which was at that time undergoing decomposition. The following were the general results of the investigation:

1. There is no essential difference in the action of bullets on the living and on the dead body. With reference to this subject, Dr. Küster calls attention to the fact that, in consequence of the greater toughness and resistance of the skin of animals, the aperture of exit is not so large as in the human body. In one case the skin was so tough that the point only of the ball penetrated the skin of the back, and its force was then diminished. On dilating the opening and introducing the finger into the wound, there was found to be just as extensive destruction of the soft parts and bones as in the human body. It was only in those parts where the skin was thinner and lay close to the bones, as in various parts of the head of the bone, that it was sometimes torn to a greater extent, but never so much as in man. The extent of injury of bones, however, was not less than in the human subject.

2. The extent of the destruction is in inverse ratio to the distance, and in direct ratio with the initial velocity of the bullet. At eight hundred paces, although the characteristic peculiarities of the wound were still present, they were generally reduced in intensity. The smallest wounds were produced by the sporting rifle (Jagdbüchse); the bullets, although put out of shape, remained entire in the body, even when discharged at short distances. Then followed the needle-gun, the Chassepôt, and the Mauser rifle, which produced frightful destruction of the bone and soft parts.

3. The destruction of the tissues is produced by the lead becoming heated by collision against a solid substance, and consequently broken up, but without being melted. The bullet is mechanically divided; it leaves the finest particles of lead in the recesses of the wound, while the fragments of larger size pass out along with pieces of shattered bone. On this point Dr. Küster differs from Professor Busch, who supposed a melting of

the lead to take place. Busch's view appears to derive confirmation from the fact, that when a lead bullet is discharged against an iron target, the lead is spread out in the form of a star; and this, it is argued, shows that it becomes melted. But Schädel, of Heidelberg, hung a small bag of powder before the target; the bag was repeatedly torn by the splinters of the bullet, but without producing an explosion, which must have taken place if the lead had been melted. There must also be a great difference, according to whether the bullet, travelling with full force, is completely arrested, or meets with an obstacle which it can overcome.

At the meeting of German naturalists in Wiesbaden, Professor Busch related some experiments to show that lead loses its cohesion in proportion as it is heated. If two bullets, one cold and the other heated, be allowed to fall on a stone from a height of six feet, no impression will be made on the first, while the second will be distinctly flattened. That a heating of the ball does take place is an evident result of the physical law, that whenever it meets with resistance a part of the force is changed into heat; and further, when a bullet remains sticking to the target it is always warm. Again, when a bullet is discharged from a short distance into a heap of moist sand, the edges and the further end of the channel made by the bullet are always warm. By these facts, the manner in which the injury is produced in the animal body is easily explained. The bullet shatters the first bony lamella with which it comes into contact, becomes heated, and is consequently broken into several fragments against the projecting portions and angles of the bone. In correspondence with this destruction of the bullet, the wounds made from short distances by the Chassepôt and Mauser, which have the greatest initial velocity, were frightful. Most of the bullets passed through the animals' bodies, reduced by one-half or more, and greatly altered, and made on the target an irregular impression, surrounded by a crown of small pieces of lead. Along with these were found fragments of bone, muscle, hair, etc. Dr. Küster does not remember having once seen a simple bullet-opening in the target.

The next point was to observe whether hardened balls have the same effect. This was *a priori* not improbable, as Pirogoff had noticed the remarkably extensive splintering produced by the copper bullets of the Tscherkesses. Dr. Küster, however, found that—

4. The injuries described are produced only by bullets of soft lead, not by those made of hard lead. Bullets of hard lead are used with one only of the modern weapons—the English Henry-Martini rifle. The hardness is produced by amalgamation of the lead with tin in the proportion of 12 to 1. The initial velocity of this rifle is nearly as great as that of the Mauser, and yet the wound produced by it is very much smaller. While with the latter the aperture of entrance into the bone was irregular, and very often extensively splintered, and while the amount of crushing increased in extent in the track of the ball, the Henry-Martini bullet always made a simple and more or less circular opening. If the edge of a rib were hit, the loss of bone formed the segment of a circle corresponding to the circumference of the ball. The aperture of exit was also generally roundish, though larger; there was either no splintering, or it was limited to the immediate circumference of the aperture. The hole in the target was without exception simple, and the ball, when found in the target, was not at all, or only slightly, misshapen. Dr. Küster has never found splinters of lead in the track of the wounds made by

these bullets. In one case only did he find a bullet of this kind much misshapen; it had been discharged at a distance of one hundred paces, and remained sticking in a bone. Dr. Küster states, as a fact of importance, that at a distance of a hundred paces, the Henry-Martini bullets, with one exception, passed through the greatest diameter of the body of a horse, while the Mauser bullets frequently remained in it. This is explained by the greater resistance which the latter have to overcome in consequence of the greater amount of misshapement which they undergo; it also shows that the passage of a ball right through the body generally indicates less danger than when it remains in it.

These results, Dr. Küster says, are capable of practical application in several directions. In the first place, they are a gain to forensic medicine. The statement made in text-books, that gunshot wounds are more extensive in the living body than in the dead, and that this affords a means of distinguishing whether the injury has been inflicted during life or after death, can no longer be tenable. No distinction exists in this respect, at least with the arms with which the experiments were made. On the other hand, a careful examination of the wound, especially when it passes through bone, may very well show whether the ball was of soft or hard lead, and allow some estimate to be made as to whether it came from a distance or was discharged near the part. A still greater gain, however, is to be derived by military surgery from the investigation. The opinions previously entertained as to the action of shot have been shaken by the introduction of the modern weapons, and require reform. In future, judging of the severity of an injury, it will be important to ascertain at what distance and from what weapon the shot was discharged, and whether it was of hard or of soft lead. The penetration of the bones of an extremity by a Chassepôt or a Mauser bullet at short distances will, in nearly all cases, demand immediate amputation.

Dr. Küster next refers to the bearing of the question on the interests of humanity. The use of explosive bullets of small calibre is forbidden by international agreement; but, if it be shown that bullets of soft lead, at least at short distances, act just like explosive bullets, and that a close combat with such bullets can be nothing but a horrible butchery, the members of the Geneva Convention must use every effort to obtain an international verdict against the use of them.

In some of the actions of the late war, when the combatants fought at short distances, the surgeons were struck with the frequency and severity of the injuries of the bones, and the size of the apertures of exit. At that time the reason of this was not understood, and it was supposed that explosive bullets were used. The researches of Dr. Busch and Dr. Küster have explained the matter; and Dr. Küster says that he owes it to a brave opponent to state with satisfaction, that the French stand thoroughly acquitted of the charge of having committed an act of unworthy and interdicted barbarity.—*Br. Med. Jour.*, 1874.

NEW FACTS ON TRANSFUSION WITH LAMBS' BLOOD.—At the recent Congress of the German Surgical Society several papers were presented on transfusion of blood. One by Dr. Kuester, of Berlin, another by Dr. Hasse, of Nordhausen, were read, and provoked interesting discussions. Dr. Kuester opposed the plan of using defibrinated blood, without giving specific reasons for so doing, and objected to Dr. Hasse's plan of conveying blood from the animal's artery directly into the vein of the patient. His reasons were (1), that there is danger of phlebitis or pyæmia from the clots,

etc., and (2) it is difficult to estimate the quantity of blood transfused. He gave the histories of eight patients on whom transfusion had been performed. The operation had been done thirteen times in all—in twelve with direct arterial transfusion, and in one by Hasse's method. The diseases were (1) gunshot fracture of the thigh, with waxy degeneration of the kidneys, (4) phthisis at a late stage, (1) phthisis with rectal fistule, (1) typhoid fever, with exhausting intestinal hemorrhages. The radial artery was used ten times, and the posterior tibial twice, in the other case the vein. Of these patients two only were living, the others survived from one to two weeks, and were often surprisingly improved, but at length yielded to their maladies. During the operation the symptoms were extraordinarily severe, chiefly from great pain in the sacral region and excessive dyspnea. After the operation there was a sharp chill, followed by sweating; then the temperature rose to 103° F. on an average, but fell in from five to six hours to the normal. In favorable cases a general improvement commences at this time. The great dyspnea was due, he thought, to the fact that the blood of ruminants contained such an abundance of carbonic acid that it is not oxidized with sufficient rapidity. In using human blood in a similar way, he had not met with dyspnea, though more blood was transfused. A chill and rise of temperature followed, however, as with the blood of animals. On the whole, he preferred human blood. He believed that failure in many cases was due to the selection of improper cases, such as patients in the last stages of consumption. Dr. Hasse followed with a paper in which he advocated the use of his apparatus, and denied that the blood was more liable to coagulate in it than in any other. In regard to his method, he added the following particulars: It was imperatively necessary to drain the blood from a certain length of vessel, both in the artery of the animal and in the vein of the patient, and then to tie all collateral branches in two places, between which these branches should be severed. The peripheral end of the lamb's artery should then be securely tied, while light pressure was brought to bear on the central end. Digital compression was perhaps best; but a delicate pair of spring forceps might also be used with advantage. To close the central end of the patient's vein temporarily, he employed digital compression or a rubber ring. If this latter was slipped over the limb, it was easily adjusted and easily removed. A fold of the walls of the vessels was then raised with the vein forceps, and small portions were snipped out with curved scissors; the exposed portions of the vessels were then carefully cleansed, and the canula, previously filled with a solution of carbonate of soda ($\frac{1}{4}$ per cent. in water), introduced. At this point care was requisite to prevent the ingress of air, but there was no great difficulty, with proper manipulation. Turning the cock, the arterial blood would flow rapidly into the patient's vein, driving before it the soda solution, and it could readily be seen through the glass tube if any air-bubbles entered. When a sufficient quantity of blood had passed, the rubber ring was slipped over the limb, effectually compressing the vein. The canula was then removed and allowed to discharge into a graduated vessel for a period of ten minutes, by which the quantity of blood transfused during the period of the operation was readily calculated. The final steps consisted in removing the intermediate portion of vein and closing the wound with sticking-plaster. Dr. Sanders remarked that he was well satisfied with Hasse's apparatus, having employed it eight times,

and only had conglutination in one case. One of his patients had severe hamaturia, but recovered after losing about ten pounds of flesh. Prof. Thiersch called attention to the fact that many lambs were sold in the market that were known to have chronic joint affections, and it was likely that their blood would be poisonous. Dr. Hasse, in reply to several points, said that a case of hamaturia, mentioned by Prof. Hueter, followed indirect transfusion with human blood, and that in forty cases in which his direct method was employed, he had only six cases of hamaturia, and those not of as severe character as the one above alluded to. In reference to the animal, he recommended the selection only of perfectly healthy lambs, not over eight weeks old. Old sheep were not suitable for this purpose. He further observed that the more carefully the operation was performed, the less often did hamaturia or hamaglobinuria (Pontick) occur. This complication was not the result of transfusion from the lower animals, for it occurred, and with many times the severity, where defibrinated human blood was used. Dr. Heller, of Dantzic, has recently reported a case (*Berl. klin. Woch.*, 32, 1874) in which he operated by Hasse's method in cancer of the pylorus, but the patient died in five hours. Dr. Thurn (*Ibid.*) reports five cases in which he has tried what is virtually the same method. One of the patients, a consumptive, died at the end of four weeks, the others all did well. —*Berl. klin. Woch.*, 29, 31, 32, 1874.

CONGESTION AND APOPLEXY OF THE KIDNEYS AND THEIR RELATION TO CEREBRAL HEMORRHAGE.—Ollivier has performed a number of experiments to determine the nature of the changes that take place in the kidneys after cerebral hemorrhage. The results of his observations are as follows: The quantity of urine was found to be increased, and contained albumen, but the time of the appearance of albumen was not constant. Sugar was detected in some cases. The changes in the kidneys that followed the albuminuria were in all cases congestions; in one case ecchymosis beneath the capsule, and in another scattered apoplexies in the cortical substance. These changes in the kidneys were unilateral, either on the same or on the opposite side from the brain affections. In those cases where both hemispheres were involved, the congestion was more intense in that kidney which was on the opposite side from the hemisphere from which the hemorrhage first originated. With the exception of a single case, the hemorrhage always preceded from the left hemisphere, and from the region lying about the fissure of Sylvius. The corpus striatum and optic thalamus were in each case either partly destroyed or almost entirely separated by the extravasated blood from the rest of the brain. The amount of blood which escaped was always large, and reached the crura cerebri on the anterior portion of the pons varolii; and when a circumscribed collection was found in the corpus striatum and optic thalamus, there were also other collections scattered throughout the crura cerebri or pons varolii. Ollivier believes that just at present we are not in a condition to determine with certainty, from the presence of albumen in the urine in these cases, that a definite point in the brain is affected. He believes, however, that, under such circumstances, where the symptoms indicating disease of the pons varolii are absent and albumen appears in the urine, it points to a hemorrhage either in the base of the brain or an extensive extravasation compressing it.—*Arch. Gén. de Méd.*, Feb., 1874; *Méd. Chir. Rundschau*, July, 1874.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, October 1, 1874.

CONTAMINATED DRINKING-WATER.

THE occurrence of much sickness, and two or three cases of death, as the apparent result of drinking contaminated water at one of the fashionable hotels, has directed the attention of the profession and the public anew to an old subject. It is well, when such unfortunate results as those to which we refer take place, that we, as a profession, improve the opportunity to impress an important sanitary fact upon the community. Although every one must regret the circumstances which rendered investigation necessary, still, directing the attention of the public generally to the necessity of purity in drinking-water is always timely.

From the testimony of some physicians of this city who attended several of the guests of the hotel in question, it appears to us quite evident that to the impurity of the water used, all, or nearly all, of the blame is to be laid.

It appears that in the cellar of this hotel was a neglected cistern which had been covered up for a time. This circumstance, together with the fact that carcasses of rats and decaying vegetable matter were found floating in the water, explains the reason why the contents became foul and very dangerous to health. This of itself was so direct a violation of the ordinary and fundamental principles of sanitary science, that it becomes difficult for us to understand how an intelligent manager could have allowed its existence at all, and especially in a building used as a first-class hotel, having a large patronage and claiming all the advantages which belong to a fashionable resort in one of the most charming and healthful regions of the country. However, it but shows how much is yet to be done in the way of educating the people on sanitary matters, and especially in

impressing upon the minds of such as have the health of our families in their keeping the responsibilities which rightfully belong to the positions they occupy.

The condition of this neglected cistern was very bad, to begin with; but, worse than this, there appears to have been some connection with it and the pipes through which drinking-water was supplied to the guests. As soon as the water became infected sickness of a very significant character began to show itself among the inmates. Some were merely indisposed, while others were seized with all the symptoms which characterize septicæmia. Such at least is the testimony of some of the leading physicians of New York, who from the facts presented to them, and the symptoms of the patients under their direct observation, give it as their deliberate opinion that the drinking of contaminated water was the cause of the sickness.

Of course, as soon as the difficulty was discovered, every means were taken to remedy it, but, alas! too late for some, who have since died. It is well, however, that the cause of all the trouble was found out at last, and it is equally fortunate that the subject has, in connection with the hotel in question, been forced upon the serious attention of the public at large. It is a matter, presented as it has been through the columns of the daily press, which every one can now understand, and understanding can appreciate the necessity for guarding against any similar negligence in future, as much in the capacity of house-keepers as in that of hotel proprietors.

The importance of having a good supply of pure water is so impressed upon the managers of the aqueducts supplying large cities, that extraordinary care is taken to prevent contamination. If this were not so, we should at short intervals have a widespread epidemic of typhoid symptoms, with all the attendant phenomena now so well recognized as due to such septic influences. In isolated localities, however, where each individual, or set of individuals, depends upon their respective sources of water supply, the case assumes quite a different aspect. The lakes, springs, or wells very often become the receptacles of poison, which soon sacrifices precious lives. There is hardly a physician who has practised in localities in which each inhabitant has an independent water supply, who has not been able to trace many anomalous, dangerous, if not fatal symptoms, to this latter source. Old wells are particularly dangerous in this respect, unless they are far enough removed from sewers to make infection impossible from these, or from a saturation of the surrounding soil with sewage of any kind.

We knew of an old physician who was so thoroughly impressed with the fact that bad drinking-water produced dangerous disease, that he always inquired particularly of the character and sources of the supply. This was evidently a hobby; but we are convinced that his investigations in this re-

spect were not only perfectly reasonable, but eminently judicious. As practicing physicians we all agree in the importance of such inquiries, but we fear that very few look into the matter with that thoroughness which, in a sanitary point of view, it so justly demands. Let us therefore take another lesson on the subject, impress ourselves with its great importance, and be ever ready to utilize our knowledge in the cause of preventive medicine.

CONCERNING VIVISECTION.

AGAIN, as a profession, we are called upon to defend the utility of vivisections. The president of the Society for the Prevention of Cruelty to Animals, after having apparently exhausted every other topic bearing upon his famous specialty, has made a little departure. No one wonders at his efforts to magnify his office as custodian of the humanities, or as the champion of those extreme sympathies which are fostered by enthusiastic humanitarians. No one can blame him for feeling the responsibilities which are thrust upon him by a community who are so indifferent to the claims of the brute creation; and all right-minded and unprejudiced individuals are ever ready to thank him for reminding them of the fact that the same God that made man made the brute. There is a great deal of poetry in all this, which we believe the public at large are willing to offset against the sterner and more practical business of life which forces itself upon unromantic and plodding routinists. When we are informed that calves should go to the slaughter standing; that cattle should be butchered only in a certain way; that hydrophobic dogs should have all the rights of execution to which as friends of man they are entitled; that turtles should not lie uncomfortably upon their backs, or that oysters should not be swallowed alive, our sympathies are awakened, and we are quite ready to do our duties in the premises. We are hardly ready to cry over the misfortunes of the brute, as this may give a ridiculous aspect to our enthusiasm; but are willing to be humane, and the champion of animal rights gains his legitimate victory. On general principles no one is hurt, and the brute community are benefited. So long as this is the case no one can complain; every one is satisfied, and the lower creation have their claims allowed.

If there is a ludicrous element in this struggle for animal rights we in charity overlook it, at least so long as no important interests are assailed. No one loses anything by this stimulation of sympathetic feeling, provided it does not overleap the bounds of ordinary common sense, or militate directly against the necessities and utilities of a higher humanity. The latter is the case when Vivisection is assailed on the score of cruelty. So far, however, as the charge of cruelty is concerned, it can only be conscientiously made in igno-

rance of the manner in which vivisections are performed. It is well known to the profession that all operations, with very few exceptions, are performed under ether, the animal suffering no pain whatever, and in fact no other inconvenience than that attending the mere taking of the anæsthetic. It is very easy to raise a sensation upon the subject when it is presented in a certain light, and so far such sensations keep alive an interest in the Society, which, from a business point of view, is very proper; but when the vast interests of medical science are threatened by such action, and there is the possibility of the passage of a law hindering scientific investigation by their means, we are forced to look upon the matter in a very serious light. Eight years ago there was an effort made by Mr. Bergh to secure the passage of such a law, and its defeat was secured only by the timely and convincing arguments of Prof. Dalton, made before the State Medical Society, and afterwards transmitted, with the unqualified endorsement of that body, to the legislature. We believe that there is a promise of a repetition of the same effort, and in that view it is well that the attention of the profession should be directed again to the subject in order to take a proper defensive stand. We can no more afford to favor the discontinuance of vivisection than we can to argue against the utility of dissection—if we are willing to admit the former practice as unnecessarily cruel, we must likewise acknowledge that the latter is sacrilegious.

To the successful and continued cultivation of experimental physiology we owe some of the most remarkable, useful and brilliant discoveries in scientific medicine, and these discoveries could have been made in no other way than by vivisection. Without experiments upon living animals we should still be in ignorance of the circulation of the blood, the nature and mechanism of respiration, the formations of different parts of the nervous system, the distinction made by Sir Charles Bell between the fifth pair and facial nerves, the operation of transfusion of blood, the mechanism of artificial respiration, the treatment of serpent bites, and the separation of bone from the periosteum. Besides these discoveries we make no mention of others of less importance. Nor only have discoveries been made, but by means of vivisection we are constantly increasing our range of observation, improving our methods of investigation, and preparing the way for still more brilliant and satisfactory results.

When it is proved by the most enthusiastic advocates of animal protection that experimental physiologists are barbarous, unreasonable, and cruel; that they do not take every means in their power to mitigate suffering; that the discoveries yet to be made can be possible by other means than vivisection, then we shall be prepared to say that Mr. Bergh is right and that the profession is wrong.

Reviews and Notices of Books.

MATERIA MEDICA FOR THE USE OF STUDENTS. By JOHN B. BIDDLE, M.D., Prof. Materia Medica and Medical Jurisprudence, Jefferson Medical College. Sixth Edition, Revised and Enlarged. With Illustrations. Philadelphia: Lindsay & Blakiston. 1870. 8vo, pp. 434.

The profession generally are very well acquainted with the merits of this work, and have attested its particular adaptation to their wants by calling for successive editions. As a whole, it is a good book for the general student, presenting in an intelligible, succinct, and practical manner the value of the different articles of the *materia medica*. Some fault may be found with the arrangements of the subjects, and some dissension from the views of the author in regard to the therapeutic action of some of those remedies most in use; but these objections are more than outweighed by other notable features of the work. This sixth edition has evidently been revised with much care, and keeps up the reputation of the work.

LACERATION OF THE FEMALE PERINEUM AND VESICO-VAGINAL FISTULA: Their History and Treatment. By D. HAYES AGNEW, M.D. Philadelphia: Lindsay & Blakiston. 1873.

In a short introduction the author states that applications constantly received for the Pennsylvania Hosp. Reports and the *Medical and Surgical Reporter*, in which papers the subjects of his book appeared several years ago, induced him to place them before the profession in their present form. But even without such an incentive a treatise on so important lesions as lacerations of the perineum and vesico-vaginal fistula, which cause so much annoyance and distress to the patient, and which, during the recent years, excited considerable interest among the profession, would have been welcomed both by the gynecologist and the general practitioner.

The first part of the book is devoted to the history and treatment of lacerations of the perineum. Dr. Agnew wastes no words, but gives in clear and concise language, successively, the anatomy of the parts concerned, the causes, results, and treatment of these lesions. With regard to the time of and the contraindications to the operation, he furnishes important hints.

His mode of operating does not materially differ from that of many others, except in the manner of inserting the first suture, by which the independent closure of the septum becomes superfluous. The author believes that the division of the sphincter ani, as practised by J. Baker Brown, is not necessary to a cure, and that superficial sutures may be dispensed with. In support of this, he gives the history of several cases, all of which terminated favorably.

The subject of the second part of the book is Vesico-vaginal Fistula. Here, as in the first part, Dr. Agnew commences with the history of the disease, next enumerates its causes, etc., and finally describes the different methods of operating, as performed by Dr. Marion Sims, N. Bozeman, J. H. Simpson, J. Baker Brown, and others. But, strangely, the method of Dr. G. Simon, of Heidelberg, finds no mention, although he has been most successful in the operation of vesico-vaginal fistula, and as Prof. G. Thomas, in his treatise on diseases of women very properly remarks, has labored more earnestly and achieved more for it, with the exception of Dr. Marion Sims, than any one else.

Further on, the author states his own plan of treat-

ment, for which he claims nothing original, and which is in all essential points the same as that of the gentlemen referred to above. The different steps of the operation are clearly described, also the after-treatment and removal of the sutures. The causes of failure and the sequels of the operation are briefly explained, and the closing pages of the volume contain the report of a number of interesting cases treated by the author, which altogether makes the book a most desirable addition to any physician's library.

A STUDY UPON MENSTRUATION FROM THE POINT OF VIEW OF ITS INFLUENCE UPON CUTANEOUS DISEASES. (ÉTUDE SUR LA MENSTRUATION AU POINT DE VUE DE SON INFLUENCE SUR LES MALADIES CUTANÉES.) Par H. DANLOS. Paris, 1874.

In this well-written little brochure the author alludes to the fact that the subject under consideration has not till now been treated of in a systematic manner, and he alludes to its importance. He studies the question as influenced by the epoch of puberty, during the period of sexual life, and at the age of the menopause, and arrives at the following conclusions:

There is an evident sympathy between the utero-ovarian apparatus and the tegumentary system. This sympathy shows itself either by eruptions of which the evolution coincides with the menstrual epochs, or with the development of uterine disturbances, or by the disappearance of a morbid condition of the skin at the establishment of puberty or when dysmenorrhœal troubles cease.

In order to explain this, we may consider that cutaneous affections have, by tendency to urticaria, by their hyperæsthesic (herpetides), or neuralgic (zona), or anæsthetic (leproïd), character, a certain analogy with nervous affections; and that of all the organic systems of the economy the nervous system is the one which receives the *contre-coup* of uterine troubles (hysteria). Thus we would be led to regard cutaneous manifestations due to menstruation or its disorders, as reflex neuroses.

It is well to add that this sympathy is not evident in all patients, and that we only observe them, at least in a high degree, in quite a limited number. He cites some apposite cases of eczema, erysipelas, pemphigus, acne, scleroderma purpura, and melanoderma; but still some of his cases are unsatisfactory. Though hardly appropriate to his subject, he details a case of interest. It was that of a woman who, at the early part of one period of lactation, developed a pemphigoid eruption, and in a subsequent pregnancy again manifested the same lesion. This affection has recently been called herpes gestationis.

ON CARDIAC LESIONS IN FACIAL ERYSIPELAS. (DES MANIFESTATIONS CARDIAQUES DANS L'ÉRYSIPELE DE LA FACE. By Dr. A. SEVESTRE. Paris: A. Delahaye. 1874.

The author alludes in his introductory chapter to the importance of the study of the visceral lesions which occur during the course of the essential fevers, and also to the fact that during the course of facial erysipelas the heart has seldom been examined. Indeed the bibliography of the subject is as yet very scant. The author pays a grateful tribute to Dr. Jaccoud, of Paris, and states that it was this eminent physician who first called his attention to these lesions, which he has studied with great care. The result is a small, well-written *brochure*, which at the end contains the author's conclusions very succinctly stated. They are as follows:

1. That during the course of facial erysipelas we may observe troubles of the heart. These manifesta-

tions, without being very frequent, are so much so that they cannot be regarded as coincidences. They are of two kinds: sometimes consisting of lesion of the endocardium, more rarely the pericardium; sometimes it consists of a myocarditis.

2. Endocarditis develops itself at the *début* of the erysipelas; it can be developed at its termination; but in the greatest number of cases it appears while the cutaneous eruption is in an active condition. Its duration is variable, disappearing ordinarily nearly at the same time as the erysipelas, sometimes before it, and it may leave a permanent lesion. Pericarditis is more rare. It is ordinarily of a dry character and limited in extent, and is scarcely ever observed except when associated with endocarditis. Sometimes the endocarditis is the sole lesion. Cases of pericarditis with effusion are almost exceptional.

3. Myocarditis and fatty degeneration of the muscular fibres of the heart may be observed in erysipelas, as also in variola, typhoid fever, and other similar affections.

4. The cardiac lesions in erysipelas (endocarditis as well as myocarditis) are not in connection with the cutaneous lesions, but they arise, as do the latter, from the general disturbance of the organism. The knowledge of these lesions confirms the comparison which can be established between erysipelas as the infectious diseases.

The author alludes to the fact that we find visceral lesions after burns, and also after some general eruptions, which are probably due to reflex influence; but he thinks, as he says in his conclusion, that this feature does not obtain in the affection under consideration.

A CONTRIBUTION TO THE STUDY OF THE NECROSIS CAUSED BY PHOSPHORUS. (CONTRIBUTION À L'ÉTUDE DE LA NECROSE DE CAUSE PHOSPHORÉE.) Par Dr. A. JAGT. Paris: A. Delahaye. 1874.

THE author of this excellent little brochure runs rapidly over the list of authors who have from time to time written on this subject, and while he accords them the respective merits of their works, he thinks he also, from his observation, can contribute somewhat to general knowledge. His attention was drawn to the subject by the death of a patient in whom the necrosis had extended to the base of the skull, and who also presented the visceral lesions peculiar to phosphorus poisoning. As an attest of the value of the work it is well to state that it has been written under the suggestion and with the kindly assistance of the celebrated French surgeon M. Verneuil. The work is essentially a clinical study, and the author has appended to it a series of aphorisms, which we quote, which give a better idea of the contents of the book than an analytical review would do. These conclusions are as follow:

1. Necrosis can, in extending to the cranial bones, invade successively the malar, palatine, and turbinated bones, vomer, ethmoid, and temporal, and even the occipital bones, necessarily inducing death, and giving rise to symptoms varying with the organs which are attacked.

2. The principal causes of this extension should be attributed to the prolonged presence of necrosed bone in the tissues, and to a failure of the free discharge of pus.

3. In individuals subjected to phosphorus vapors, and afflicted with necrosis, the propagation of the osteoperiosteal inflammation is by means of continuity.

4. The eliminating process of the bone entrains of necessity an arrest of the morbid process.

5. The rapid course of the phosphoric osteo-periostitis, and its well-marked extension, is inimical very often, especially by its consequent profuse suppuration, to the process of bony regeneration.

6. Prolonged bony suppuration, and the digestive disorders which they entrain, induce death by producing visceral lesions, such as amyloid and fatty degeneration of the viscera.

7. Every instance of fatty degeneration in this disease should not be attributed to phosphorus.

8. Except in certain peculiar cases, but very rare ones, in which no expectant course can be pursued, the surgeon should in a general manner consider as urgent and necessary surgical intervention before the sequestrum becomes movable, as the necrosis is rapid and extensive, and the general condition rapidly deteriorates. This intervention should be guided by the special indications of each case. The author gives an excellent lithograph of a skull, the base of which was extensively involved. He also details the case fully.

UPON URINARY FEVER. (DE LA FIÈVRE DANS LES MALADIES DES VOIES URINAIRES.) By Dr. ALBERT MALHERBE. Paris, 1873.

THERE is certainly no more interesting, and though, unfortunately, not very clearly understood, subject in the range of pathology than the one treated of in this brochure. The author has, under the guidance of M. Guyon, of the Necker Hospital, Paris, carefully followed up a large number of cases of genito-urinary diseases, of which he gives histories; and deducing from them their salient points, has arrived at the following conclusions regarding the subject:

1. We observe during the course of diseases of the urinary organs, and after operations upon them, certain febrile conditions which have been termed *uræmic fever*. This fever, always serious, may rapidly induce death.

2. *Uræmic fever* manifests itself under two forms: the acute form, with distinct severe invasions, but irregular in their duration and apparition; the mild form, in which remittance in type is noticed. It can be complicated with certain phlegmasiæ, pericardiac, articular, or diffuse, in the intermuscular connective tissue of the limbs. These phlegmasiæ frequently suppurate even when they involve the articulations. They are grave in character.

3. *Uræmic fever* appears always to be the manifestation of an ephemeral or permanent lesion of the kidney, which produces, as a consequence, a profound disturbance of the urinary secretion, and, as a result, the retention of urinary ingredients in the blood.

4. The lesion of the kidney may be either a simple congestion or an interstitial nephritis.

5. The interstitial nephritis which complicates urinary diseases may terminate either in suppuration or in atrophy of the kidney.

6. The symptoms of this fever are of two kinds: the reactional symptoms, due to the renal inflammation; the symptoms of intoxication, due to the retention of excrementitious materials of the urine.

7. The principal therapeutic agents to combat this fever are sudorifics and alcohol; locally, dry cups to the kidneys. Sulphate of quinine is far from meriting the reputation which it enjoys in the treatment of urinary fever.

8. Surgical interference is limited to the cases where there is stagnation or retention of urine. The re-establishment of the flow of urine by means appropriate to the nature of the trouble is the leading indication.

The work is clearly written, and is certainly an honest attempt to explain rationally the peculiar combination of symptoms by their causes, their course, and by an examination of the lesions which they leave after them.

Correspondence.

NEW DISCOVERIES IN HYDROPHOBIA.

PINE RIDGE PAPERS.

III.

AT least I imagine I have made a discovery, and have, luckily for myself, distanced all my competitors in the human race for fame. But if a man finds that he has brains, it is incumbent upon him to show them to advantage. I must therefore be excused for being a little positive in some of the statements I have to make. When I first announced the intention to discover Kanine I was determined to find it, as I had a theory of hydrophobia which could not amount to anything unless the said discovery was made. A medical friend of mine, to whom I confided my designs, informed me that I was two hundred years behind the times, and that an instrument had been figured by Galen to facilitate inoculation with this very material, which had, by the way, a very similar name.

I confess this rather staggered my enthusiasm; but as I afterwards found that his assertions were based upon the hearing of several evasive and unsuccessful specialists, I was encouraged. There is no question in my mind but that the active principle of the laryngeal mucus is this Kanine or extract of Bark; and also that hydrophobine, which I expected was a deposit peculiar to the nerve centres, is identical with it. It will not serve any useful purpose to tell how I obtained the extract. Suffice it to say, that it was by an entirely new process which I defy any one to imitate. The fact is, I have invented an apparatus especially for the purpose, a description of which I intend to make public any time the profession choose to doubt its wonderful manner of working. As no one can be prepared at present to appreciate its adaptation to the purpose, and no one but myself can make it work at all, I do not expect that any advantages will be taken of me in the shape of suggestions for improvement.

Kanine, by a little stretch of the imagination, may be said to be a myxomatous material, at least so far as the number and arrangement of its ingredients are concerned. Contrary to what I at first expected, it has a striking affinity for water, its union with the latter being marked by a sensible rise in the temperature, a bubbling sonorous sound, with the production of froth upon the surface in which are suspended oil globules and granules. These phenomena are sufficient to distinguish it from all known extracts.

As yet it is impossible to say what particular effect this substance may have when injected into the circulation of animals. With the assistance of an enterpris-

ing newspaper reporter, I have already surreptitiously introduced it into the circulation of several healthy dogs in my neighborhood; but knowing the prejudices of the community against such a course, the determination is to keep the matter quiet for the present, and study the results from a thoroughly independent standpoint. My design by such a course is to give such dogs as may become infected, a chance to go through the different stages of the disease in a perfectly natural way, without the element of imagination having anything to do with a diagnosis. The point to be established is this: in case any of the owners of these dogs are bitten I can prove that they (the dogs) really had hydrophobia, and that they were not simply angry at the time the bite was inflicted. This may appear to some to be a trivial matter, but I believe in establishing premises to any argument—in striking for truth at its very root. Principles, not men, is my scientific motto.

At first I had a great deal of difficulty in demonstrating some remarkable microscopical changes in the nerve tissue. If you do not prepare specimens in a particular way, nothing is to be seen. The element of time is a most important one. With a pardonable but impatient anxiety to see what was to be seen, I yielded on two occasions to the importunities of my friend the reporter, to place slices under the microscope before the time was up. My experience teaches me that nothing less than three hours will do, no matter what process you may employ. My plan is peculiar and original, and here I am again reluctantly compelled to refer, in passing, to my new analysing apparatus. To this I have an attachment, an electric battery and freezer, so arranged that currents from both can be sent through the specimen alternately, thus greatly expediting the result. A gentleman much given to electricity, who happened upon me unawares, and while the apparatus was working, informed me that my arrangement was an infringement upon one of the patents on electrical machines. If this be so, I am very willing to fight it out so long as any medical journal will give me the space to do it. And this, by the way, can give me no mean advantage in the way of an advertisement of my particular specialty. But this will be, of course, secondary to the principle involved of proving to the world that I am capable of making useful discoveries and sticking to my text at all hazards. Until disputed, I claim my plan to be original and in advance of the age.

As no time is to be lost when once the specimen is ready for the microscope, many inexperienced persons are apt to be disappointed in what they may wish to see. To prevent this, I have caused to be constructed an attachment to my apparatus, in the shape of a double-back-action concentric, parallel-tunnelled slicer, worked by a lever, and this lever connected with the negative pole of the battery. This knife operates directly upon the specimen while in the preparatory mixture, and transfers it rapidly to a slide before the granules have a chance to change their positions. Electricity is the motive power in this case. The arrangement of its blades is such that every section is cut so as to show a gradual and varying thickness from the $\frac{1}{16}$ to the quarter of an inch. The obvious advantage of this is, if you fail to see anything in the thin section, you are sure to find it in the thicker portion, of course taking into account the ordinary difficulties of transmitting light through the larger end.

If all these conditions are fulfilled, any experienced microscopist can find what he desires to see.

Now as to microscopic appearances in this disease, they are sufficiently numerous and important to warrant a reference. For myself I prefer the thicker por-

tions of the specimens for examination under the microscope, because any good results which may be obtained are wholly due to skill in the use of the instrument. If any one aims at high art in microscopy, the more difficulties there are to encounter the better able is he to maintain a superiority—and this is, after all, what we are all modestly striving for.

Of course all the elements of nerve tissue are present if the specimen is duly placed upon the slide and the cover in position. After this, the most important matters to be alluded to are focussing and light. The nerve cells are best brought out by pressure of the object glass upon the cover. You are sure of a short focus by this plan (and I believe in a short focus), at the same time the cells themselves are seen to be much enlarged. My assistant has offered what he believed to be an original suggestion, that this enlargement was due directly to pressure. I, however, had the same idea long ago until I proved myself mistaken by noticing that the cells still remained the same size after the pressure was removed. I have also noticed that the oil globules and granules which are so abundant can be made to change their relative positions by a delicate and judicious regulation of this pressure. This fact has a very important bearing in the estimation of the relation of the elements of any tissue to each other.

Now as to treatment. This is really a very important point in any disease. It is unnecessary for me to say that my experience has been very large, and that what I am about to recommend is of particular value. Permit me to state that I have tried everything in the shape of medicine that has ever been tried before, but I found myself utterly at sea until I struck on a plan of my own.

When speaking of the discovery of Kanine I remarked that I had a theory as to the nature of hydrophobia, and my treatment is necessarily founded upon it. In the first place, Kanine is the active principle of the disease. When an animal is bitten, the granules which make up the bulk of this new substance find their way through the nearest nerve into the nervous circulation. They lie dormant for a while, like the syphilitic corpuscle, then, after they have become powerful and multiplied, everything is ready for the explosion. By a sort of reflex influence they are transferred to the medulla, where they show a peculiar affinity for the roots of the nerves which originate in that quarter. As a result of their presence the new cells are much irritated, enlarge, and finally become the victims of a chronic fatness better seen under the microscope than described. Then the irritation, in accordance with well-known neurostatic laws, is transferred to the ends of these nerves, and the larynx secretes the thick mucus which forms the grand receptacle for the Kanine. This animal bites another, and so the chain of circumstances is kept up.

There are two things to take into account in the treatment. The first to prevent the nervous centre from becoming irritated, and the second to prevent the accumulation of the mucus. Of course the best plan is not to be bitten at all, but once bitten the granules are sure to get the start of even the first physician who arrives on the scene. The next best thing is to neutralize their effects—and my method of applying galvanism is the thing. I have devised an electro-galvanic muzzle which not only keeps up a constant supply of static electricity to the medulla, but by means of its connection with a negative pole in the anus keeps the whole spinal column in a state of lively interchange of molecular elements. It is this very action which destroys the Kanine granule, and which, at the same time, quiets the irritation of the whole cerebro-spinal system. This

method is an improvement upon the one lately advocated in the treatment of tumors, and known as "working up the base."

In applying the muzzle I have a word of caution to offer. I need not say it is a very ticklish little operation, and is not likely to be well received by the patient. I have been in the habit of entrusting the application to my assistant, and have never had cause to regret it. In fact, I think in all the operations around hydrophobic dogs, it is always prudent to leave them to a trusty student. As proof of this I may state, in passing, that I have just attended the funeral of the attendant who was bitten in the buttocks, and whose case I referred to in my previous paper.

As for the mucus in the larynx, that is removed by an aspirator, which I have modified for the purpose. The instrument is attached to a collar, is worked by means of a concentric screw, and only while the animal is making convulsive efforts to swallow. The end of the screw impinges against the under jaw, and any movement of the latter sets the former in motion. It is needless to say that the animal is invariably relieved. One of my assistants who was bitten by rolling backwards over a barrel upon a hydrophobic dog, and who is troubled with this Kanine mucus, wears an aspirator in his shirt collar. He has written me a strong certificate, which he is quite willing, on his own account, to have freely advertised.

Just as soon as the mucus accumulates in any undue quantity the convulsive efforts to swallow commence, and then the beauties of my instrument come in, relieving the patient just in the nick of time. I have been informed that it has evacuated from one dog-patient three quarts of mucus in twenty-four hours. What could a poor dog do with that quantity of secretion in his larynx? The answer is obvious even to a first-course medical student. My mucoid assistant says he would not be without it. He thus eloquently refers to its utility in his certificate: "I have used the Pine Ridge Aspirator for a long time. My very life hangs upon its working. Existence would be impossible without it. It is a boon to the race. I cordially recommend it to everybody who has been bitten by a mad dog, or who is likely to be bitten. I find it best to have it always on hand," etc. The last two sentences are particularly strong, and were inserted by myself over his signature, to make the apparatus sell.

In these papers I have tried to go over, in a cursory manner, the whole history of hydrophobia, and have taken particular pains to point out the properties of the active principle of this disease—Kanine. If I have succeeded in directing the attention of the profession to this subject, and proving that no one but myself knows anything about it, I shall be amply repaid for the trouble I have taken. To such as have a more than ordinary interest in the further study of this disease, I would refer them to my forthcoming work upon the subject. Price, \$5.00. * * *

PINE RIDGE, ON THE HUDSON.

SOLUTION OF QUININE FOR HYPODERMIC USE.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—I notice, in a recent number of the MEDICAL RECORD, among the "Notes of Practice" from Bellevue Hospital, the formula for the solution of quinine, which I have been in the habit of using for hypodermic injection. The reporter speaks of thirty

minims as containing between two and three grs. of quinine. It would be more correct to say three and four grs., as there are fifty grs. in each fluid ounce. He also speaks of using alcohol. This complicates the solution and had better be left out. I used it only because, for convenience, and to be sure of retaining the carbolic acid in a liquid form. I use, for all purposes, a mixture containing equal parts of the two. My assistant, Dr. G. W. Murdock, in preparing this formula frequently, has lately improved upon it, inasmuch as the solution now contains only about five minims of strong sulphuric acid instead of eight. It is a serious error to state, as in the article referred to, that the acid (sulphuric) is "to be added drop by drop until the solution clears up," as in that case, one compounder might have five minims, and another ten or fifteen, according to his care and skill in manipulating. Even careful apothecaries, with my written directions before them, have failed in making a clear solution with the proper quantity of the acid. Finding that the carbolic acid rather interferes with the solubility of the quinine, I now direct only two minims to the ounce. So that the formula reads:

B. Quinia disulphatis	gr. i.
Acidi sulphurici	℥ v.
Acidi carbolici	℥ ij.
Aque destillat.	℥ i.
M.	

And it had better be manipulated as follows: Place the quinine—say 400 grs.—in a mortar, rub up thoroughly, distribute the strong sulphuric acid (℥ xl.) over it; rub it in until well mixed; add cold water (℥ viij.); place in porcelain dish over a lamp, and let it come to the boiling point, stirring with a wooden spatula. When cold, add the carbolic acid (℥ xvi.) and shake well in a bottle. It should then be perfectly clear, though it should be filtered to separate the small foreign particles which are usually floating in it.

COLD SPRING, N. Y.

F. D. LENTE, M.D.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from September 5th to September 18th, 1874.

ABADIE, E. H., Surgeon.—Relieved from duty in Mil. Div. of the Atlantic, to proceed to St. Louis, Mo., and await orders. S. O. 200, A. G. O., Sept. 11, 1874.

SUMMERS, JNO. E., Surgeon.—To report to the Comd'g Gen'l Dept. of the Platte for duty as Medical Director of that Department. S. O. 200, c. s., A. G. O.

SMITH, J. R., Surgeon.—Assigned to duty as Post-Surgeon at Fort Monroe, Va. S. O. 200, c. s., A. G. O.

WRIGHT, J. P., Surgeon.—Assigned to duty as Chief Medical Officer, District of New Mexico. S. O. 96, District of New Mexico, Sept. 7, 1874.

STORROW, S. A., Asst. Surgeon.—To report in person to the Comd'g General Dept. of California for assignment to duty. S. O. 200, c. s., A. G. O.

HARTSCOFF, A., Asst. Surgeon.—Assigned to duty as Post Surgeon at Fort Laramie, Wy. Ty. S. O. 126, Dept. of the Platte, Aug. 29, 1874.

NOTSON, WM. H., Asst. Surgeon.—Ordered to New York City for examination for promotion before the Army Medical Board, and at its conclusion to report to the Comd'g General Dept. of the Platte for assignment. S. O. 200, c. s., A. G. O.

HUNTINGTON, D. L., Asst. Surgeon.—Relieved from duty in Dept. of the Columbia, and will report in person to the Commanding General Dept. of California for assignment to duty, in addition to his duty as a member of the Medical Examining Board, now in session at San Francisco, Cal. S. O. 203, c. s., A. G. O., Sept. 16, 1874.

WILLIAMS, J. W., Asst. Surgeon.—Assigned to duty as Post Surgeon at Fort Rice, D. T. S. O. 193, Dept. of Dakota, Sept. 5, 1874.

BROOKE, JOHN, Asst. Surgeon.—Assigned to duty at Fort Cape Disappointment, W. T. S. O. 124, Dept. of the Columbia, Sept. 4, 1874.

KINSMAN, J. H., Asst. Surgeon.—Granted leave of absence for one month, with permission to apply for an extension of five months. S. O. 189, Dept. of Dakota, Aug. 31, 1874.

BARTHOLOMEW, JNO. H., Asst. Surgeon.—Ordered to New York City for examination for promotion before Army Medical Board, and at its conclusion to report to the Comd'g Gen'l Dept. of the Columbia for assignment. S. O. 200, c. s., A. G. O.

CARVALLO, C., Asst. Surgeon.—Ordered to New York City for examination for promotion before Army Medical Board, and at its conclusion to report to the Comd'g General Dept. of the Missouri for assignment. S. O. 200, c. s., A. G. O.

LAUDERDALE, J. P., Asst. Surgeon.—Assigned to duty at Fort Wingate, N. M. S. O. 143, Dept. of the Missouri, Sept. 10, 1874.

ELBREG, F. W., Asst. Surgeon.—Ordered to New York City for examination for promotion before the Army Medical Board, and on its conclusion to report by letter to the Surgeon General. S. O. 200, c. s., A. G. O.

HALL, J. D., Asst. Surgeon.—Assigned to duty as Post Surgeon at Fort Benton, M. T. S. O. 193, c. s., Dept. of Dakota.

EWEN, CLARENCE, Asst. Surgeon.—Granted leave of absence for twenty days from October 1, 1874, on condition that he furnishes, at his own expense, a substitute during his absence. S. O. 135, Dept. of the Gulf, Sept. 9, 1874.

* Medical Items and News.

MEDICAL BOARD OF BELLEVUE HOSPITAL.—The following is the Medical Board of Bellevue Hospital as constituted by recent resolutions of the Commissioners of Public Charities and Correction.

Consulting Physicians and Surgeons.—John T. Metcalfe, B. W. McCready, William H. Van Buren, Isaac E. Taylor, Fordyce Barker, Lewis A. Sayre, Alexander B. Mott, and John J. Crane.

Visiting Physicians and Surgeons.—Austin Flint, Sr., James R. Wood, Alonzo Clark, Henry B. Sands, Alfred L. Loomis, Stephen Smith, Wm. B. Eager, Ernst Krackowizer, Edward G. Janeway, Frank H. Hamilton, Francis Delafeld, Thomas M. Markoe, William H. Thomson, Erskine Mason, Gouverneur M. Smith, and John W. S. Gouley.

VELPEAU.—An anecdote is told of Velpeau, the eminent French surgeon. He had successfully performed,

on a little child five years old, a most perilous operation. The mother came to him and said:

"Monsieur, my son is saved, and I really know not how to express my gratitude. Allow me, however, to present you with this pocket-book, embroidered by my own hands."

"Oh, madame," replied Velpeau, sharply. "my art is not merely a question of feeling. My life has its requirements like yours. Dress, even, which is a luxury to you, is necessary for me. Allow me, therefore, to refuse your charming little present in exchange for a more substantial remuneration."

"But monsieur, what remuneration do you desire? Fix the fee yourself."

"Five thousand francs, madame."

The lady very quietly opened the pocket-book, which contained ten thousand francs in notes, counted out five, and after politely handing them over to Velpeau, retired. Imagine his feelings!

MALPRACTICE—PROPOSED LAW.—The Northeastern Ohio Medical Association has proposed to the Legislature a law with the following requirements: 1st. That in every case of malpractice the question shall be referred to a board of three medical men; one to be chosen by the patient or his or her next friend, one by the surgeon charged with malpractice, and these two shall make choice of an umpire. 2d. That it shall be the duty of these arbitrators, after hearing the testimony on both sides, to give the written opinion of the majority to the contestants in the case. If this opinion be adverse to the charge of malpractice, and the plaintiff shall still proceed to action at law, that then he be required to give bail for the costs, and in the event of a failure to establish his case, he may be made to answer in damages to the defendant for his loss of time and expense incurred in the defence.—*Philadelphia Medical Reporter*.

THE GRAPE CURE.—The headquarters of this remedy are at Merau, in the Tyrol, of which province it was some time the capital. Apart from the specific benefits of the "cure," Merau has much to recommend it in the way of climate, to which, we suspect, the grape treatment owes not a little of its efficacy. In August, September, and October, its population, 4,500, is considerably reinforced by German, Russian, and Italian visitors, who, with a sprinkling of English and Americans, have come for the "cure." Accommodation is comfortable and cheap—cheaper, while not less comfortable, than in most of the Italian and French places of resort. Invalids suffering from chest affections—bronchitis or consumption in its pre-tubercular stage—are the chief subjects of the grape treatment. Less than three pounds of grapes a day is not enough for efficacy. The patient begins with one or two pounds per diem, dividing the quantity into three portions—one taken an hour before breakfast; the next before dinner, which comes off at 12.30 or 1 P.M.; and the last in the afternoon or evening. The grapes are eaten *sub Joco frigido*, and after two or three days the quantity is increased by half a pound until it reaches three or four pounds. This amount often suffices the patient, who finds, as a rule, that he gains in weight and in strength also. Chronic liver complaints, especially when due to excess in wine-drinking, are, it is said, remarkably relieved by the "grape cure," the potash salts in the fruit supplying the element which the wine, in the process of manufacture, has lost. Hepatic dropsy has been known to be mitigated in this way. Patients should not be discouraged if, after the first day or two, they feel not so well

as they were before; while one signal point in favor of the cure is this: that no special diet is enforced. Indeed, the grapes themselves become so satisfying that indulgence in other food is hardly necessary. Before trying the "cure," however, the patient should have his case thoroughly examined by his physician, who will tell him how and to what extent he may avail himself of the "Natur therapie of Merau."—*The Lancet*.

HAY-FEVER.—Dr. Geo. M. Beard, of this city, is engaged in the study of the so-called hay-fever with a view of proving it to be of nervous origin. For this purpose he has issued blank circulars to such as may be interested in aiding him in making out statistics.

PHTHISIS.—To stop the ravages of consumption in a family that had lost several of its members by the disease in Lewiston, Me., the body of the last one who died was disinterred and reburied with the face downward.

INHERITANCE OF DEFORMITIES.—The heredity of anomalies of organization has been demonstrated in several instances. One of the most singular of these is the case of Edward Lambert, whose whole body, except the face, the palms of the hands, and the soles of the feet, was covered with a sort of shell, consisting of horny excrescences. He was the father of six children, all of whom presented the same anomaly at the age of six weeks. The only one of them who lived, transmitted the peculiarity to all his sons, and this transmission, passing from male to male, persisted through five generations. Mention is also made of the Colburn family, where the parents for four generations transmitted to the children what is called sexdigitism, i.e., hands and feet with six digits each. Albinism, halting, hare-lip, and other anomalies, are in like manner reproduced in the progeny.—"*Heredity*," in *Popular Science Monthly*.

HEMATOMETRA IN A CASE OF UTERUS, FROM NON-COMMUNICATION OF ONE OF THE CAVITIES WITH THE VAGINA.—The patient was 21 years of age, and entered the Christiania Hospital March 19th, 1873. She had suffered for three years from pains in the right iliac region; these pains increased during the menstrual flow, which was regular but scanty. On examination there was found in the right iliac region a mobile, elastic tumor, three or four inches long and one broad; just below this, and somewhat nearer the median line, there was another tumor, filling the pelvic fossa, and extending half an inch above the symphysis. On examination, no trace of the vaginal portion of the uterus was found. In making a diagnosis, retro-uterine hamatocele, uterine fibroid, and pelvic cellulitis were excluded, and it was believed to be a case of ovarian tumor displacing the uterus. A puncture was made through the vagina into the most prominent portion of the tumor, and a small quantity of a thick, brownish fluid removed by aspiration. Symptoms of peritonitis occurred on the fourth day, and the patient died on the ninth day after the operation. At the autopsy it was found that the uterus was divided into two portions, that each of the halves was regularly furnished with Fallopian tubes and ovaries, but that the right cavity had no communication with the vagina. Hence it became gradually filled and distended by the retention of the menstrual blood. There were also found signs of old and recent peritonitis and commencing abscesses in the left kidney, which was larger than usual. The right kidney was wanting, but the suprarenal capsules were present on both sides.—*Nord. Med. Ark.*, vi., 1. 1874.

ANALYSIS OF THE AIR IN ROOMS WHERE THE PAPER HANGINGS CONTAINED ARSENICAL COLORS.—Hamborg alludes to the well-known fact that observations have already shown the danger of breathing the air of rooms where arsenical papers are used. The way in which such poison operates has been variously explained by different observers. Some have supposed that the fine particles of coloring matter became separated from the paper, and, floating in the air, are inhaled with the breath. Chemists have been at variance, some finding arsenical gases in the air of such rooms, and others arriving at negative results. Hamborg's experiments were made in a room where the color employed was Schweinfurt green.

His apparatus was as follows:

a. A U-shaped tube for the reception of the dust.
b. Three U-shaped tubes, filled with cotton, to completely separate the solid particles of arsenic from the air.
c. Two bulb apparatuses, containing a solution of nitrate of silver, to collect any arsenic which might be dissolved in the air.
d. Two gasometers of fourteen litres' capacity, alternately filled with water, to establish an aerial current.

The air was conducted through this system of tubes from the 16th July to the 16th Aug. of 1873. The quantity of air thus examined amounted to 2,160 litres. In the course of the experiment the solution of nitrate of silver gradually deposited a black precipitate, resembling the arsenite of silver, and after the removal of the silver by nitric acid, the characteristic arsenical ring was obtained by the Berzelius-Marsh apparatus.

The author concluded from these experiments that arsenic was present in the air, and probably under the form of arseniuretted hydrogen.—*Nord. Med. Ark.*, vi., 1. 1874.

A MODEL ADVERTISEMENT.—A recent Journal—not of the regular school—contains a long advertisement of a celebrated practitioner, from which the following extract is taken:—

Have yeez pains in yer bones, or a botherin' ache
In yer jints after danein' a jig at a wake?
Have yeez caught a black eye from some lounderin'
whack?
Have yeez vertebral twists in the spine av yer back?
Whin yer walkin' the strates are yeez likely to fall?
Don't whisky sit well on yer sttomach at all?
Sure its botherin nonsense to sit down and wape,
When a bit av powder 'ill put yeez to slape;
Shtate yer symptoms, me darlins, and niver yeez donbt,
But as sure as a gun I can shtraiten yeez out.
Come thin ye poor craythurrs, and don't yees be scairt!
Have yeez batin' and lumberin' thumps at the hairt?
Wid ossification and acceleration,
Wid attenuation and ragurgitation,
Wid amaciation and axacerbation,
Wid praprecipitation and hapitization,
Wid praocneupation and avaporation,
Wid hallycination and acrid saceration,
Wid black arruption and purtification,
Wid great jactitation and conagulation,
Wid square titilation and cowlid perspiration?
Be me sowl! But I'll bring all yer woes to complation;
Unless yer in love—thin ye're past all salvation.

SLOW PROGRESS OF HOMOEOPATHY IN GREAT BRITAIN.—The *Medical Press and Circular* notices a leading article in the *Homoeopathic Review*, in which the latter laments over the unattractiveness of the homoeopathic practice, and makes an appeal to its readers to unite in seducing, if possible, the rising generation of the medical profession. The *Review* makes the statement that "of the towns in England above

10,000 and below 20,000 population at the last census, 45 possessed no qualified representation of homoeopathy at all, and twelve other towns had only one each; of the towns between 20,000 and 50,000 population, no less than 38 had no resident homoeopathist—14 of them had only one each, and 5 other only two each; of the towns between 50,000 and 100,000, 9 had no homoeopathic physician, 7 had only one each, and 6 others had only two each; while there were, and are actually, 4 towns above the 100,000 limit in which no homoeopathist has settled."

The *Review* further says—. . . "Neither can we feel satisfied that our hospitals and dispensaries do at all what they might do in the way of influencing third and fourth years' students. What has London done in this matter with its hospital of sixty beds? What has Birmingham with its well-tried staff and influential committee? What have the Liverpool dispensaries, which admit their 10,000 or 12,000 cases a year? It is not from these places that our recruits have come or are coming. . . . The local influence of these institutions on the members of the profession, and on the students in our metropolitan and provincial schools, is practically nil."

ACTION OF IODIDE OF POTASSIUM UPON THE BLOOD.—The reactions of the iodide of potassium, when administered medicinally, are thus described: In the stomach the iodide either undergoes no change, the elements of ordinary articles of food being incapable of decomposing it, or else by means of the chlorine hydriodic acid is formed, by which the ultimate reactions are not modified. Entering the circulation in an exceedingly dilute state, the iodide of potassium is at once decomposed by the superabundant carbonic acid into free iodine and carbonate of potassa. Now the iodine will have the greatest affinity for those substances in the blood with which it makes the most complex combinations, this affinity being most intense at the moment of the iodine becoming free. Therefore, of these substances in the blood those first acted upon would be the "miasmatic matters and ferments," next to these the fibrinous and then the albuminous substances, and last of all, the fats. The iodine acts upon these substances by virtue of its disposition to take the place of their component hydrogen. It, however, does not form permanent compounds with them, but, having broken up their chemical union, facilitates their oxidation in the oxygen of the blood. The free hydrogen combines with an equivalent of iodine, forming hydriodic acid, which is in turn attacked by the oxygen, iodine is again eliminated, and so the process is continued.

On the other hand, the other component of the iodide of potassium undergoes changes which supplement the action of the iodine. As the compound is decomposed the potash is changed into the hyperoxide of potassium, the only oxygen compound upon which the iodine does not act. Here we have, besides the iodine, a powerful decomposing agent, which, by its strong oxidizing effect upon organic substances, assists the consumption of the blood elements. The hyperoxide is reduced to potassium, which again combines with carbonic acid, and carbonate of potassa is produced as at first.

Hence the action of the iodide of potassium depends upon the decomposing effect of free iodine upon the substances contained in the blood, and their oxidation and consumption by the hyperoxide of potassium—"a result," the writer observes, "which is confirmed by clinical experience."—*Prof. Kammerer, Virchow's Archiv*, 1874, and *Memorabilien*, xix., 4.

SPECTROSCOPIC ILLUSTRATION FOR DR. WATERMAN'S ARTICLE.

Original Communications.

THE IMPORTANCE OF THE SPECTROSCOPE IN FORENSIC CASES.

A PAPER READ BEFORE THE MEDICO-LEGAL SOCIETY OF NEW YORK, APRIL, 1874.

By S. WATERMAN, M.D.,

NEW YORK.

MR. PRESIDENT AND GENTLEMEN:—No sooner were the brilliant discoveries, by the aid of the spectro-scope, in chemistry and astronomy made known, than the attention of scientific and professional men was directed to the inquiry, Whether the marvellous analytical powers of this instrument could not also be employed in the service of medicine? This inquiry, upon whose solution some of the best minds of the continent were employed, has given a highly satisfactory and affirmative answer, and its adaptation to physiological research will furnish us the material for this evening's consideration.

By means of spectrum analysis we have become acquainted with the laws governing vital processes. By it we have been enabled to lift the curtain, beyond which, since eternity began, those mysterious processes were carried on, which man sought continually to understand, upon which the most strange and conflicting theories prevailed, and which he erroneously thought could never be unravelled. Spectrum analysis has carried us far beyond our former conceptions of the laws of life, health, and death, and forensic medicine comes in for a fair share of the information and benefits thus accumulated from the advance of this science. A few years ago it would have been possible to tell you all that the spectro-scope could do in forensic medicine, in the space of half an hour; at this present day, the material that has been accumulated could not be exhaustively laid before you in a dozen lectures. Spectral analysis applicable to forensic medicine has become a science by itself, compact, reliable, well-founded, and far-reaching, capable of solving most important legal questions; its application is simple, and it responds to the minutest amount of material. Indeed, it is the extraordinary delicacy and sensitiveness of the spectral test which gives to its application so great a value, and so extensive a scope. It responds distinctly and immediately where the highest magnifying powers of the best microscopes can no longer give us any information; it gives us a valuable reaction for every alteration which blood undergoes when acted upon by physical or chemical agencies; it analyzes the flames of gases, and those of mineral and metal poisons, and unravels the secrets of crime with wonderful alacrity and unimpeachable certainty.

By spectral analysis we understand a scientific process in which light, solar or artificial, is made use of to analyze and to demonstrate substances both organic and inorganic. The instrument employed consists of a system of prisms and lenses, by means of which rays of light are broken up into a series of colored tints, called a spectrum, and which offers to the eye all the colors of the rainbow with great beauty and brilliancy. The instrument thus employed is called a spectro-scope, or if connected to a microscope, a micro-spectro-scope. It is well known what a prism is, and the changes which white light undergoes when passing through it. In the first place the rays, as they pass through a prism, are bent out of their course; they spread fanlike

to the right and to the left, they disperse, and this we call the refraction of rays. But we witness another and more interesting phenomenon. The white rays in passing through the prism are decomposed, broken up in a number of beautiful tints, arranged in never-changing order, presenting red, orange, yellow, green, blue, and violet. This prismatic band we call a spectrum. We distinguish between an interrupted and a continued spectrum. When artificial light is passed through a prism, the colored band is not traversed by any lines, and the spectrum is therefore a continued one. When, however, sun, moon, or star light is used, the spectrum is found to be traversed by many lines, and this is therefore called an interrupted spectrum.

In order to see these lines well, we admit the rays through a narrow slit in a shutter leading to a darkened room. In the spectro-scope such a slit is attached to one of the tubes.

Newton, although he examined this subject in all its bearings, never saw the sun lines, because he obtained his spectrum by a round hole in the shutter, and the rays that entered overlapped each other and gave him a diffused spectrum. Wollaston described these lines in 1802, but did not understand their importance. Fraunhofer, a learned optician at Munich, used them first for purposes of measurement in 1814. He designated the most prominent of these lines by the letters of the alphabet, from A to H, and they have since been known as the Fraunhofer lines. Kirchhoff left us a map of these lines, a masterpiece of correctness and skill, containing many hundreds of sun lines, and our distinguished Rutherford has photographed them right from the sun himself. The exactness of these two mappings is truly wonderful. Angstrom has given us a map containing many thousands of these lines. The orbs receiving their light from the sun have all these lines in the exact position of the spectrum. Fixed stars, like the resplendent Sirius and others, give quite different arrangement of sun lines, and some of the comets give only one or two bright lines, and no black lines at all. Professor Draper, of this city, whose merits in this direction are gratefully acknowledged, has given us a map containing a great number of sun lines, invisible under ordinary circumstances, but which can be made visible under certain favorable conditions; these additional lines are made evident at both the red and violet part of the spectrum, making it of course longer than usual. The human retina is not sensitive to the light waves beyond the red and the violet part of the spectrum. As to the prevalent theory of light, the entire universe is filled with an ethereal substance too subtle to be weighed or measured, in which the "celestial hosts" move without resistance. This ether penetrates all matter, and permeates the innermost atoms. It is in a condition of ceaseless motion; its waves travel with inconceivable velocity, but differ among themselves in degree of velocity and length of each wave. The vibrations least in velocity produce sound, those coming next produce heat, and those having the highest degree of velocity produce light.

The following eloquent description of the oscillations is given by Dove:

"Let us suppose in the midst of a dark room a slender iron bar is suspended and in motion, and there is also an apparatus present by means of which the swinging motions are continually increased. We enter the room at the moment the bar makes four oscillatory movements per second. Neither ear nor eye gives us any intimation of the presence of the swinging bar. But the movements increase, they reach thirty-two per second. Hark! a deep base sound reaches our ears

it rises in pitch with the still increasing oscillations, it passes through all middle stages up to the highest, shrillest note. We are yet full of wonderment, when all sound dies away, and the silence of the grave again surrounds us. But from the region where the sound proceeded we are made sensible of an agreeable warmth: the oscillations still increasing we feel the warmth radiating in all directions, in the manner a chimney fire radiates. All is yet dark. The oscillations are now counted by the millions in a second. Behold yonder dawning light; it grows more brilliant, the bar begins to glow, first in red color, then in orange, yellow, green, blue, and violet, until all again sinks back in night and darkness." At this stage you have to count the oscillations by the billions per second. Four hundred and fifty billions are requisite to produce upon the retina the sensation of red light; 500 billions to impress it with orange; 550 billions of oscillations per second will make us sensible to yellow; and 800 billions will impress the retina with violet light. Beyond this our eye is incapacitated to appreciate any increase of oscillations, although, as we have already adverted to, these oscillations exist, and can be made manifest by artificial means.

Thus Nature speaks to us in soft and musical notes when near; but when she communicates with us from regions that can be measured only by sun distances, she sends her greetings upon the swift pinions of light. Science has interpreted her cosmic voice, and upon this frail wave the human mind soars upward to the verge of creation.

The Fraunhofer lines are of the greatest importance in spectral analysis. Through them we can register any changes we observe in the spectrum, and measure the breadth and the distance of absorption bands from each other. We know now that these lines are produced by various metals in an incandescent condition in the sun, and they can be produced artificially by burning these metals and minerals and comparing the spectra of these vapors. Thus iron, which has a very great number of lines in the sun spectrum, has its most prominent line at E. C, F, and G are peculiar to burning hydrogen. Magnesium yields the C line, and the H lines, according to Angstrom, are peculiar to calcium. The D line has a historical significance. Burning sodium yields this line. All the progress in spectroscopy is connected with this line. It is the source from which all the wonderful discoveries in solar and terrestrial chemistry had their origin. This line D, called also the sodium line, can be resolved into two or even more lines by the aid of strong light and the combination of several good prisms. The nickel line lies right between them. The coincidence of the D line with that of burning sodium attracted the attention of Professor Kirchhof, of Heidelberg. There was one thing in this coincidence that he could not at first explain. The sun line, as you see here, is a black line; the line of burning sodium is a bright yellow line, as you see here; yet both occupy precisely the same position in the spectrum. One day, whilst examining a flame of burning sodium, he caused the sun rays to pass through the sodium vapor, and lo! he obtained a black line instead of the bright yellow one. He had found the solution of his query. He at once reasoned that there must be burning sodium in the sun, and that there must be a vaporous envelope which absorbed the yellow line and converted it into a black line. Thus, by a most logical and ingenious mode of reasoning, and by a lucky accident, he demonstrated that these lines had a common origin, and that therefore any sun or stars that gave this D line had sodium in an incandescent con-

dition as one of their constituents. Since then all other black sun lines have been reversed by various scientists. Thus was the foundation laid for the greatest discoveries of the age, and a new and almost infinite vista was opened into the nature and composition of worlds, of which, a quarter of a century ago, we had not the least presentiment.

Leaving the historical part necessary to our subject, let me say a few words as to the manner of making examinations by the spectroscope.

The solids must be brought to a state of incandescence by heat. We employ for this purpose, where no very great temperature is necessary, a Bunsen burner; where greater heat is necessary we resort to the electric arc, which is capable of fusing every metal known.

When metals are thus heated up to an incandescent state, they emit rays of all degrees of refrangibility. If we examine then the evaporating substance spectroscopically, we find peculiarities in the spectrum enabling us to diagnose its nature. Fluids are placed before the slit of the spectroscope in suitable glass vessels with plano-parallel walls, or we may use suitable glass tubes. When a ray of light is made to pass through these fluids, ere it impinges upon the prism, we observe an absorption of light in various parts of the spectrum, varying, of course, with the fluid employed; they are called absorption bands. Some colored fluids have one or more bands, changing in position, depth of shading, distinctness of outline, breadth and manner of appearance, furnishing landmarks so distinct and permanent that a recognition of a particular spectrum is made easy, even to the man who is not accustomed to use the spectroscope. As sources of light to examine fluids, we use petroleum or oil flames, and where a maximum light is necessary we may employ the oxygen line-light, the oxygen spirit-light, and at times, with great advantage, the magnesium light. Gases are examined by means of electric induction sparks. Usually the gases resist the passage of these sparks in their natural state of density. We therefore exhaust a part of the gas with the air-pump. We use thin-bored thermometer tubes, with a bulb on each extremity, into which electrodes of platinum or aluminum are fixed. All other metals would oxidize in the extreme heat generated. The tubes are filled with the gas we desire to examine; the air-pump is then applied until the $\frac{3}{16}$ to $\frac{1}{16}$ part of the ordinary atmospheric pressure is left. In this state of attenuation the gas offers but slight resistance to the passage of the spark. Intense heat is generated, and brilliant and beautiful light is emitted, of various colors, changing, of course, with the different gases employed.

Thus no known substance can defy the analytical powers of the spectroscope. Every known gas, metal, alkali, or alkaline earth, when thus acted upon by sufficient heat, gives out light peculiar to itself, producing a spectrum differing from the spectrum of any other known substance. Some substances absorb all the colors of the spectrum, with the exception of a single bright band, of which sodium and thallium give an example; others are readily recognized by a spectrum of many bright lines dispersed all over the prismatic field. Of this, barium, cesium, and rubidium give an example. It is true that the degree of heat employed often modifies the spectra—not indeed as to the position of the characteristic lines and bands of each substance, but as to their number and brilliancy. Thus thallium, for example, gives one green band when evaporated by the heat of a Bunsen burner; but when it is volatilized by the far higher heat of an electric induction spark, we see, in addition, several bright

lines in the violet. The same is true of lithium, calcium, and others. But all these modifications are known, and are as much signs of recognition as every other modification can be.

And now let us consider the extraordinary delicacy or sensitiveness of this spectrum test, which by far surpasses any other test previously known to the analytical chemist.

Suppose we divide one pound of our common table salt, the chloride of sodium, into 500,000 equal parts; one of these parts, or minute atoms, we call a milligramme. In order to weigh out such a milligramme it is necessary to employ the most delicately constructed scales; the weigher himself must possess a high degree of dexterity, and he must proceed with the greatest possible care. But with this performance he has pretty nearly arrived at the limit of possibilities. But what if we should require of this experienced chemist to take one of these milligrammes and divide it again for us into 3,000,000 equal parts? Could he perform this feat? Certainly not. The human mind cannot conceive the minuteness of such an atom of matter. The spectroscope, however, does not recoil from that supernatural task. It demonstrates the presence of such an inconceivable atom with the utmost precision and certainty. The dusting of a book in the remotest part of this hall will set aloft a current charged with sodium chloride, which is present everywhere, and cause a flash in every flame that lights this room, and this yellow flash will yield the sodium spectrum, and thus reveal the presence of this metal.

This sensitiveness of reaction is not confined to the sodium chloride alone. The $\frac{1}{1000}$ milligramme of barium chloride gives a very distinct reaction. Lithium reacts with the greatest promptness to the $\frac{1}{1000000}$ part of a milligramme, strontium to the $\frac{1}{100000}$ of a milligramme, cesium to the $\frac{1}{10000}$ part of a milligramme. Thallium, a powerful poison, as well as arsenicum, plumbum, antimonium and nickel, and many others, responds to very minute quantities of material also. This sensitiveness led to the discovery of five new metals, two of which were discovered by Bunsen. He obtained from forty-four tons of the waters from the spring at Turckheim 200 grains of a mixed salt, which the spectroscope showed to be cesium and rubidium.

Interesting as this subject unquestionably is, I must leave its consideration for another more favorable occasion.

THE SPECTROSCOPICAL ANALYSIS OF THE BLOOD.

In the past, and before the spectroscope had entered into the service of medical jurisprudence, the microscope was to a great extent relied upon to demonstrate the presence of blood; at the same time the chemical arsenal was ransacked to furnish reactions for the detection of traces of blood. Whoever ponders over the painfully tedious and oftentimes faulty proceedings devised and carried out for this purpose, will not fail to hail and appreciate the modern methods of investigation. Chemical analysis is difficult, and often impossible with very minute traces of blood. The microscope can demonstrate blood only within comparatively narrow limits. So long as the blood-corpuscle can be obtained, and if it is a solitary one only, if well defined, the presence of blood can be made out; but when, by some chemical or other means, the cell form of the blood-corpuscle has been destroyed, when, by a process of disintegration, every trace of its outline has disappeared, when it has lost its characteristics as blood, and is only presented to us in extremely minute proportions as an amorphous substance, as a coagulated, physiologically altered

pigment, the highest magnifying powers of the microscope become perfectly useless; it has arrived at the limits of its demonstrating power, and it delivers, without hesitation, the further solution of inquiries into the hands of the spectroscope; and it is here that its wonderful analytical powers prove of the greatest advantage, and their greatest usefulness in forensic medicine.

In order to fully appreciate these powers we must beforehand know what possible changes may be produced upon blood by chemical means, and in what manner the spectroscope responds to each particular change; and of these I am compelled to speak in the briefest possible manner.

Nothing is easier than to detect blood by the spectral analytical process; and the $\frac{1}{10000}$ part of a grain of the coloring matter of the blood is sufficient to give distinct prismatic reactions. Gorup Besoncz says, whenever the peculiar blood bands appear, the presence of blood is unquestionably decided. The coloring pigment of the blood has been produced in crystalline form, and is known as crurine, hæmoglobine, and hæmato-crystalline. This substance or these crystals possess all the optic properties of blood. Every change that blood undergoes, these crystals undergo likewise; and every modification of the spectrum, which is produced upon blood by chemical means affecting the integrity of the blood, is as faithfully reproduced in solutions of this hæmato-crystalline. These crystals are the true factors in a man's life. Through them the respiratory, the oxidizing processes within the economy, become possible. They are the sole element of the blood capable to absorb and attract oxygen from the air; they bind it loosely, and are at all times ready to part with it and to give it up to oxidizable tissues; and in exchange they greedily absorb carbonic acid, which they meet in the capillaries, as resultants from oxidation, and carry it back to the lungs, to be exhaled as effete material. Freed from carbonic acid, they again absorb all oxygen they meet in the lungs, and by the heart's action this vital gas is carried to every recess of the economy. These crystals are indestructible, preserving their crystalline structure and other peculiarities almost forever; and whenever, in the animal economy, their quantity is diminished, or their integrity assailed, there is corresponding reduction in the capacity for life and health. No putrefactive process can annihilate their integrity, and they can be demonstrated, it is said, in the mummy entombed thousands of years ago. They are double refractors, and possess the highest atomic weight known. Their stability and indestructibility admirably fit them to sustain the functions subserving animal life.

We will find that these qualities of hæmato-crystalline are of the greatest importance in medico-legal cases. When the outer form and integrity of the blood-corpuscles have been destroyed by the various means which the criminal may find within his reach, and when the microscope sends our questions back unanswered, it is yet perfectly practicable to produce the crystals, and the spectral analytic test furnishes us the much-coveted information in full amplitude.

Let me say here a few words regarding the inquiry whether we are able to tell in a given case whether the blood is human or not. We cannot with our present knowledge and means decide the question in a direct manner. The blood of all animals gives the same spectral appearances, they all have crystalline materials in their blood; even the lowly rain-worm yields hæmato-crystalline, which proud humanity has claimed as an exclusive inheritance. But we are not so helpless in this respect as we formerly were. We may at

times, by exclusion, give a negative answer. The microscope can tell us, where the size and form of the corpuscles differ from those of man, and whether such blood belongs to inferior animals, for example, the frog's blood; it can also inform us by the peculiar mode of crystallization what it is not. We know that human blood, and that of many carnivorous animals, crystallizes in prisms; the blood of the guinea-pig, of the rat, the mouse, and other rodents, crystallizes in tetraheders; the blood of the squirrel forms hexagonal tablets; hamster blood crystallizes in rhomboheders; and fish blood in fine prismatic needles. We can also obtain a vast deal of information, in forensic cases, from our knowledge that the blood of various animals differs in solubility. Human blood solves very readily; the blood of the monkey, the hedgehog, and others solves equally easily. The blood of the guinea-pig, the squirrel, the rat, and other rodents, on the contrary, solves with great difficulty. There is also a great difference in the sinking capacity of the corpuscles; horse blood, for example, possesses the greatest sinking power, forming rapidly a layer of blood-corpuscles in the serum when collected in a glass vessel. Some blood crystallize readily, others with far greater difficulty. These facts assist us to some extent in inquiries, when we have to pass an opinion on the identity of human blood.

OPTIC RELATIONS OF BLOOD AND ITS CRYSTALS.

When undiluted blood is spectroscopically examined, we observe a dark spectral field, relieved only by a tiny red line at the extremity of the red part of the spectrum. When the blood is diluted with water, several parts of the spectral field are cleared up in a well-known and regular manner, until, at a certain degree of dilution, two absorption bands become visible, arising out of the darkness at the orange and green part of the spectrum, between the Fraunhofer lines D and E. These are the bands given by oxidized or arterial blood. Examine them well. The first band, near D, is narrower than its mate, and darker; it is very distinct also in its outlines. The second band is broader, but less dark in color, and its outlines are blurred. When the process of dilution is carried further, these bands become paler, contract somewhat, and finally disappear. Oxidized or arterial blood has this spectrum from beginning to end, and presents no other modification; nor is there any substance known that will present the same spectral phenomena.

When the blood is deprived of its loosely bound oxygen, which can be done mechanically by the exhausting pump, or chemically by reducing agents, as we call them, such, for example, as ammonium sulphid, tin oxydul and others, we immediately witness a change in the aspect of the spectrum. "A change comes over the spirit of its dream." The two oxygen blood bands disappear and make room for a broad, dark band, occupying the space between D and E. This band is called the reduction band, or band of Stokes, who first saw and described it. Blood deprived of its oxygen is called reduced or deoxidized blood. It corresponds to the venous blood in the animal economy. We must, however, not suppose that reduced blood is tantamount to altered blood, for all that is necessary to restore its two oxygen bands is to shake the blood or the hæmato-crystalline solution up with air, or add some substance that will give up its oxygen to the blood. This process can be repeated many times with the same results. Remember these facts, for they are of the highest importance in the analysis of blood. Suppose we were called upon to analyze a specimen of blood, and we find it cannot be reduced

by these means, would you not at once perceive that such blood must have been acted upon by some powerful agent, destructive to its functional integrity? Such an effect will be produced upon blood by carbonic oxide, by nitrous oxide, prussic acid, and other irrespirable gases. If a question should arise, whether a person died from asphyxia, and by what agency, I think we can satisfactorily answer the question by aid of the spectroscope. Where there are not any external signs of violence, the question is reduced to this: Is asphyxia the result of poisoning with irrespirable gases or not? Formerly, and even now, where experts are not fully up to the progress of spectral analytical processes, great stress was laid upon the dark color of the blood, engorgements in the lungs, arteries, and veins, and other like symptoms. We have learned by experience that these symptoms are far from being conclusive or characteristic, and they ought never to have any undue weight in a court of justice or in criminal proceedings, for we find the dark, sticky, or black fluid blood, and engorgements in lung, liver, spleen, veins, and arteries in many diseases, as pathological results, such as in narcotic or alcoholic poisoning, in cholera, in yellow fever, and septic diseases. Often, indeed, the phenomena of suffocation during life offer no specific marks, whatever may have been the mechanical causes producing it; and we find also often no characteristic post-mortem changes in the organs, because of the short duration of the violence employed, admitting of no demonstrable anatomical change to take place: in the blood, however, can be found the record of the characteristic changes peculiar to death from suffocation. When we find the blood of a person that died from asphyxia responding to the action of oxygen, and to the reduction test, we can safely say that he has not been poisoned by irrespirable gases. But when the reduction cannot be effected, consequently the blood is no longer in a state of integrity, it is also perfectly safe to say that the asphyxia is due to the action of some of the irrespirable gases, or some other poison, and we shall by and by show that the spectral test enables us to decide what particular gas or poison has been the cause of the asphyxia in a given forensic case.

When blood or a hæmato-crystalline solution is acted upon by any acid, except prussic acid, or by an alkali, or by alcohol, chloroform, and some other agents, it is split up, or chemolized, as we term it, into albuminous substances and a coloring matter which contains all the iron that is contained in the blood, but none of the sulphur of the original compound. This is hæmatine. It is important to remember this fact, for, as you here see, hæmatine is the product of decomposition or chemolysis, yet many text-books still repeat the error of the past, which called the undecomposed coloring matter of the blood hæmatine.

Hæmatine and its compounds can be crystallized. If a hæmatine solution is placed before the spectro-scope we obtain a band peculiar to this substance, and quite distinct from the oxide blood spectra. There are a number of hæmatine spectra; the modification depends upon the agent that has been employed to separate hæmatine from the original compound. We here present some of the modifications.

Hæmatine has strong affinities for oxygen, also for carbonic acid. It can subserve, therefore, the processes of life to some extent, far less energetic however, than hæmato-crystalline. It can likewise be reduced by reducing agents. The spectral bands of reduced hæmatine, as you can readily see for yourself, offer great differences from those of Stokes' band of hæmato-crystalline.

Hæmatine is found in the human economy in disease only, especially in Addison's disease, in which the suprarenal capsules are affected. When it is therefore found, we know at once that it is the result of pathological conditions in the blood.

The one-banded hæmatine spectrum, resembling somewhat the band of Stokes, is produced by the action of potassium alcohol upon the blood. A comparison will show that this band is situated so as to have the D line for its centre, it is less broad than Stokes' reduction band, which stretches from D to E.

There is a five-banded hæmatine spectrum resulting from the action of acidulated alcohol upon blood. Here is a four-banded spectrum, produced by the action of sodium sulphate neutralized by acidified alcohol given by Dr. Thudicum.

A new substance has also been obtained by Dr. Thudicum, from blood, called cruentine. It has also quite a number of spectra. Cruentine can also exist in a double state of oxidation, that is to say, it can be oxidized and deoxidized at pleasure. A few of these spectra may be seen on the diagram. Be pleased to compare now all of these spectra, and you will find that they differ from each other quite sufficiently to make a mistake nearly impossible. In very doubtful cases we may resort to actual measurement; means to this end are provided for in all good spectroscopes. You will agree with me, that the harvest which the spectroscope has gathered in the analysis of blood is very abundant, and of the highest importance in forensic medicine.

The man who is called upon to act as an expert in medico-legal cases must be familiar not only with the chemical or microscopic tests, but ought to possess a thorough knowledge of the various spectra of blood, and no blood analysis ought to be considered perfect and beyond assailability which ignores or is not verified by the revelations of the spectroscope.

Having placed before you the most interesting optic changes to which blood can be brought by chemical as well as physical means, we are now well prepared to understand how this analysis can be utilized in the detection of crime.

The "man of blood," after he has committed his deed of darkness and death, what is he most likely to do? The history of medical jurisprudence is full of information on this head. He will naturally try to efface the traces of blood, the terrible "tell-tale drops." For this purpose he will use almost anything at hand; water, soap, alcohol, acids, alkalies, oils, and others. But science can foil him in his efforts to evade the consequences of his crime. The indestructibility of the hæmato-crystalline leaves traces and landmarks perfectly intelligible.

We can call down as witnesses and as judges the fiery messengers of heaven to lay bare his deeds of blood, and as the genial trembling sun ray filters brightly through the analyzing prism, it reveals to us the presence of blood, it tells us even of the means he has employed to efface his crime. Light and science are the terrible avengers from which he can never, never escape; they follow him with never-tiring step, until they grasp him in their toils and give him over to justice and retribution.

When the blood itself is found, even in very minute quantities, upon the floor, the wall, the clothing, the instrument of death, its demonstration by the spectral analytical method is perfectly easy and reliable. We scrape the wood, the wall, the weapon in order to collect all the traces we can, then we dissolve it carefully in a few drops of water, perhaps add a trace of ammonia, and submitting it to a micro-spectroscopic ex-

amination we will get a definite optical reaction. If maceration has been used, we still often obtain sufficient blood for spectroscopic analysis to establish our case. Where boiling has been used, the hæmato-crystalline has been coagulated, for it is simply a crystallizable albuminoid, and in this state it will not give any longer the two blood bands at D and E. We must then act upon the coagulum with acids, and try to obtain the hæmatine spectrum. Where acids, alkalies, soap, alcohol, and other agents have been employed, we may obtain the hæmatine or the cruentine spectra, and thus demonstrate blood. This has been done successfully in several very interesting medico-legal cases on the continent. In these examinations the spectroscope renders us the highest possible services, whilst the microscope is unable to give us any response whatever.

But with these services its usefulness in this direction is by no means at an end. When blood is acted upon by heat and acetic acid, minute crystals, table-shaped, are obtained, known as hæmine. They can be obtained from hæmatine also. The crystals have frequently demonstrated blood from very scanty traces. Here the microscope again becomes useful. It does not, however, at all times crystallize readily. Under the spectroscope hæmine gives a band far out on the red part of the spectrum, where we meet also one of the bands of chlorophyll; it lies at C.

Another substance found in old extravasation of blood within the economy was described by Virchow and named by him hæmatoidine. It is probably modified hæmato-crystalline; its peculiar and characteristic spectrum has been given by Preyer. It is of value in forensic medicine to determine whether an extravasation of blood, found at post-mortem, is of recent date, or has been there for some time.

The spectrum of hæmatoidine is here shown; it is a chloroform solution of hæmatoidine; its bands are found in the blue and violet part of the spectrum, one well-marked band between C and F, and another between F and G. They require the maximum illuminating power, magnesium light or that of oxyacetylene light.

Spectral analysis will also assist us to determine in forensic cases whether blood spots found upon wood, stone, furniture, clothing, weapons, plaster-of-Paris walls, are of recent date or old. This inquiry has come up recently in Boston, in the well-known case of Alley, who stood before a jury charged with murder. The State medical expert stated in his direct medical examination that old blood spots could not be distinguished from blood spots of recent date. I have published my views in Dr. Brown-Séquard's Archives of Scientific and Practical Medicine, No. 5, and I think I have proved that the expert fell short in his testimony, and placed himself at variance with the accepted and exact results of spectral analysis.

When a solution of old dried blood is prepared and properly concentrated and spectroscopically examined, we behold one black band coincident and overlapping the C line. The rest of the spectrum is all dark. I have shown you, this is not the case when fresh blood is examined; then you find simply a red band near C. This absorption band at C is characteristic of old blood. Having seen and examined this band, and diluted our solution with about fifty per cent. of water, the spectrum clears up and gives us in addition to the band at C our two cheerful bands, so well known and so often alluded to, but yet beyond these three bands the spectrum is still overcast. Let us set our solution aside for twenty-four hours and then examine it again, and note the remarkable and characteristic

change that has taken place. At first, when only one band in red was visible, and all the rest of the spectral space covered with darkness, it seemed as if the hæmato-crystalline had lost its power to absorb oxygen from the air; it seemed as if by age a complete necrosis or death of the blood had ensued; but now, behold! the two cheerful bands betoken a resurrection from death, typical and beautiful to behold. A further dilution brings out these bands in all their old, bold outlines; but the band at C disappears gradually and is seen no more. Set your solution aside for another twenty-four hours in a closed vessel, and then examine spectroscopically. You will find the three bands have disappeared, and you now behold the broad reduction band between D and E. What has caused this change? I will tell you. Your solution has entered a putrefactive process, evolving sulphuretted hydrogen and other gases of decomposition, which in their turn have consumed all oxygen. You have indeed a fair specimen of reduced oxyhæmato-crystalline before you.

To show you that this is precisely the case, take your solution and shake it well up with air. On spectroscopic examination you will find that the reduction band has disappeared, and our old welcome oxygen bands have reappeared between D and E. They look as beautiful and as well defined as ever. What has now taken place? Simply this: your blood solution has again exercised its life function of uniting with the oxygen of the air, the deoxidized blood has become oxidized, it has saturated itself with the staff of life, showing that after long years of death apparent, the hæmato-crystalline has preserved its integrity and its capacity to renew its vital mission when brought again in proper condition.

We have now seen how, by the aid of the spectral analytical process, we can demonstrate blood, when altered in almost any possible way and manner, and that we have the advantage over the criminal in his efforts to hide his crime. But how, if he has resorted to fire to burn up his victim? Can the spectroscope help us then? It can, gentlemen. I present you here this beautiful spectrum of many light and dark bands. It is the spectrum of ash from human remains. To see this spectrum well the ash is moistened with a little diluted chloric acid and then exposed to the heat of a Bunsen's burner, or acted upon by an electric induction spark. A very ingenious apparatus has been invented by Mitscherlich. In a narrow glass tube, closed at one end, and the other end bent to a right angle, is placed the substance in a fluid condition, which is to be analyzed. The open end is filled up with a bundle of fine platinum wires, properly secured. By means of capillary attraction the fluid in the inverted tube is sucked up, and is consumed rapidly, heat being supplied by a Bunsen's burner or other means. As the metallic or mineral solution is thus consumed, their spectra can be quickly and enduringly observed and studied. There is another very ingenious apparatus, invented by Becquerel, which I shall describe presently, and another, a very beautiful apparatus, invented by our countryman, Dr. Morton.

The spectrum from the ash of human remains is one of the most beautiful we can behold. It is not, however, a simple spectrum, but a combination of several spectra. This also is of great practical value in spectral analysis. In the present case the spectrum is made up of six different spectra, which are readily pointed out. They belong to so many elements found in the human system, to wit, sodium, potassium, lithium, cesium, rubidium, and calcium.

We learn, then, from the ash of human remains, that

there are six metals in its composition; iron and magnesium do not appear in this spectrum.

POISONS.

All poisons, except a few vegetable narcotic poisons, and their alkaloids can be discovered by the spectral analytical method. The spectral relations of a number of vegetable poisons and their alkaloids have been studied, but those of many others are still awaiting investigation. Spectral analysis is but a decennium old, is therefore yet in its infancy, and it has not therefore accomplished all, within the range of forensic medicine, that it may accomplish in the future.

When called upon to analyze a metal or mineral poison, we must bring it to a high state of incandescence by a Bunsen burner or by the electric arc. You have all heard of the manufacture of Bessemer steel; by this process several tons of cast-iron are converted into cast-steel in less than twenty minutes. In this process oxygen is employed in order to burn out all the carbon and all the silicon of the cast-iron, and the heated gases issue forth in a flame of the furnace. This flame varies in appearance, as the carbon and silicon disappear, and it is of the utmost importance to know the exact moment when all the carbon and silicon is burned out, otherwise the entire cast is lost. The spectroscope will point out when this exact moment is reached, by a peculiar spectrum from the flame, when the access of oxygen to the mass must be cut off. Our procedure is similar. The spectroscope analyzes the flame of each metal and mineral, and gives us the peculiar and characteristic spectrum of each. Good chemists know these spectra well; the spectroscope has become an indispensable aid to them to determine the nature of metallic ores and substances, and in every well-arranged chemical laboratory you can find charts containing the spectra of the various metals and minerals.

The salts of metals, too often used for poisoning purposes, are given or taken in fluid form, such as arsenious acid, corrosive sublimate, antimony, lead, copper, and others, and we are called upon to demonstrate them from the organs and tissues of the human economy. Here we must proceed in a different way. A considerable number of these salts may be recognized at once, according to Thudicum, by holding a small piece of the tissue into the colorless flame of a Bunsen burner; the flame is analyzed by the spectroscope; or we may place the fluid in Mitscherlich's apparatus; or, still better, we may employ the apparatus devised by Becquerel, consisting of a series of glass tubes into which the positive and negative electrodes of a powerful electric battery are introduced. The electric discharge passes through the liquid we desire to analyze, and as the induction spark passes from pole to pole, the substances are evaporated which are present in soluble form in the solution. The effect of the inductors can be so regulated that the interruption of the current, and consequently the electric sparks, follow in such rapid succession that the spectrum becomes quiet and almost stationary, the apparatus works uninterruptedly for hours like a heating apparatus; for, during all this time, with the substance we desire to analyze under these favorable conditions, we can quietly observe the steady spectrum, and ascertain by it the nature of the substance to be analyzed.

The time allotted to me precludes the possibility to go into a more extended detail. Becquerel's apparatus is well described by Becquerel himself and by H. Schellin in his work on spectral analysis.

Viewing, then, the progress we have made in this

direction, it is to be regretted that in the Wharton trial the analytical powers of the spectroscope were not brought in requisition. This trial has shown us the wonderful mystification of the old analytical methods. The contradictions were disheartening and humiliating to the medical profession. There could not have been an assailable point to the answer which the spectroscope would have given to the question, whether the substance found was arsenicum, antimony, or gelsemium. The possibility to work with minute quantities would have made it convenient to observe the spectrum for many hours, and would have given an opportunity to many to verify and observe the revelations of spectral analysis.

POISONOUS GASES.

I regret that time enough is not at my disposal, and that therefore I can bestow but a brief consideration upon the usefulness of the spectral test in cases of poisoning with irrespirable gases. Of these, poisoning with carbonic oxide or charcoal gas happens most frequently. Whether in a given case this gas has destroyed life, or whether suffocation from other causes has taken place, will often be a question for the medical jurist to decide. The facility with which it is generated; the certainty with which it acts its fatal results upon the animal economy; the gradual and gentle manner with which it creeps over its victim, producing effects upon the brain, rather agreeable than otherwise, until the entire blood mass is saturated with its treacherous vapors, and the sleep of dreams passes insensibly into the sleep of death; the facility with which traces of this gas can be removed by simply admitting fresh air into the chamber of death; the absence of disturbing influences upon the corpse, all these circumstances admonish us, that to detect poisoning with this gas we must avail ourselves of science's most advanced resources. The post-mortem appearances of persons destroyed by this gas are by no means characteristic. We find the blood of a purple-black color, engorgement of arteries and veins, clots in the heart, and other changes in the lungs, liver, and other organs; but these are found in many other diseased conditions also, and are by no means peculiar to poisoning with carbonic oxide alone, and every intelligent jury would hesitate to render upon such feeble testimony, a verdict of death. Carbonic oxide gas, as well as all other irrespirable gases, exerts its destructive force upon the blood specifically; it alters it in a manner that it becomes unfit to carry on the vital processes, and it is therefore but logical to suppose that we must find in the blood the traces of this poison.

And so it is indeed. We have spoken of the crystalline material of the blood, of its being so eminently adapted to the purposes of life, we have admired its many wonderful qualifications and its beautiful spectrum; but this substance has its weak points also. It has the most fickle disposition imaginable. Oxygen is its natural companion, so also is carbonic acid; but it runs away with many of the irrespirable gases like a fickle woman with a preferred lover, without remorse or compunction. It unites with peculiar energy with these poisonous gases, and forms combinations and unnatural alliances with them so firmly and tenaciously that a subsequent separation becomes almost a matter of impossibility. So firm is this unnatural union, that they go together even through the crystallizing process, and we are able to procure crystals of all these combinations. No wonder, then, that we hail with satisfaction the performance of the spectral analytical test, by whose aid we are able to determine and detect the agent that causes asphyxia.

In the case of carbonic oxide two bands, very much resembling the two oxygen blood bands between D and E, are seen. On exact measurement, however, we find differences in position. But when blood saturated with carbonic oxide is acted upon by reducing agents, it is found that they have no power of reducing it. The broad Stokes band cannot be produced. This irreducibility is by Gangee considered decisive in forensic medicine, showing that death has taken place from the inhalation of carbonic acid gas. But we have no other means to show this irreducibility than by the spectral analytical process.

PRUSSIC ACID.

Hæmato-crystalline has the same fatal affinity for prussic acid. We find the blood of a brown color, and the peach-blossom smell is so decided, especially immediately after death, that we may conclude without spectroscopic examination that death has resulted from prussic acid. It is, however, a singular fact that this subtle poison does not decompose hæmato-crystalline into hæmatine. We possess ample means and optical phenomena to decide the question of poisoning by this gas by the spectral analytical test. It is an interesting chapter indeed, but its details must be passed over this evening.

SULPHURETTED HYDROGEN.

Concentrated sulph. hydrogen gas, when inhaled, is a rapidly destroying poison to animal life. It has been used for homicidal purposes. If a stream of this gas is passed through a blood solution, it rapidly causes the hue of the blood to change into a dark brown color. Experiments made by Hloppe Seyler upon dogs and rabbits show the terribly destructive effects of this gas; even when mixed with twice its volume of oxygen it produces fatal consequences. The rehearsal of the symptoms is painful to listen to. The dyspnoea and convulsions are fearful in character, the glazing, protruded eyes, the distortion and paralysis are rapidly produced. This gas is around us; it is generated whenever animal or vegetable matter undergoes putrefactive transmutation; it reaches us from our defective closets and ill-conditioned sewerage. If long inhaled, even in smaller quantities, it creates zymotic disease, favors septic processes. The latest investigations claim that the sulphur is separated in the economy, favoring coagulation and the formation of embolic material.

The action of sulphuretted hydrogen upon the blood cannot be definitely and absolutely proved by chemical means, and in forensic cases its action can only be fully and satisfactorily substantiated by the spectro-analytical test. Blood saturated with this gas has its definite spectrum. It is the band in red, of which we have already spoken as being peculiar to old blood stains, and it is possibly the action of this gas, which is evolved during the process of drying up, to which this band owes its presence, and which betrays its evanescent character when such blood is brought to a state of watery solution, and then exposed to the vivifying effects of oxygen.

But how is it possible to introduce this offensive gas into the system for criminal purposes? It may be injected into the rectum and intestines, where its action would be as deadly as if inhaled by the lungs, and yet we would not find any direct evidence of this gas in this organ.

PHOSPHURETTED HYDROGEN.

Like the foregoing gases this gas is also highly poisonous; animals exposed for a very brief period die, even if they afterwards have been exposed to fresh

air and oxygen. Its presence can be readily detected, by chemical means, through the breath of the animal. A paper moistened with a solution of nitrate of silver held before the mouth of an animal thus poisoned will show the formation of silver phosphate.

It acts equally poisonous when injected into the rectum. The prismatic test shows the presence of this gas by peculiar and characteristic modification of the spectrum, aided by certain chemical reactions, and this test may be employed whenever the chemical tests are doubtful or unattainable.

I have to pass over the action of anesthetics and their peculiar action upon the blood, and also the *resumé* of what progress has been made to detect by the spectral analytical methods the presence of alkaloids, such as strychnine, morphine, veratrine, atropine, and many others. It would require far more time than we have this evening. Perhaps I shall have an opportunity to speak to you on these subjects at a future occasion.

I have thus laid before you an outline of the utility and importance of spectroscopic analysis in forensic cases.

I hope I have in some measure justified the interest you have taken in the subject. I hope also to have been able to impress you with the great responsibility resting upon the medical expert who is called to decide in cases of life or death.

There is no doubt in my mind that many a life has been sacrificed by medical testimony, lacking the breadth and depth and the foundation of true science. I have still less doubt that many a hardened criminal has escaped conviction and well-merited punishment, from a deplorable ignorance of scientific facts, which now are happily at our command. It is evident, and held so by the best physicists abroad, that no blood examination is perfect and unassailable that is not verified by spectral analysis, and that no conscientious verdict should be given, and judgment of death pronounced in cases of poisoning, without the positive proofs attainable from the same source. If I mistake not, the aim of your Society is improvement of medico-legal knowledge, in conformity with the spirit of scientific progress, and I have no doubt you will see to it that the exceedingly important information, which in an imperfect sketch I had the honor to lay before you this evening, shall not be discarded in the courts of justice where your influence extends, alike important to the accused as to society and the State. If I have by my discourse thrown any light on the modern mode of investigation, and stimulated you to renewed efforts, I shall be amply repaid for my labors.

A CASE OF EARLY MATERNITY.

By E. A. GOODRIDGE, M.D.

FLUSHING, L. I.

THE following notes of a case of early pregnancy, which came under my observation during the summer and autumn of 1873, will probably be of general interest to the profession, and I accordingly give them to THE RECORD for publication.

G. J., a well-developed colored girl, born in this town on the first day of March, 1861, and, therefore, 12 years of age in March, 1873, was brought to my office early in August of the latter year, for treatment on account of abdominal enlargement, which the mother, a woman of more than the ordinary intelligence of her race, thought to be a "dropsy." Aside

from the enlargement the girl was in perfect health. Suspecting that all was not right, I sent her away without treatment, expecting the case would determine itself in a short time. I next saw her about the middle of September. There was no doubt at this date as to her condition, and she confessed having had intimacies with a young white man of the neighborhood. She also gave me her age as indicated above. The statements of the mother and other friends likely to know her age agreed with that of the girl, and with my own knowledge concerning her. She began menstruating shortly after her eleventh birthday, and continued to do so regularly till the month previous to her twelfth birthday, when conception probably took place. Gestation was completed without the occurrence of any functional derangement worthy of note. There was no œdema whatever or other evidence of renal disease.

Labor came on at 3 A.M. of November 25th, and advanced regularly through the first stage, which lasted five hours, the head presenting in the left occipito-iliac position. Strong expulsive efforts soon after began and recurred with recession for two and a half hours, when delivery was effected, the whole duration of the labor having been seven and a half hours. The infant was a female weighing seven pounds. There was a copious lacteal secretion on the third day, after which time the mother continued to supply sufficient nourishment for the sustenance of her child.

The mother's age at the time of delivery was 12 years 8 months and 25 days.

CASE OF TRAUMATIC TETANUS

TREATED WITH

PHYSOSTIGMA VENCUSOSUM.

COMMUNICATED BY PHILIP S. WALES,

MEDICAL INSPECTOR, U. S. N.

I AM indebted for the notes of the following interesting case to the courtesy of Dr. Fisher, in whose practice it occurred.

David Boyle, aged 8, residing at the corner of 10th and F streets, Washington, fell from a small tree on the 28th of August last, causing a compound fracture of the carpal and of the radius at its epiphysis. The lower fragment was reduced, with but little difficulty, by slightly enlarging the wound. The soft parts were then brought together by strips of adhesive plaster, the arm placed in a comfortable position, and cold water dressings applied. The limb became largely swollen up to the shoulder and suppuration was established. The former dressings were then discontinued and linseed oil and carbolic acid substituted.

September 5.—Dr. Wales was called in consultation in the evening; the patient was now apparently doing well; suffered no pain, and the swelling of the arm had subsided.

September 6.—This morning the patient presents the unmistakable physiognomy of tetanus, with beginning stiffness of the muscles of mastication, inability to open the mouth, and contraction of the cervical muscles. In consultation it was determined to give the Calabar bean a fair trial. With this view a hypodermic injection of one-third of a grain of the extract (Trommsdorff's preparation) was made over the right mamma, and, ten minutes later, a third of a grain, dissolved in glycerine, was given by the stomach. It was thought that a very decided impression had been

made; the pupils were contracted to a diameter of one-sixteenth of an inch, but when the eyelids were opened to a bright light they *expanded*. In two hours the above-mentioned dose was repeated. The pupils were now less mobile when exposed to a strong light. The effect of the drug upon the skin could not be correctly appreciated, as the patient was bathed in a copious perspiration before it was administered. The amount of urine was increased; pulse 125. In the evening the hypodermic injection was again repeated and ten square millimetres of Squibb's calabarized gelatine given by the stomach. The latter dose was repeated every three hours during the night. 7th.—Both Dr. Wales and myself felt convinced that the medicine has had manifest beneficial effect. The pupils were contracted, the chin could be voluntarily depressed as to separate the teeth an inch. There has been but three paroxysms since the administration of the bean and these of very short duration, and the muscles were not so firmly contracted. While we were present a violent paroxysm ensued which curved the body a little in the opisthotonic position; but this only lasted a minute, and during the time the respiration was arrested, pupils widely dilated, lips blue, and the pulse, which had hitherto reached 135 beats, came down to 90, when the spasmodic exacerbation passed off, the pupils resuming their contracted condition and the pulse its former frequency. We repeated the calabarized gelatine; in two hours another paroxysm of short duration occurred and the patient died, asphyxiated, at 12 meridian.

Original Lectures.

NOTES UPON CASES PRESENTED AT THE CLINIQUE

OF

J. M. DA COSTA, M.D.,

JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

(Phonographically reported for THE MEDICAL RECORD.)

CASE I.—CHRONIC DYSENTERY.

GENTLEMEN:—The first patient presented to-day is Mrs. M., *æt.* 46. She has been sick eight weeks. The first thing she noticed that was wrong with her was passage of blood from the bowels. During the last eight weeks she has passed blood in small quantities from the bowels, and she estimates that she has six or eight discharges every twenty-four hours, and these are accompanied by a bearing-down sensation.

This part of the history suggests close inquiry regarding the state of the alimentary canal.

We now find that she has suffered from hemorrhages previous to the present attack. Two years ago she had her first attack of hemorrhage; sixteen months, the second attack; and this is the third attack.

In the interval between the hemorrhages her health has been poor: there is a general sense of weakness in the bowels, and continued diarrhoea.

We have in this case, then, a persistent looseness of the bowels, with occasional hemorrhages of considerable severity; and there is history of disease of the bowels antedating hemorrhage. There has been loss of flesh and strength; the patient presents a pale appearance, but has no fever at the present time. Pulse weak, 80 per minute. Tongue pale, not coated. There is general abdominal soreness, but the particular

region of soreness is along the course of the large bowel, ascending, transverse, and descending colon. The patient especially winces when pressure is made along the course of the descending portion of the colon.

It is quite evident that we have here a case of chronic alteration of the mucous membrane of the large bowel, and, most likely, ulceration. To be quite certain of such a case, it must be positively determined that no such thing as hemorrhoids are present, which might possibly give rise to such amount of irritation, and also account for the passages of blood. This question has been fully investigated by my clinical assistant, who assures me that piles are not present.

We have no other supposition, therefore, but that we have to deal with disease of the bowels, especially of the large gut; and that there is ulceration of the mucous coat of the large intestine in places, which occasions the hemorrhage. In other words, the case is one of *chronic dysentery*.

Prognosis.—With regard to prognosis, a good deal depends upon the length of time it has lasted. The existence of the disease for several years, and the recurrence of hemorrhage, does not give us the most favorable case for treatment. It will be our endeavor, however, to remove this morbid condition of the mucous membrane of the bowel and the ulceration.

Treatment.—We might, in this case, prescribe bismuth in large doses; and it is a remedy which sometimes can be prescribed with great benefit.

I have also seen good results, in this class of cases, from the use of oxide of silver; and this is the treatment which will be adopted in this case.

The oxide of silver is unquestionably preferable in this case, because there has been such recent hemorrhage. The patient has already been taking the remedy in one-grain doses three times a day, and the treatment therefore, thus far, will be continued.

The use of opium, by means of suppositories, will materially aid in restraining the frequency of the movements from the bowels and the excessive discharge. The patient will therefore receive, at bedtime, a suppository containing one grain of opium, which will be repeated in the course of the night if the discharges are excessive.

The diet is also a question which claims our attention.

A plain, nourishing, and easily digested diet is alone proper. It may consist of arrow-root, rice, unlone meat, beef-tea, milk, and only a limited supply of vegetables.

CASE II.—CHRONIC DYSENTERY.

Mrs. B.—, *æt.* 51. This woman has ten or twelve passages during the day, and about the same number during the night. The passages are accompanied with a great deal of bearing down; have a slight admixture of blood; but there has been no hemorrhage, as in the preceding case.

The patient has lost flesh; no fever; tongue slightly coated. First attack. There is more or less of vertigo and pain in the side. There is slight soreness over the abdomen. The present condition has lasted about six months. This case, gentlemen, is also evidently one of chronic dysentery in which there are many movements from the bowels, but the discharges contain but little blood.

As regards the early history of the case, we have not many fixed data. The patient is of the opinion that her sickness is due to hard work and exposure.

Her occupation (apple-woman) is such as necessitates considerable exposure to atmospheric vicissitudes,

and her supposition is very likely correct. This class of people get thoroughly chilled, are constantly upon the move, which condition of affairs has doubtless given rise to intestinal trouble that has lapsed into this chronic condition.

Upon farther examination we find that the patient has great debility and disposition to sweating, but no cough. Physical examination of the chest determines that the respiratory murmur is normal, hence we may exclude any tubercular element from the case. There is no cardiac disease. We now have these two cases of chronic dysentery together. Here is a case which might be treated in the same manner as the preceding one; but I am of the opinion that, with this patient, the bismuth will do better than the oxide of silver.

In this case we have no element of hemorrhage or ulceration, but what we have is probably a chronic catarrhal condition of the mucous membrane, a chronic swelling and thickening of the mucous membrane of the bowel, and to relieve this condition the bismuth is very valuable. We shall therefore make the following prescription in this case.

R. Bismuth subnitrate..... grs. xv.
Dover's powder..... grs. iij.
M.

Administer such a powder four times a day. If the discharges are excessive, and not controlled by the opium contained in the powders, the occasional use of an opium suppository will be of great service. The diet should be similar to that recommended in the preceding case.

CASE III.—PNEUMONIA.

James C—, æt. 5. This boy has been sick three days. The thing complained of by the mother is that the boy cannot get his breath. He had a somewhat similar attack two years ago; but, apparently, recovered perfectly. Since three days ago he has suffered from oppression in breathing, has been feverish, has had a tight, oppressive cough, but no expectoration. He is unable to lie in bed on account of the difficulty of breathing.

Physical Examination.—Great heat of skin; tongue coated; pulse, 120; respiration, 32.

Percussion, anterior: Dulness upon left side slightly marked at apex; becoming distinct at the middle portion and downwards.

Posterior: Dulness more marked over lower portion of chest upon the left than anteriorly, and there is considerable difference between the right and left chest posteriorly.

Auscultation: Over the region of dulness upon the left side moist bronchial breathing heightened in pitch, and evidently distinctive of consolidation.

At the upper portion of the lung it is to be noted that there are some subcrepitant râles, but not the evident consolidation that is found at the lower portion of the lung.

Anterior: At the lower portion of the left lung there is heard a harsh murmur, but not the distinct tubular respiration which is heard posteriorly.

Over the right lung, posteriorly, at the inferior angle of the scapula, and along the edge of the scapula, there is also marked tubular respiration.

Anteriorly, there is no dulness upon the right side, nor harsh murmur, as heard upon the left side. This case, gentlemen, is interesting in the following particulars:

First, it is a pneumonia; second, it is a case of double pneumonia; and third, it is a case of pneumonia affecting the posterior portion of the lungs

almost exclusively. The bronchial breathing does not extend anteriorly at all upon the right side, only to a very limited extent upon the left side, and there is not true tubular respiration; hence there is scarcely any consolidation anteriorly upon the left, and none at all upon the right side of the chest. It is a case, then, in which nearly all the pneumonic process present is limited to the posterior portion of the lungs, the anterior portion of both lungs comparatively escaping. This is a rare occurrence.

Again, it is a true *lobar* pneumonia, a true consolidation. It is not the common form of pneumonia which occurs in childhood.

The most common form of pneumonia in childhood is broncho-pneumonia, and is characterized by only very little consolidation; there is not the marked tubular respiration and the phenomena we have here. This case is like the pneumonia of adults, excepting the peculiarity that it affects so purely the posterior portion of the lungs. It is like the pneumonia of adults in being a true consolidation of pulmonic texture. This is a point worthy of careful consideration. I am of the opinion that true pneumonic consolidation, like that which occurs in the adult, is of much more common occurrence in children than is ordinarily supposed.

In the matter of diagnosis it is doubtless frequently overlooked, from the fact that quite commonly too much stress is laid upon percussion, and too little stress is laid upon auscultation.

Our time does not permit the farther discussion of this question; but the fact is before us. We have here a case of pneumonia such as occurs in the adult, and it is a case of double pneumonia affecting a section of each lung.

Treatment.—The first thing to be done is to place the patient in bed. While dismissing him, it may be worthy of notice that we may have a pneumonia *without* cough or expectoration, and nothing but the physical signs will give the true meaning of the symptoms which may be present in the case. When the patient is placed in bed he should be thoroughly dry-cupped. If he were not a pallid, weak child, ill-fed, and with nutrition at a low point, leeches or wet cups would be applied to the chest. As it is, dry cups only will be employed. Internally, he is to take a powder containing the following remedies:

R. Digitalis..... gr. $\frac{1}{2}$.
Dover's powders..... gr. i.
Nitrate of potash..... grs. iij.
M.

There is but one defect in this prescription, and that is with regard to the quantity of ipecac it contains; that is not so large as we could wish, hence we will add to the above powder one-sixth of a grain of ipecac. Administer one of these powders every three hours.

What does this prescription mean? We have the digitalis to control the circulation; we have the ipecac to act upon the secretions, and especially upon the secretions of the pulmonary structure, bronchial tubes, and air-passages; we have the nitrate of potash, which acts upon the skin, and at the same time is among the remedies which are used in the treatment of pulmonic consolidation.

The entire action of the powder is to promote secretion from the lung itself, and thus lead to expectoration; and in the nitrate of potash we have an agent which is in some degree a solvent and an internal antiphlogistic. The small amount of opium in the Dover's powder will not interfere with the general

outline of treatment, and will relieve the general discomfort of the patient. Good food and plenty of milk also form an important part of the treatment.

CASE IV.—CHRONIC VOMITING.]

Mrs. B.—, æt. 39. Has been sick four years. Occasional attacks of vomiting are almost the only symptom of which she complains. These attacks occur at intervals of varying length, and usually last three or four weeks. The present attack has continued longer than usual, it now being seven weeks since it came on. The patient ordinarily has three or four such attacks during the year, and while suffering from them everything that is taken into the stomach is soon ejected, except perhaps tea and coffee, and not infrequently these articles also are vomited. It is also vomiting unassociated with eating. In the interval between the attacks of vomiting the patient suffers more or less from indigestion, more or less from constipation, sometimes three or four days passing without a movement from the bowels. The patient is unable to trace these attacks to any cause.

We have here the history of some gastric disorder that has lasted four years. The leading features of the case are—weak digestion, constipation, and aggravating attacks during which vomiting is the prominent symptom. The next question that arises is, *What does the patient vomit?* The material which is vomited is mostly mucous, and has a disagreeable odor. This material is vomited irrespective of the presence of food in the stomach. The tongue is white, fully coated, and carries indentations of the teeth upon its sides. There is no pain upon pressure over the stomach or in the back. Uterine disease may be excluded, and the function of menstruation is performed normally.

There are one or two suppositions with regard to the case before us. Persistent irritability of the stomach, accompanied with vomiting, suggests the presence of ulceration; but this case is wanting in the pain, vomiting of blood, and the continuous character of the symptoms which accompany ulceration. It is probable that the true solution is to regard the case as one of *atony* of the stomach, associated with chronic gastric catarrh. There is probably a catarrhal swelling with altered secretion from the mucous coat, together with atony of the organ. The vomiting without pain suggests this.

The anterior history—that of an old dyspeptic—and the vomiting of large quantities of offensive mucus also point to the same condition. There may be present in the material vomited some such substance as the *sarcina ventriculi*, and that requires a microscopical examination to determine its presence.

We shall therefore regard the case as one of chronic gastric catarrh, and treat it accordingly.

In this particular case, in which there is absence of marked soreness or inflammatory irritation, looking upon it rather as one of chronic catarrhal condition of the mucous membrane with altered secretion, the remedy which suggests itself to me as most likely to allay the vomiting and change the character of the discharge is an *acid*. I admit that if this case had all the evidences of chronic inflammatory action, we should not resort to acids to control the vomiting; but taking the character of the case before us, I believe that acids will prove of service. We shall therefore administer muriatic acid in a solution of pepsin as follows:

R. Liq. pepsine..... 3 i.
Acid muriatic dil. gtt. v.
M.

Administer such a dose four times daily. The diet should be restricted to skim-milk, endeavoring by using small quantities of this to restore the lost digestive tone. When the patient can retain the milk without vomiting, we may resort to other diet, but this is sufficient for the present. As a result of long experience I have found that in these cases of prolonged irritability of the stomach a blister over the epigastrium is of great service. We therefore recommend a small blister to be placed over the epigastrium in this case.

The constipation is also to be removed, if possible; and for that purpose I suggest the following pill to be taken every night, or every other night, according to the necessities of the case:

R. Aloe soc..... gr. $\frac{1}{2}$
Rhei..... gr. ij.
Ext. belladonna..... gr. $\frac{1}{4}$
M.

The patient will return in one week.

Progress of Medical Science.

LEAD AS A CONSTITUENT OF ENAMEL THE CAUSE OF CHRONIC POISONING.—The patient, a corpulent man, 36 years of age, suffered at one time from a severe attack of typhilitis. From this, however, he had recovered some time, when he began to complain of intense pain in the abdomen, and was considerably emaciated in a short time. His face became yellow, and he continued to suffer from fulness and pain over the caecal region, and shooting pains through the breast and stomach. Percussion over the abdomen was dull, sleep and appetite disturbed; pulse and temperature were normal. At first typhilitis was suspected, and a dose of castor-oil administered, after which a passage was obtained. The faces consisted of large boggy masses. The stomach became reduced in size, but the pain still continued, extending over the back and through the extremities. The stomach was tense and contracted, and on applying pressure the pain was *not* increased, but vomiting was produced almost instantly, consisting of green masses. The bowels were very constipated, and only moved when a drastic cathartic was administered. After four weeks had elapsed, a slate-colored band made its appearance on the gums, and bladder-tenesmus became apparent. Upon this appearance a diagnosis of lead poisoning was arrived at. Soon after this the sister of the patient was similarly attacked.

The source of the lead poisoning was shortly afterward detected. The jar used as a receptacle for vinegar was found to be much corroded, and nearly all the enamel was removed by the vinegar. The vinegar possessed a disagreeable sweetish taste. One "schoppen" was placed in the jar for ten hours, when on examination 0.09 grm. of metallic lead were found. The jar, when full of vinegar, must have contained, after standing ten hours, 1.8 grm., and after standing one week must have contained 30.24 grms. of lead in solution. About one jar of vinegar was consumed per day, which was quite sufficient to produce lead poisoning in the family.

RETROGRADE METAMORPHOSIS OF THE GRAAFIAN FOLLICLE.—The following results are summed up by Slavjansky as obtained from his anatomical and physiological researches:

1. The Graafian follicles develop themselves from the primordial follicles, and are growing towards ma-

turity from the first month of birth to the fortieth year.

2. The larger number of follicles do not mature, do not rupture, do not discharge their contents, but pass over into a condition of atrophy, which is analogous to the formation of the corpora lutea.

3. The development and ripening of the Graafian follicle does not take place periodically in a regular manner, and there is no connection between it and menstruation.

4. Menstruation is a physiological phenomenon, unconnected with the development and ripening of the Graafian follicle.

5. The rupture of the more or less ripe follicle is associated with congestions of the genital organs, which are as yet unexplained matters.

6. Certain diseases, such as fevers, poisoning, etc., cause atrophy of the follicles where there has previously been a parenchymatous inflammation of the ovary.—*Allg. Med. Central Ztg.*, 54, 1874.

APOMORPHIA AS AN EXPECTORANT.—During the last two years the muriate of apomorphia has been used at the Polyclinic in Heidelberg, and is regarded as successful and reliable. Dr. Jurasy, desiring to test its power as an expectorant, gave it in minute doses in cases of tracheitis and bronchitis of the larger and smaller tubes. The results were gratifying. It liberated the firm and tenacious mucus, the sputa became copious, and the cough was much relieved. The auscultatory signs showed also that there was a decided improvement. The formula employed was Apomorphia mur. gr. $\frac{2}{10}$ — $\frac{1}{4}$; acid. muriat. gtt. v.; syr. simplicis $\frac{1}{2}$ ss.; aquæ $\frac{1}{2}$ iv.; a tablespoonful every two hours. It will be seen that the dose averaged between $\frac{1}{10}$ and $\frac{1}{16}$ of a gr. and this amount did not prove too large for adults. The patients stated that after the first dose they had a slightly unpleasant feeling, which did not return after subsequent doses. Apomorphia was found to have the property of becoming greener gradually, but this was overcome by the addition of a little more muriatic acid. It should be kept in black or dark colored bottles.—*Allg. Med. Central Ztg.*, 55, 1874.

TREATMENT OF NON-SUPPURATIVE PERIOSTITIS BY EARLY AND EXTENSIVE INCISIONS.—There are certain forms of periostitis in which Ollier recommends early incisions, not only to prevent the formation of matter and necrosis, but to put an end to the severe pain which the patients suffer.

There is a painful affection which he calls periostitis neuralgia, which occurs without previous warning and without elevation of the temperature, and is characterized by violent lancinating pains, at any point in the diaphysis of a long bone, and especially in the tibia. It occurs most frequently in adults, but is sometimes observed in childhood. Its cause is obscure, though it appears, in most cases, to come from catching cold. While persons are perfectly well, either at their work or during the night, pain is suddenly felt at a certain spot, as, for example, in the tibia, and spreads from there up and down the limbs. It varies in intensity, being most marked at night, but is continuous. Motion of the limb appears at first to moderate the pain, while pressure aggravates it, and yet there are no other symptoms of inflammation. These local manifestations can last many days, in fact weeks, until at length a somewhat doughy swelling is felt extending to the bone. Active treatment now imperative, though it should be commenced earlier, for the intense pains which have continued notwithstanding the most active anti-phlogistic remedies make the diagnosis certain.

An incision should be made down to the bone, at the point of pain, and then a transverse one, so that no exudation can be imprisoned. The pain immediately subsides, and the wound heals in a few weeks. If these incisions do not give relief in a case showing these symptoms, then we have to do with an osteomyelitis, and the bone must be trephined. Sometimes incision is unnecessary, for an application of unguent. hydrarg. with calomel internally and local depletions may arrest the psoriasis in its early stages. Sometimes Ollier finds great advantage from large blisters covering the entire diseased surface.—*Gaz. des Hôp.*, 114, 1873; *Allg. Med. Central Ztg.*, 60, 1874.

ROKITANSKY.—At the meeting of the New York Pathological Society, held September 8, the following preamble and resolutions were unanimously adopted, and a copy of the same, suitably engrossed, was directed to be sent to Professor Rokitsansky:—

It is allotted to very few to have completed a period of nearly fifty years in the successful cultivation of an important branch of medical science. Such an event is worthy of the brilliant commemoration which it has recently received in Vienna, on the occasion of Prof. Rokitsansky attaining his seventieth birthday. Austria may well take pride in the distinction derived from such achievements, in the behalf of medical science and humanity, as have distinguished the career of her illustrious citizen.

The New York Pathological Society, founded in 1844, was organized under the inspiration of Rokitsansky's example, and may humbly claim to be of his offspring. It is, therefore, becoming that it should join with the numerous kindred societies of European countries in offering their homage of respect and admiration on such an occasion.

Be it therefore Resolved, That this Society respectfully tenders to Prof. Karl Rokitsansky, of Vienna, its most cordial congratulation and best wishes for his continued welfare and happiness, and begs to assure him that its members will always derive fresh encouragement from his inspiring example in the continued unwearying prosecution of his favorite science.

Resolved, That a copy of these proceedings, engrossed and duly authenticated by the signatures of the President and Secretary of the Society, be communicated to Prof. Rokitsansky.

Committee. { GURDON BUCK,
A. C. POST,
JNO. C. PETERS.

THE NEW CORPS OF VACCINATORS.—On the twentieth of September a number of Inspectors were added to the Board of Health of this city, whose duties relate solely to vaccination. Dr. J. B. Taylor, of 76 Orchard St., is the Chief of the Bureau and Inspector of Vaccinations, with a salary of \$2,500 per annum. Eleven Assistant Inspectors, having salaries of \$1,500, are to visit localities where small-pox exists, and by their labors protect the community, as far as possible, against a spread of the disease.

The following are the eleven gentlemen selected from about one hundred and fifty-six candidates:

Drs. G. W. P. Flynn, R. D. Nesmith, F. Livermore, Peter B. Wyckoff, H. R. Williams, E. A. Post, Martin J. Flemming, E. L. Pardee, Joseph E. Tucker, A. B. De Luna, and Henry Rockwell.

THE COLLEGE INTRODUCTORIES.—The introductory for the College of Physicians and Surgeons was delivered by Prof. W. H. Draper, M.D.; for University Medical College, by Prof. John C. Draper, M.D.; and for Bellevue Hospital Medical College, by Prof. R. Ogden Doremus, M.D.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, October 15, 1874.

A NEW MATERNITY HOSPITAL.

THE proposed establishment of a Maternity Hospital on Blackwell's Island will have a tendency to incite considerable discussion upon many questions which will necessarily come up in connection with it. No one acquainted with the high rate of mortality which hovered around the lying-in wards of Bellevue will doubt that the contemplated change is imperatively called for. Every precaution was taken on the part of the medical staff to prevent puerperal fever, and, as far as we know, every plan was tried that promised any good result, except the complete isolation of puerperal women from the contaminating influences of a general hospital. Now that the time seemingly has come for the trial of the last experiment, let us hope that it will be upon a sufficiently comprehensive scale to leave nothing to be desired in the way of protection against the baneful influences of hospitalism.

Already our fears are aroused by the publication of an intention to remove the Small-pox Hospital, situated on the lower end of the island, to Hart's Island, and to use the vacated building as part of the new one to be constructed. Although the intention is to make this building the administrative department, there is no reason why even its indirect connection with the other buildings should not be detrimental. But aside from this, the new hospital which would be built around this nucleus would be in very close proximity to Charity Hospital, the distance being measured at most by a few hundred yards. It is true there would be some benefit in being somewhat removed from the influences of a large hospital, but is it worth while for the sake of economy to run any risks whatever? to take any of those questionable chances which a dangerous neighborhood may offer? We admit that we may be straining a point in making this assertion, and that our fears in regard to the immediate vicinity may be, to a

certain extent, groundless; but certain it is, even with such a construction, that it would be better to isolate the new hospital as much as possible to begin with.

If we were to select any particular place in the vicinity, which would be farthest removed from any large institution, we should select the centre of the island, between the Ahns-House and the house of the warden of the Penitentiary. Aside from this locality being eligible in this respect, it has the great advantage of being high ground. The old Small-pox Hospital would be too small for the purposes intended, and this alone should be a powerful argument, in an economical point of view, against its use as a part of the new Maternity.

The pavilion plan would be the one to adopt. We believe that such is the intention of the Commissioners in any event. We have an idea that no hospital should have any other kind of construction, and especially does this apply to an institution devoted to the care of lying-in women. The details of construction can be intelligently discussed only when some general plan is agreed upon, when the conditions to be fulfilled are thoroughly and intelligently appreciated. The main object to be sought is the protection of individual patients. This we believe can be best carried out by the so-called "cottage plan," giving each patient the advantage of complete isolation during the most dangerous period of confinement, at the same time that all the benefits which belong to a well-regulated institution are enjoyed. Each of these apartments, although connected, should be entirely independent, the only means of communication being a common corridor. A large pavilion for convalescents is also a necessity, and this it strikes us could be divided up into suitably sized wards, say four in number, three only of which are occupied at a time. By this means each ward would be thoroughly aired once in three weeks, the great advantage of which can be readily appreciated by any one who has had any experience with hospital epidemics.

We do not, however, propose to go into any extended remarks upon hospital construction, but desire in connection with the new project to allude to another matter of hardly less interest. This Maternity Hospital should have all the requisite facilities for training nurses. There is such a demand in this country for the teaching which such an institution can give, that its appointments as a model of its sort will never be complete unless this demand is met. Experiments in this direction in other countries has met with brilliant successes, and the existence of skilful midwives and intelligent nurses has become one of the necessities of our civilization. We believe that a system of education could be inaugurated in a large and well-managed maternity, which would in large measure supply the great necessity for competent female accoucheurs, for skilful and conscientious midwives, for careful, intelligent and well-trained nurses. We

earnestly hope, when the proposition shapes itself into a certainty, that among other appointments will be such a training school for nurses.

VIVISECTION.

It would seem that the present crusade against vivisection is not only based upon the assumed fact that such experimentation is useless, but that it is carried on to gratify the barbarous propensities of professors of physiology in particular, and all other investigators in general. It is certainly strange that Mr. Bergh, the champion of animal rights, should attempt to argue with the whole profession upon a question, of which, as a layman, he can know nothing. It is too late in the day to affirm that experimental physiology has accomplished nothing; it is absurd to say that it has no discoveries to make in future, and ludicrous to assert that God never intended us to make use of the lower animals for our good; or in other words, that we have no business with discoveries which may be the results of vivisections. It is pretty evident that Mr. Bergh has a very bad case. He has certainly to advance some better arguments in favor of his clients than he has yet done to produce an impression upon the next Legislature. The Medical Society of the County of New York has already taken up the matter, and has unanimously passed strong resolutions in favor of vivisection. The Medical Society of the State has also declared itself unequivocally on this point, and stands ready to repeat its action at the next session, if there be any effort on the part of Mr. Bergh to alter the laws of the State to suit himself. We have always been opposed to one-man power, and it is time that the President of the Society for the Prevention of Cruelty to Animals should be shown the necessity of narrowing his sphere of usefulness to its harmless and legitimate limits. From being simply good and humane in the first place, he has become, in turn, enthusiastic, ambitious, conceited, and aggressive.

DEATH FROM AN ANÆSTHETIC.

ANOTHER death from chloroform in a dentist's chair occurred recently in Boston, and again the old question of using this anæsthetic is brought up for discussion. We believe it is definitely settled, by all who know anything of chloroform, that it is an exceedingly dangerous agent, and that it should not be employed unless in exceptional cases. There are certain surgical and obstetrical operations in which its use is incomparably serviceable, and in which a choice should always be in its favor against ether. The end in such cases justifies the means. In dentistry, however, there is no reason why chloroform, in consideration of its danger, should have the preference of ether, and the dentist who administers it not only runs the usual risk of losing his patient, but of being reprimanded by a Coroner's jury. It would be a reflection

upon the judgment of dentists in general if a law were enacted forbidding them to use chloroform in their operations, but they have, nevertheless, invited such a course by their persistent and defiant antagonism to a general professional sentiment upon the subject.

THE COLLEGE INTRODUCTORIES.

THE INTRODUCTORIES before the medical schools of this city were well attended, and what is better, were well delivered. We are glad to see a disposition in the speakers to descend to the practical, and to cease prating of our honorable profession, the great dignity of medicine, and other like sentimentalism. While all this is mawkish to outsiders, it does no possible good to the student. In the present addresses special subjects were taken up and discussed in a practical and truly creditable manner. We have no doubt that the audiences were all satisfied that medicine was a useful science, by the practical demonstrations that they witnessed. If not, they ought to have been. Certain it is that the lecturers did their duty.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, September 9, 1874.

DR. GURDON BUCK, Chairman.

NECROSIS OF LOWER JAW.

DR. A. C. POST presented some specimens of dead bone, which he had removed by operation from the lower jaw of a child between one and two years of age. The peculiarity of the case was, that the sinus leading to the dead bone was below the base of the jaw, that there was no communication with the cavity of the mouth, neither was it necessary to make any in the operation.

He also exhibited a vesical calculus weighing two hundred and forty-two grains, which he had removed by the bilateral operation, on the 25th of June last, from a middle-aged man, a patient of the Presbyterian Hospital. In connection with the specimen, he exhibited an instrument known as Sims' rectum dilator, which he had found in this operation, and in others of a similar nature, to be of great service in dilating the opening without running the usual risks of tearing the parts.

He exhibited, lastly, a lipoma removed from the shoulder of a middle-aged woman, and which had existed in that locality for eighteen years. During all this time it had undergone no apparent change in structure. By the use of very fine waxed-silk sutures, union by first intention occurred throughout the entire extent of the wound.

EMBOLIC ABSCESES—RESECTION OF RIBS AND PORTION OF SPINE—MENINGITIS.

DR. A. JACOB presented a portion of the thorax taken from a young man who was admitted to the Mount Sinai Hospital about a year ago. When admitted the diagnosis of the case was intermittent fever, which fever was accompanied with very severe head-

ache. His fever had lasted unusually long, and the headache was still quite severe when Dr. Jacobi first saw him (Oct. 1). His spleen was markedly swollen, and his treatment by quinine was continued. His headache did not disappear entirely.

He was then examined a little more closely, when it was found that he suffered from incompetency of the mitral valve, in consequence of which there was an hypertrophy and dilatation, especially of the right side of the heart. This condition explained the reason why the spleen did not diminish, as it should do, and why the headache, likewise the result of venous congestion, lasted so long.

The patient was then treated symptomatically and improved; but he was never well enough to leave the hospital. Now and then he would have a little fever, again, some pain about his joints, and again, he would complain of palpitation and other heart symptoms.

In this condition he remained in the hospital some time, when, one day, after he had more fever for a week, the attention of Dr. Jacobi was directed to a swelling in the sacral region; at the same time there was another swelling on the left side of the chest, corresponding to the centre of the tenth rib. Fluctuation was discovered in these swellings, and an examination of the heart showed that the murmur had altered in character. During this examination a slight swelling was also discovered in the intercostal space of the fourth and fifth ribs. This latter swelling was very small, and did not give any fluctuation. The diagnosis of embolic abscesses was then made, and a few days were allowed to elapse before these abscesses were opened. The first one opened was in the lower portion of the spine, and a week afterwards the abscess over the tenth rib was evacuated. About this time the abscess between the fourth and fifth ribs had disappeared, and the conclusion was that it had burrowed somewhere inside. As no severe pleuritis had occurred it was thought that the abscess could not have found its way into the chest cavity, and hence the conclusion was that it had insinuated itself somewhere between the thoracic wall and pleura. For a long time, however, there did not seem to be any justification for cutting down upon the original site of the swelling, and without any distinct guide. Meanwhile the two other abscesses were treated locally by injections. After the incisions were made the fever became less, and the general condition of the patient was better.

In the course of the next two weeks a moderate amount of pleurisy set in on the left side. It was not very amenable to treatment. He had fever that lasted for weeks, and it was found that the pleura became thickened and the respiratory murmur gradually diminished. One day, when the abscesses were being injected, a slight swelling between the fourth and fifth ribs again showed itself. This afforded the hint for an incision at that place, which was accordingly made a few days afterwards. Although no probe could be passed between these two abscesses, to show any communication, yet by injecting one or the other the fact was palpable.

Treatment was thus continued for several months, and the general condition of the patient appeared tolerably well. His pleurisy had ceased increasing, and there was very little fever for a number of weeks. Then fever set in again. Examining the middle abscess it was found that a small portion of the tenth rib was bare, also that dead bone could be reached through the lower opening. This was during June of 1874. About this time the middle opening (over the tenth rib) closed gradually, and it was feared, that as the man lay constantly on his back, the pus would find

its way between the pleura and thoracic wall to the posterior part of the chest. Consequently, the wound was dilated and a portion of the tenth rib excised. A large amount of offensive pus thus found an outlet. Injections were used thrice daily for a few days, when the discharge improved in character. On introducing a probe into the wound at the time, it was possible to pass it in an oblique direction upwards as far as the fourth rib. A drainage tube was introduced into this tract, and through the tube carbolic acid solution was injected two or three times a day, and later iodine in solution. As a result of this treatment the discharge ceased very rapidly, although not entirely, and the general stamina of the patient was improved. In such a condition the patient remained for a long time, until new fevers set in, and until it grew probable, in fact almost certain, that all the pus could not be discharged, that it had, in fact, found some recess beyond the reach of the injections.

After continued external and internal treatment the wounds were again carefully examined. It was then discovered that, in addition to what has been stated, the bones of the sacrum were in a curious condition. The upper wound being still contracted, a portion of the fifth rib was excised, with the good result of increasing the discharge of pus, which at this time was not so offensive as formerly. While the patient was under ether the lower opening was examined, when it was thought absolutely necessary, after consultation, to remove the posterior portions of the lower lumbar vertebrae, including two spinous and a part of the corresponding transverse processes. Just before the completion of this operation, by same accident the meninges were cut into or otherwise injured, and about an ounce of cerebro-spinal fluid escaped. It was hoped, notwithstanding this accident, and in spite of his low condition, that no meningitis would result. His fever went down immediately after the operation, the temperature from 106 became 100, and remained at that point for three days. After that time the patient became feverish again. The fever could not be explained in the beginning, as there were no peripheric symptoms which pointed to meningitis. His feverishness continued, however, for some days, at the end of which time he became drowsy, with slight convulsive movements, and finally died six days subsequent to the last attempt made to relieve him.

The post-mortem examination, as far as the brain and spinal cord were concerned, revealed the lesions of very intense meningitis. The autopsy was made during Dr. Jacobi's absence from town, but it was reported to him that there was a good deal of infection of the dura mater of the brain. Some of this condition was still visible at the presentation of the specimen to the Society. Besides this, there was a good deal of thickening of the dura mater and pia mater, as well as deposits of a fibro-purulent character, on the surface of the brain. The falx cerebri was very much roughened and thickened. There was nothing abnormal in the substance of the brain itself. The meninges at the point of injury showed no signs of inflammation.

Dr. J. next exhibited the chest walls, and pointed out the seats of the different operations performed during the life of the patient. In the neighborhood of the middle wound was a fistulous tract leading therefrom to the abscess which was opened during life. The two pleurae were very much thickened, the lung compressed and pushed upwards and posteriorly, and an abscess was found about four inches to the left from the upper incision and resection, in close juxtaposition to the compressed lung. It contained about two ounces of pus. The pericardium was firmly ad-

hering to the pleura. The heart was found enlarged, especially on the right side, caused by vegetations upon the mitral valve. Some of these vegetations became separated, coincident with the change in the character of the murmur, and escaped in the circulation, cutting off the supply of blood in those parts of the body which eventually became the seats of the abscesses.

Although the chances for life in the patient were very poor, Dr. Jacobi had no hesitation in expressing the opinion that death was hastened by the accident to the meninges. The escape of the cerebro-spinal fluid caused a corresponding vacuum in the cranial cavity, which invited a congestion, and that, in its turn, a high grade of inflammation. In this connection he alluded to a case of spina bifida, in an operation for which some cerebro-spinal fluid had oozed out, and in which, death occurring, the same brain lesions were discovered.

DR. MARY PITTMAN JACOB remarked that the congestions of the lung in croup were to be explained in the same manner, on account of the insufficiency of air.

DR. FINNELL exhibited a specimen of necrosis of the head of the femur, which he had excised in a boy, aged 14, who had the disease ten years. There were numerous sinuses in the vicinity of the joint, and the extremity was in the characteristic position of the disease in the third stage. The head of the bone, and the greater part of its neck, were almost entirely destroyed, as well as the surface of the acetabulum. The section was made just below the trochanters. The patient recovered with a shortening of two inches, although the extremity, from being held so long in one position, lost much of its usefulness.

DR. POST remarked that the latter condition of things appealed to the necessity of performing the operation as soon as all other means were found unavailable.

ACUTE ATROPHY OF LIVER.

DR. J. MESSENGER presented a specimen of acute atrophy of the liver, taken from a man aged forty-three. The patient was as good a specimen of perfect health as he ever saw, until, by continuous and protracted drinking of large quantities of brandy, he had finally produced serious trouble with his liver. The first thing that attracted notice was the distention of his abdomen, and a slight jaundice, which however deepened into an almost bronzed appearance of the whole body. Increased temperature was made with the aid of an axillary thermometer, but at no time was the heat above 102°. The pulse was weak and frequent. Insatiable thirst was a prominent feature in the case. Highly colored and scanty urine, with very large quantities of deep yellow-colored urates. The urine had a specific gravity of 1030, smelled badly, and stained whatever white fabric it came in contact with a deep yellow color. The skin was dry and harsh, and rough to the touch. A peculiar heat was also felt when the hand of a healthy individual was brought in contact with it. The tongue was very dry and rough, like that of a patient suffering from typhoid fever of a severe type. The dejections from the bowels were of light clay-color, floated lightly upon water, and were almost odorless for a while. Physical examination showed that the liver extended about four inches below its normal level; was very tender and smooth. Abdominal distention was very marked. Palpation and succussion indicated a collection of fluid.

Acute disease of the liver was diagnosed by Prof. A. Clark, Drs. J. J. Crane, Vosburg, and E. H. M. Sell. After using all the means, which are too nu-

merous to mention here, tapping was resorted to eight successive times, and about twenty gallons of liquid, very albuminous yellow, were drawn off. From twenty-one quarts down to three at each séance were drawn off at different times. Vegetable diuretics seemed to have more effect in relieving him than any or all others. Under the influence of them all of the aforementioned symptoms were greatly mitigated. The urine became more copious, the jaundice disappeared, the dejections from the bowels became, to appearance, quite healthy-looking, the appetite and digestion became natural also. Notwithstanding all this, the patient became more and more enfeebled, and after a severe sickness of about eight or nine months, death came to his relief.

But a limited examination (*post mortem*) was allowed us. The peritoneal investments of the parietal wall and viscera of the abdomen were nearly all adherent, and in some places could not be separated. They were torn through to get at the liver, which was found very much diseased, nothing having undergone any very great amount of diminution from the size, as is generally laid down in the books. A fibrous tissue had taken the place of the ordinary hepatic lobules and cells. But a small portion of the healthy structure of the liver remained.

OVARIOTOMY.

DR. SELL presented a specimen of fluid from an ovarian cyst, which he tapped, September 3d, and made, in substance, the following remarks:—The subject of the specimen I present is Mrs. M., aged 55 years 9 months, widow for 14 months, having been married 31 years 4 months, and is the mother of five children. The eldest died at 10 years, would now be 31 years; the youngest, now living, is 14 years. She also had three or four miscarriages.

Her general appearance has that peculiar pinched expression described as the *facies uterina*, or *facies ovariana*. Her complexion is rather sallow. Emaciation progressed for the last four months. Habits of life temperate; surface of body natural, slightly moist. Temperature of skin and extremities normal: in axilla, 98.2°; in vagina, 99.2°; pulse, 120, falling to 90; and respirations 18. Considerable edema over lower part of abdomen.

A large tumor, oval in shape, inclined very slightly toward the right side. Measurements: 1. Girth at umbilical level, 42½"; 2, from ensiform cartilage to umbilicus, 11½"; 3, from umbilicus to symphysis pubis, 12½"; 4, from right ant. sup. sp. of ilium to umbilicus, 13½"; 5, from left ditto to umbilicus, 13½". But slight mobility of the tumor, whose parietes, especially below, are very thick. Lineæ albicantes, as well as dilated veins on the abdomen, but few. Fluctuation almost entirely confined to the region above the umbilicus. But little crepitus, and scarcely any tenderness, save a little on pressure on the right side, four inches from the spine of the ilium, but no soreness.

Percussion elicits dull sounds, and auscultation reveals a faint bruit all over the abdomen. The uterus, situated rather high and a little to the left, measuring about three inches, is movable, but stationary on moving the tumor.

The os and cervix uteri are slightly dilated, otherwise normal to the touch. Vagina, rectum, and anus are normal. The patient commenced to menstruate at 17 years, and ceased at 50 years. Has no dysuria, incontinence, nor irritable bladder. Urine normal, except less in quantity.

Tongue is clean; appetite not very good; some

thirst and flatulence; bowels regular. Sleeps not long at a time. Mental condition good; no hysteria nor neuralgia; no cough nor expectoration. Rests best on her left side. Pulse pretty strong, 120 per minute, falling shortly to 90, showing the influence of an involuntary fear. Heart sounds normal.

First signs of ill-health commenced about 2½ years ago, having a pain in her left groin, on coitus. There was no vaginal fulness, no bearing down of uterus, no pressure on the bladder, no pain, numbness or weakness of the legs, nor any nausea.

Dr. B. F. Vosburg, her usual medical attendant, discovered, about 2½ years ago, a non-fluctuating tumor, size of a large fist, in the left iliac region.

Dr. V. saw the patient but seldom, as her condition did not require medical treatment. The rate of the tumor's enlargement was gradual and slow, no changes in its situation, and no movements felt. There was no dyspnea, no tympanites, no febrile attacks, nor cyst inflammation.

In the winter of 1873 and '74 she had four or five attacks of local peritonitis, for which she was treated with opium and cinchona, and since those attacks the tumor enlarged at least to double its former size.

There never were any signs of ascites, nor any discharges pointing to a spontaneous rupture of the cyst, neither through the uterus, vagina, bladder, bowel, nor abdominal wall.

The patient losing ground, her appetite failing, her sleep being much interfered with from pain, chiefly in her back and down her thighs, and emaciation progressing constantly for the last four months, Dr. V. saw that unless something was done for her speedily her health must fail rapidly. Hence the doctor called me in consultation on the above date, when, after as thorough an examination as was possible under the circumstances, without an anesthetic, we concluded that tapping should be performed, both to relieve the patient as well as to clear up the diagnosis. While we were certain of having to deal with an ovarian cyst, it was not quite so clear with what particular kind, save that its larger portion was solid.

Tuesday, September 3d, was accordingly appointed as the day for the operation. At 10 A.M., assisted by Drs. Vosburg and Messenger, I made another thorough examination, and a spot about two inches below the umbilicus, and a little to the right of the linea alba, where some fluctuation was manifest, was thought available; and here, after dividing the skin, I tapped, using the valuable trocar of Mr. Chas. Thompson, of Westerham, employed by Mr. Spencer Wells.

At first nothing came, but after waiting a little we were pleased to see a viscid fluid like thick jelly, of a grayish tint, pass with difficulty through the canula, which is three lines in diameter. It required six hours for sixteen pounds of this fluid to flow through; the last half pound, being very thick, was removed by attaching an aspirator to the tubing, by which means all the air was exhausted. The wound I closed by passing a hare-lip pin deeply across the opening, and twisting several turns of silk around it.

The *microscopical examination* of this fluid revealed the contents, which are ordinary in a *multilocular colloid cyst*. A teaspoonful of the following mixture was ordered at bedtime: R. Ex. cypripedii fl., ex. asclepiæ fl., ex. dracontii fl., ex. scutellarie fl., aa. With this the patient sleeps very well, and can now rest on both sides.

On the 5th of September, second day after the operation, she was up and about, as usual, but feels a great deal better than she did for some time before the tapping.

Another examination, made September 19th, assisted by Dr. R. Newman, corroborates my former diagnosis, viz., that the tumor is a multilocular colloid ovarian cyst, with much solid matter.

The dimensions were found but a fraction smaller than before tapping, sixteen days ago; however there is much less tension, and the patient continues to feel much better, enjoys better appetite, and sleeps well. The conclusions arrived at are as follows: that when necessity demands, ovariectomy should be attempted in preference to tapping, as the latter affords too little relief in comparison to the amount of danger incurred from peritonitis and inflammation of the cyst.

The unfavorable points for ovariectomy in this case are the following:—

1. The necessary long incision required.
2. The known adhesions.

On the other hand we have—

1. Likely freedom from adhesions to the pelvic viscera, demonstrated by the knee-elbow position, as recommended by Mr. Spencer Wells in his valuable book.

2. The relative good health of the patient.

3. Her endurance of disease, as revealed during the several attacks of local peritonitis.

4. No bad symptoms following tapping.

On March 28th, 1874, Dr. Messermer requested me to tap an ovarian cyst in a young married lady, about 22 years old, in whom I had diagnosed an ovarian cyst five weeks previous. Tapping was recommended in this case in preference to ovariectomy, as the lady was apparently fast declining from a pulmonary and throat affection. She suffered greatly from dyspnea, and had a high fever. We obtained fourteen pints of a greenish viscid fluid, containing, besides several of the contents usually found in a unilocular ovarian cyst, a large amount of pus. Strange to say, this patient improved rapidly, and has not only recovered from her sickness, but we are informed that she is not enlarging.

Reports of Hospitals.

PENNSYLVANIA HOSPITAL, PHILADELPHIA.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

MEDICAL DIVISION.—DR. BRADFORD, HOUSE-PHYSICIAN.

THE following medical items were obtained from Dr. Hutchinson, visiting physician, while passing through his wards.

THE TREATMENT OF PNEUMONIA.

The chief remedies employed in the treatment of this affection, in this hospital, are quinine, nitrate of potash and Dover's powders.

The quinine is given in small doses and frequently repeated, being administered for its tonic effect. It has been used but very little in this hospital for its *antipyretic* effect, either in pneumonia or typhoid fever. In Bellevue Hospital, New York, the remedy has been very much used for this purpose, hoping thereby to prevent tissue waste. The nitrate of potash is regarded as mildly antiphlogistic, as possessing in some degree a solvent power over the exudation, and it has also some diaphoretic influence.

The Dover's powder is administered in soothing doses.

Poultices are applied to the chest and ordinarily covered with oil silk; they are believed to act as revulsives. Stimulants are used according to the condition of the pulse. Diet is sustaining, general blood-letting is very rarely resorted to.

SUBACUTE PLEURISY OR PLEURISY WITH EFFUSION.

Diuretics are mainly employed, but particularly ferruginous diuretics. The liq. ferri per acetatis, or Basham's mixture, is uniformly administered. Diet sustaining. The formula for Basham's mixture as furnished by the apothecary of the hospital is as follows:

R.	
Liq. ammon. acet.	5 vi.
Acid. acetic.	3 iii.
Tr. ferri chloridi.	3 v.
Alcohol.	3 ii.
Syrupus.	3 iv.
Aque.	3 iv.
M.	

Teaspoonful doses three or four times a day or oftener.

Paracentesis is never resorted to early, unless there are present some special symptoms which demand it.

ACUTE PHTHISIS.

The patient presented the ordinary symptoms of acute consumption; high temperature; consolidation at right apex, etc., etc. Good diet and the use of Niemeyer's pill were the chief elements of treatment.

Dr. Hutchinson remarked that he did not regard cod-liver oil as being of much benefit under such circumstances.

NIGHT SWEATS OF PHTHISIS.

Atropia and oxide of zinc are the two remedies chiefly employed for the relief of this particular symptom. Consumptive patients in general are placed upon Niemeyer's pill. The formula for the pill, which properly speaking is Heim's pill, with Niemeyer's addition, is as follows:

R. Pulv. herb. digitalis ʒss; pulv. rad. ipecac, pulv. opii puri, aa grs. v.; ext. hellenii q. s. u; f. pil. No. xx. consp. pulv. rac. iric. flor. S. a pill, t. i. d.

A scruple of quinine may be added to the above for its antipyretic effect, according to Niemeyer.

CHRONIC BRIGHT'S DISEASE.

Diet nourishing; and the administration of tr. ferri chlorid, or Basham's mixture, are the leading features of the treatment of this affection, unless special symptoms are developed. Some cases of late have done remarkably well upon the White Rock spring mineral water. Hydragogues are commonly employed where dropsy supervenes. When convulsions are present or threatening, a purge is administered, generally elaterium, and perhaps a hot-air bath. Opium has never been employed in this hospital in the treatment of uræmic convulsions.

GENERAL BRONCHITIS, WITH PROBABLE PHLEBITIS AFFECTING LEFT SAPHENA.

The patient when admitted was very much exhausted; system in a low condition, etc., etc.

The free use of stimulants and nourishment were necessary to sustain life. A few days after admission he suddenly developed symptoms indicating the presence of phlebitis affecting the left saphena. The treatment adopted for this complication was to place the limb in a straight position, with the foot elevated as

much as could be conveniently done. In that position, the limb was kept continually wet with warm water and tincture of opium. This continuous fomentation had relieved all the acute symptoms, and, so far as the leg was concerned, the patient was in a comfortable condition. It was feared that the general bronchitis might terminate in some disease of the chest of a more serious nature. He was placed upon Niemeyer's pill; the brown mixture or compound liquorice mixture and sulphuric acid with infusion of wild cherry bark. Diet sustaining.

ACUTE ARTICULAR RHEUMATISM.

Cardiac complications are commonly present when the patients are admitted. A soft blowing murmur heard at the base of the heart with the first sound is regarded as a cardiac complication, but one which will probably pass away as the rheumatic fever subsides and disappears. These patients are treated mainly by the use of bromide of ammonium, administered in doses from 16 to 20 grs. every 2 or 3 hours. Citrate of potassa is also not unfrequently administered in doses of 20 grains every three hours until the fever subsides. When the fever has subsided, quinine is administered in full doses. There is no aim in the treatment of rheumatism in this hospital to render the urine alkaline. When alkalies are pushed convalescence is rendered much more tedious.

The joints are wrapped in dry cotton. When pericarditis or endocarditis occurs, if there is excessive cardiac action of a tumultuous character, infusion of digitalis is usually administered; and if there is much effusion into the pericardium, a blister is placed over the precordial space.

CHRONIC RHEUMATISM.

The question was asked what to do for these cases—who has had any uniform success from any particular plan of treatment?

TYPHOID FEVER.

Treatment, in the main, expectant. A fair amount of nourishment, and of such articles as can be easily digested, and then treat the symptoms as they are developed. If diarrhea needs control, lead and opium; opium suppositories, perhaps tannic acid and opium suppositories, are the principal agents relied upon. If hemorrhage from the bowels occurs, about the same line of drugs is employed. In the last condition an extra amount of stimulants and nourishment may be required. The acid treatment of typhoid fever is thought well of, and very frequently muriatic acid dilute is administered from the beginning.

DIABETIS MELLITUS.

The patient has been placed upon opium three grains daily, and increased to seven or eight grains, without producing any special effect upon the disease. He was now receiving bicarbonate of potassa with the opium, and was improving markedly under this treatment. The diet was regulated to conform to the disease.

DIABETIS INSIPIDUS.

The patient was taking tr. ferri chlorid. and was rapidly improving.

METHOD OF APPLYING THE NITRIC ACID TEST FOR ALBUMEN.

The presence of albumen in the urine in exceedingly small quantities can be detected by making use of nitric acid in the following manner: fill a test tube a third or quarter full of urine, and when the nitric acid is added let it run down the side of the test tube drop by drop. Added in this manner, the acid will collect

upon the surface of the urine, and if albumen is present it will be recognized by the presence of a white line between the acid and urine, which will be delicate in proportion to the amount of albumen in the urine. Albumen in urine is much more certain of recognition when the acid is added in this manner, than when added in what may be called the ordinary manner.

FACIAL ERYSIPELAS.

Tr. ferri chlorid. grt. xx. every two hours from the beginning. The common topical application is mucilage of slippery elm; keeping the parts constantly wet with it.

In the later stages of the disease oxide of zinc ointment is applied. Phlegmonous inflammation had occurred in the eyelid of one patient and abscess had formed. The abscess was evacuated, and oxide of zinc dressing employed.

Erysipelas had been in the hospital to considerable extent, and one very interesting feature was developed in some of the cases in Dr. Da Costa's wards, namely, the occurrence of *endocarditis* as a complication.

Some deaths had occurred from erysipelas in which there were developed marked head symptoms, but no lesions were found in the brain or its membranes, either gross or microscopical.

The endocardial cases showed the necessity of close and prompt search for internal complications which may attend such general morbid conditions.

GENERAL DROPSY—CARDIAC.

Infusion of digitalis and broom tea were the remedies employed.

About a pint of broom tea was taken in twenty-four hours. The ordinary dose of the infusion of digitalis administered was a dessertspoonful, and occasionally bitartrate of potassa was combined with it.

ASCITES.

Paracentesis abdominis is resorted to only when all other means have failed, and when distressing symptoms are developed which render it necessary.

CHRONIC DIARRHŒA.

The case was regarded as being one of diarrhœa and not dysentery. Particles of food were seen in the dejections when examined microscopically.

Treatment consisted in regulation of diet; the administration of pepsine and muriatic acid; and the use of tannic acid and opium suppositories. Patient was improving.

WRIST DROP.

The case was one of lead poisoning, and had received iodide of potassium before admission.

Treatment now consisted of hypodermic injections of strychnia $\frac{1}{32}$ of a grain over the muscles daily, and the use of the constant current.

SURGICAL DIVISION.

Dr. A. Hewson, Visiting Surgeon.

By the favor of Dr. Hewson we were permitted to see something of the "earth dressing," which he recommends. The earth used is common clayey soil dried and sifted. Care must be taken in drying the clay that it is simply dried and not roasted. It should be free from all vegetable matter, sand, etc.

When applied it is wet up with cold water, and made of such consistence that it can be easily spread upon cloth.

In general, the wet clay is spread upon strips of cloth of the same width and length as strips of adhesive plaster cut for a like purpose, and then applied in

the same manner. The following is a brief reference to cases in which the dressing was seen applied. "The earths containing the double salts of alumina with lime or magnesia, rather than those with soda or potassa," says Dr. Hewson, "were early found the better preparations for surgical uses." Fuller's earth has been used, but it has been found to be rather too alkaline.

COLLES' FRACTURE.

The fracture was treated upon a Bond's splint. At first there was very much swelling. The clay dressing was applied for the purpose of subduing the swelling and inflammatory action in general. The patient said that immediate relief was afforded.

CHRONIC ULCERS.

The clay dressing is used in chronic ulcers, applying the strips in the same manner as adhesive plaster and covering the whole with a bandage. The patients are permitted to go about. Satisfactory results are obtained.

FACIAL ERYSIPELAS.

Constitutional treatment by the use of quinine and iron. For topical application, earth dressing. In one case, phlegmonous inflammation with formation of abscess in both eyelids had occurred. The sores looked healthy and evidently were healing rapidly.

CARIES OF STERNUM.

Earth dressing kept the parts in a cleanly, wholesome condition.

CHRONIC GONORRHŒA.

The case was one that had resisted every form of treatment that had been adopted, which had been numerous. Injections of earth, rendered sufficiently liquid with water that it can be thrown through a syringe, were employed, and the patient was nearly well. The remedy had been used only a short time. Acute gonorrhœa is treated in the same manner.

COMPOUND FRACTURE OF THE SKULL.

The wound was dressed with the earth dressing, and was doing well.

PENETRATING WOUNDS OF THE ABDOMEN.

The doctor mentioned that he had had in his ward within the last three months *five* cases of penetrating wounds of the abdomen inflicted with knives. In every case there was protrusion of either omentum or intestine. The omentum or intestine was immediately reduced; the edges of the wound brought together with the wire suture, and the clay dressing applied. Every one of these patients was discharged, having recovered within a week from the reception of the wound. Not a single bad symptom was developed; nor was opium used. Pyæmia was in the hospital at the same time.

SPRAINS.

Wrap them up with the earth dressing, and recovery takes place within a week.

PARENCHYMA.

This patient's hand was enormously swollen when admitted, and was exceedingly painful. A cast of the hand was made. The earth dressing was applied, and the pain was at once relieved, and the patient said that it had not pained him since. The swelling immediately began to subside, and at the end of three days the size of the hand was reduced two-thirds as determined by a second cast. The results obtained by

treatment in this case were exceedingly gratifying to the patient.

BED SORE.

The case was one of paraplegia. A large bed sore had been developed over the sacrum, and one upon each heel. These were treated with dry earth by dressing the surface until it is completely covered. The usual offensiveness of this class of sores was almost completely destroyed.

The patient was upon a water bed, but was lying in a bed of earth spread upon paper beneath him; nevertheless it was a most cleanly surgical dressing.

CHANCROID.

This class of cases has the earth dressing, and the result is recovery within a short time.

DEEP STAR-WOUND IN THE THICK OF THE THIGH.

The edges of the wound were brought together carefully, and the entire surface of the thigh covered with wet earth. The patient had not suffered pain since the application, and the amount of soreness was very trifling.

In cases of burns the earth dressing is immediately applied.

A NEW METHOD OF MEASURING THE LOWER EXTREMITIES.

Fractures in this hospital are quite commonly treated with the permanent dressing, plaster-of-Paris usually being employed. In some of the lighter fractures, such as of the arm or leg, silicate of soda is used. In thigh splints of plaster-of-Paris, in adults, accessory splints, such as the metallic strips or pieces of binder's-board, are not unfrequently added.

FRACTURES OF THIGH.

Another method of measurement. Place the feet equally distant from the long axis of the body, and then measure from the *umbilicus* to the internal malleoli.

One case was noticed in which fracture of the thigh had occurred, producing very great deformity, and was followed by a great amount of swelling, etc. The limb was placed in a long fracture box, and extension applied by means of weight and pulley at the foot of the bed. The purpose was to wait until inflammatory action had entirely or nearly subsided, and then place the limb in a permanent dressing of plaster-of-Paris.

This is the ordinary method of managing fractures accompanied with considerable swelling, etc. In some fractures which required only a light dressing Dr. Hewson has employed

THE EARTH SPLINT.

made by applying successive layers or strips of cloth upon which had been spread the wet clay. The clay sets within a short time, and makes a tolerably firm dressing.

SULPHITE OF CALCIUM.

A very common prescription made when there is fear of pyæmia, or when the patient has a coated tongue and fetid breath, is the *sulphite* of calcium. It is given in doses varying from 2 to 5 grs. every three hours. Its effect was highly commended.

In other surgical wards the following cases were noticed:—

HYDROCELE.

Two cases of this affection were present which presented some features of interest. In the first, the silver wire had been passed through the scrotum after the fluid had been withdrawn, but it had failed to bring about a cure. It was left in for forty eight hours, and was followed by a great amount of inflammation. The case was then being treated by painting the scrotum with tincture of iodine. The visiting surgeon had been very successful in treating these cases in that manner.

The second case was one in which the wire had been introduced, and had been followed by an immense amount of inflammation. The suture was retained only twenty-four hours. Laudanum and water were being applied to the tumor, which was as large as the largest-sized orange. The remark was made that the silk suture was more liable to be followed by extensive inflammation, and perhaps suppuration, than the silver suture.

HEMATOCLE IN THE THIGH.

The tumor was in the thick of the thigh, and was as large as a child's head. It was the result of a bruise. Unless some very urgent cause is present, do not open an ordinary external hematocle.

Rest and pressure by means of a roller bandage were the chief elements of treatment, and the tumor was rapidly diminishing in size.

DELAYED UNION OF FRACTURE.

Five weeks had elapsed since the fracture occurred. There was unquestionably motion at the seat of fracture at that late date.

Remove the dressing once or twice a week and subject the limb to friction, and the extremities of the bones to pretty strong pressure, perhaps permit the patient to go around and occasionally bear some weight upon the limb. In this manner union is stimulated. These manipulations, however, it was remarked, should be proceeded with cautiously, lest injury be done by accident. The phosphites and preparations of that kind are used if there is reason to believe that the delayed union is dependent upon constitutional trouble.

FRACTURE OF PATELLA.

A number of cases of fracture of patella had been treated by position alone. Place the patient in a position best favoring the approximation of the fragments, and maintain that position until such union as is ordinarily obtained takes place. The results in these cases were exceedingly good. The patients were retained on the single inclined plane for eight weeks.

COMPOUND FRACTURE OF THE LEG.

Treated in a fracture-box. Permanent dressing were not employed, for the reason that the fracture was compound. In these wards the silicate of soda is quite commonly used when permanent dressing is applied.

FRACTURE OF TIBIA.

The case was one in which there was very great projection of the upper fragment inwards. The patient was placed upon his side, and that position maintained for several days, when the deformity was markedly overcome. By means of position and the silicate of soda dressing, union was so perfectly obtained that the position of the fracture could scarcely be determined.

MEDICAL DIVISION.

EPILEPSY.

Petit Mal, with Irritability of the Nervous System.—

The case was a girl *æt.* 11 years. General convulsions were exceptional. She had what the mother called weak spells, during the occurrence of which she remains unconscious; and there is jerking of the muscles of the face, and sometimes of the arms and lower extremities. Has had as many as eleven a day, and continuing three or four days in succession. They had never been known to occur in the night. Has had actual convulsions only twice. Has been in this condition for three years. These symptoms began to appear about one year subsequent to an attack of small-pox. Close examination led to the conclusion that the case was one of idiopathic epilepsy, unless it was dependent upon the effects produced by the small-pox. That was thought to be quite possible, for at the time the child was suffering from small-pox there was considerable mental disturbance, and it was believed to be quite possible that some central complication was developed which left traces of meningeal thickening and slight irritation of nerve structure that had given rise to these attacks. Aura quite well marked. The child was quite irritable at all times.

Treatment.—The possible cause was borne in mind, and iodide of potassium was ordered, in three-grain doses, three times a day, two hours after each meal. For a more specific action upon the epileptiform seizures, bromide of magnesium was ordered, in ten-grain doses, three times a day, administered in simple syrup and water. Bromide of magnesium is well taken by children, and is sometimes better borne than the potassa salt, although its action is very similar.

Correspondence.

HYDROCHLORAL BY THE RECTUM IN VOMITING OF PREGNANCY.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—In THE RECORD for June 1, 1874, there is a communication from Dr. D. B. Simmons, attesting the efficacy of "Hydrochloral by the Rectum in Vomiting of Pregnancy." Perhaps the following history of a case treated successfully by the method proposed by Dr. S. will be interesting in connection with that article:—

On July 8, 1874, was called to see Mrs. M., age 28, extremely anæmic, pregnant with third child; found her suffering with symptoms of renal colic; pain on right side of abdomen extending down right leg, inner side; numbness covering the distribution of right anterior crural nerve, great frequency of micturition, small amount of urine passed, with heavy deposit of urates, nausea and excessive vomiting. These symptoms had continued more or less severe for seven days. Prescribed morphia with anti-emetics, which somewhat mitigated the pain, nausea and vomiting continuing.

On the 11th pain suddenly stopped, numbness passed away, nausea and vomiting as bad as before.

12th. Showed me a small calculus (uric acid) which had given rise to severe pain while passing through the urethra; does not urinate so frequently, no pain, deposit of urates not so heavy, nausea and vomiting as usual.

My attention being now directed mainly to the "sickness of stomach," I interrogated all the organs,

organic or functional disease of which would give rise to these symptoms, with a negative result, and concluded that they were of sympathetic origin due to pregnancy, which had advanced to the eighth week.

The nausea had been continuous now for eleven or twelve days, and the stomach was unable to bear anything, no matter how small the quantity; even half a teaspoonful of milk or water would come up immediately; during this time she had taken no nutriment whatever, being opposed to feeding by the rectum.

Between the 12th and 22d I had recourse to hydrocyanic acid, dil. chloroform, oxalate of cerium, bismuth, alkalies, nux vom., potass. bromid., creosote, wood naphtha, carbonic acid, hyposulphite of soda, and calomel, neither of which produced any good effect whatever. I then tried the hypodermic injection of morphia and the rectal injection of tinct. opii, which only aggravated the trouble and apparently produced a diarrhœa each time they were used.

On the 22d she was so weak as to be unable to rise from her bed. By representing the extreme gravity of the case to her I got her over her antipathy to enema-ta, and commenced the frequent injections of brandy, eggs, milk and beef-tea with starch. Deeming that I had sufficiently tried anti-emetics and anodynes (in fact I was at a loss to know what else to use), I was about demanding consultation with the view of inducing abortion, if needs be, when the article of Dr. S. was recalled to my mind.

July 23d. Administered grs. xl. hydr. chloral per rectum night and morning. July 24. Nausea and vomiting relieved, half a cup of weak tea remained on stomach; feeling so well to-day she omitted the injections, and as a result the nausea and vomiting is this afternoon as bad as ever; no sleep since chloral was given. July 25. Ordered grs. xl. chloral with potass. bromid. $\frac{3i.$ per rectum three times a day. July 26. Injections retained; sleeps well, no vomiting, no nausea. July 27. Condition the same. July 28. Injections omitted. July 29. Nausea and vomiting have come on again, though not very severe; again ordered chloral and potash. July 30. Neither nausea nor vomiting; retains food well.

Continued the injections until the 1st August, when they were stopped; has remained well ever since, anorexia disappearing, and rapidly gaining in strength.

Respectfully yours,

W. H. MORSE, M.D.

231 E. 7TH STREET.

THE NASAL DOUCHE,

WITH A MODIFICATION IN CONSTRUCTION AND USE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—When the nasal douche was introduced in the profession, it was hoped and felt that the problem of the treatment of naso-pharyngeal catarrh and ozena had been solved, as far as local treatment was considered; but after long and patient trial, the results have not been satisfactory; consequently the douche has fallen into disrepute, being regarded as a medium capable of doing much harm, and at best of but little good. The only credit that can be ascribed to it is, that it clears a temporary breathing space through the nostrils. The volume of water passing through the nozzle, as ordinarily used, is insignificant and never reaches the vault of the pharynx or the superior sinuses of the nasal cavity, as Dr. Beverley Robinson has shown in his communication to THE MEDICAL RECORD of August 1st, to which article I would call the attention of the reader.

I have used with much success the douche, after the following modification: I remove the glass nozzle and substitute a gutta-serena tube five inches in length and one-fourth of an inch in diameter, curved at the free end, corresponding nearly to that of a posterior nasal syringe, slightly flattened transversely. Thus prepared (the patient assuming the usual position, the head inclined forwards and downward) I carry the tube back into the pharynx, the stream is now forced against its vault, passing through the posterior nares, flooding the entire nasal cavity, flowing over the floor of the hard palate, and out anteriorly, clearing out all debris, if the solution is continued sufficiently long to soften the inspissated mucus, as may be seen on microscopic examination.

The tube may be grasped by the teeth, and, after some experience, a doucheful may be passed through in this manner without the least inconvenience to respiration or removal of it.

It is easy to understand that by this method violence cannot be done by the forcing of bubbles of air or water into the Eustachian tubes, as the current is directed from them.

I have derived the greatest benefit from a solution composed of carbolic acid, from ten to twelve drops to a doucheful of water, at a temperature of 103° F., or somewhat above blood heat.

The tube that I have used is made by Mr. Philip H. Schmidt, of No. 1275 Broadway.

GEORGE THOMPSON, M.D.

41 E. 10TH STREET, NEW YORK.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from September 19th to October 3d, 1874.

SMITH, J. R., Surgeon.—When relieved by Assistant Surgeon Koerper, to proceed to Fort Monroe, Va. S. O. 190, Mil. Div. of the Atlantic, September 24, 1874.

KINSMAN, JOHN H., Assistant Surgeon.—Leave of absence extended to November 1, 1874. S. O. 205, A. G. O., September 18, 1874.

KOERPER, E. A., Assistant Surgeon.—In addition to his duties at Detroit, Mich., to relieve Surgeon Smith of his duties at Fort Wayne, Mich. S. O. 190, c. s., Mil. Division of the Atlantic.

Medical Items and News.

NOMINATION OF OFFICERS IN THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK FOR THE ENSUING YEAR.—At the stated meeting held on Monday evening, Sept. 25, the following nominations were made of officers to be elected at the October meeting:

For *President*, H. B. Sands, J. O. Stone, J. C. Peters; for *Vice-President*, G. A. Peters, T. Addis Emmet; for *Recording Secretary*, A. E. M. Purdy; for *Corresponding Secretary*, F. A. Castle; for *Treasurer*, S. Caro, F. P. Farnham; for *Censors* (five to be chosen), E. Eliot, H. T. Hanks, S. Caro, J. C. Peters, R. A. Barry, A. H. Smith, C. M. Allin, A. Jacobi, F. P. Foster, C. P. Russel, J. E. Janvrin.

Delegates to State Medical Society (twenty-one to be elected): J. A. Monell, H. G. Piffard, T. R. Pooley, F. A. Castle, A. Jacobi, S. A. Raborg, L. De F. Woodruff, G. Bayles, J. C. Dalton, M. H. Henry, S. Caro, E. C. Harwood, J. P. Garrish, R. J. O'Sullivan, J. M. Smith, J. H. Emerson, W. H. Hall, C. M. Allin, A. B.

Crosby, J. E. Janvrin, D. B. Hunt, F. P. Foster, F. V. White, A. H. Buck, Mary Putnam Jacobi, A. S. Jones, R. D. Nesmith, G. B. Fowler, E. Krackowizer, A. W. Stein, E. D. Ramsdell, F. B. Lawson, J. H. Leveridge, H. P. Farnham, H. B. Sands, A. E. M. Purdy, C. W. Packard, E. C. Simmons, H. T. Hanks, E. B. Warner.

RELATIVE TO VIVISECTION.—At a stated meeting of the Medical Society of the County of New York, held Monday evening, Sept. 25th, the following preamble and resolutions were unanimously adopted:

WHEREAS, It is believed that a movement has been inaugurated having for its object to abrogate or practically nullify the clause in the present law for the Prevention of Cruelty to Animals which declares that "nothing in this Act shall be construed to prohibit or interfere with any properly conducted scientific experiments or investigations," therefore,

Resolved, 1. That, in the opinion of this Society, investigations in Physiology and Pathology, by means of experiments on animals, are and have been the most fruitful source of increased knowledge with regard to the causes of disease and its means of prevention and cure.

2. That these experiments and investigations are habitually carried on by medical men without cruelty; nearly always without suffering to the animals employed, and never with any wanton infliction of pain or distress.

3. That authoritative interference, inspection, or control of these investigations by persons unacquainted with their methods and objects would necessarily defeat their aims and practically prevent their performance.

4. That the suppression of experimental investigations of this nature would arrest the progress of physiological science; would obstruct the acquisition of knowledge in regard to the causes of disease, and would be accordingly a disaster to the profession of medicine and to the welfare of mankind.

Also, *Resolved*, That for these reasons the members of this Society earnestly hope that the legal provision now existing, which recognizes the importance and value of such investigations, will be continued in full force and effect.

A MEDICAL JOURNAL IN JAPAN.—We have received two numbers of the *Modern Medical News*, the Japanese of which is *Kin-Se I-Setzu*. We are, however, inclined to the former name. The journals in question are curiosities in their way, not only in the character of paper, but in the manner of printing, binding, and type-setting. It is unnecessary to say that they are printed in the language of Japan, and would be very unintelligible to most searchers after the curious in medical literature. We have no doubt, however, that the articles are of real merit, and that the editor, Dr. Eldridge, has satisfactorily performed the duties of his office.

Of the woodcuts we can judge for ourselves, and say that they are really first class. We shall gladly place Dr. Eldridge's journal on our exchange list, and shall hope to be the means of informing him and his readers of the progress of medicine on this side of the Atlantic. It gives us pleasure to print the following letter from Dr. Eldridge, which explains itself:

HAKODATE, JAPAN, July 15, '74.

EDITOR OF THE MEDICAL RECORD.

SIR:—I send here with numbers I. and II. of the *Kin-Se I-Setzu*, or *Modern Medical News*, a bi-monthly medical journal in the Japanese language. This, the first medical journal published in Japan, is primarily in-

tended for a large class of native physicians who have already become somewhat acquainted with Western medical science, either by means of oral instruction or through the few existing translations of medical books, but who have no knowledge of any language save their own. The *Kin-Se I-Setzu* is published at Yedo, at the expense of the Imperial Government, and has, so far, a circulation of one thousand copies.

The contents of No. 1, March, 1874, are:

1. Introduction, by Editor; 2. Introduction, by native Assistant; 3. On Removal of Tumors by the Elastic Ligature; 4. On the Relief of Pain, No. 1.; 5. Quarantine Hygiene and the Cholera; 6. Diagnosis of Fatty Tumors by Cold; 7. Ergotine in Hemorrhage; 8. Easy Substitute for Proper Surgical Needles; 9. Removal of Foreign Bodies from the Ear; 10. Inspection of Imported Drugs and Medicines.

Of No. II., May, 1874:

1. Lectures on Urethral Stricture, by Editor--Lecture 1; 2. Surgery without Hemorrhage (Esmarch's method); 3. Apparatus for Digital Dislocations; 4. Government Inspection of Coal Oil; 5. On the Relief of Pain, No. 2; 6. Necessity for Education of Midwives in Japan; 7. Use of Salts of Copper in Cholera; 8. The Nitrite of Amyl, a new remedy in Asthma; 9. Rules for the Administration of Arsenic; 10. Oxide of Zinc in Diarrhoea of Infants; 11. Tincture Ferri Chloridi in Small-Pox; 12. Gelatine Suppositories in Faecal Accumulation; 13. Treatment of Syphilitic Onychia; 14. Tincture Ferri Chloridi in Post partum Hemorrhage; 15. Ergotine in Hemorrhage, Further Note on; 16. Glycerine as a Vehicle for Medicines, with Table of Solubilities; 17. New Sign of Death; 18. Worms in Heart and Blood-vessels of the Dog in China and Japan.

I am well aware that the *Kin-Se I-Setzu* can be of very little value to you, save as a curiosity; but I nevertheless request your assistance in a difficult, laborious, and peculiarly unremunerative work, by asking that my journal be placed upon your exchange list.

Very respectfully,

STUART ELDRIDGE, M.D. (U. S.).

In charge Gov't Medical School, Hakodate,
Editor *Kin-Se I-Setzu*.

Address,

Care U. S. Consul,

Hakodate, Japan.

LAWS OF THE STATE OF NEW YORK RELATIVE TO CERTIFICATES OF LUNACY.

INSTANCES have come to our notice in which the lack of information in our courts regarding the new law relative to commitment of insane persons to asylums has given unnecessary trouble and expense to both physicians and friends of patients, and we therefore publish the first three sections of Article I., Title First, Chap. 446, of the Laws of the State of New York, as passed May 12th, 1874; these being the ones chiefly of interest to the examining physician.

Section 1. No person shall be committed to or confined as a patient in any asylum, public or private, or in any institution, home or retreat for the care and treatment of the insane, except upon the certificate of two physicians, under oath, setting forth the insanity of such person. But no person shall be held in confinement in any such asylum for more than five days, unless within that time such certificate be approved by a judge or justice of a court of record of the county or district in which the alleged lunatic resides, and said judge or justice may institute inquiry and take proofs as to any alleged lunacy before approving

or disapproving of such certificate, and said judge or justice may, in his discretion, call a jury in each case to determine the question of lunacy.

§ 2. It shall not be lawful for any physician to certify to the insanity of any person for the purpose of securing his commitment to any asylum, unless said physician be of reputable character, a graduate of some incorporated medical college, a permanent resident of the State, and shall have been in the actual practice of his profession for at least three years; and such qualifications shall be certified to by a judge of any court of record. No certificate of insanity shall be made except after a personal examination of the party alleged to be insane, and according to forms prescribed by the State Commissioner on Lunacy, and every such certificate shall bear date of not more than ten days prior to such commitment.

§ 3. It shall not be lawful for any physician to certify to the insanity of any person for the purpose of committing him to an asylum of which the said physician is either the superintendent, proprietor, an officer or a regular professional attendant therein.

At present no printed blanks corresponding to the provisions of this law are to be obtained in the courts; we therefore append forms for a medical certificate, and for the Judge's certificate of qualification.

(FORM OF MEDICAL CERTIFICATE.)

STATE OF NEW YORK, } ss.:
COUNTY OF , }

I, , a resident of , in the county aforesaid, being a Graduate of , and having practised as a Physician, hereby certify, under oath, that on the day of , I personally examined of* , and that the said is insane, and

a proper person for care and treatment under the provisions of Chapter 446 of the Laws 1874.

I further certify that I have formed this opinion upon the following grounds, viz.: †

And I further declare that my qualifications as a Medical Examiner in Lunacy have been duly attested and certified by ‡

Sworn to and subscribed before }
me this day of , 187 . }

(JUDGE'S CERTIFICATE OF QUALIFICATION.)

STATE OF NEW YORK, } ss.:
COUNTY OF , }

I hereby certify that , of , is personally known to me as a reputable Physician, and is possessed of the qualifications required by Chapter 446 of the Laws of 1874.

FRANCIS EDMUND ANSTIE, M.D., F.R.C.P., who was so well known to all our readers, died at his home in London on the 12th of September. *The Lancet*, on the editorial staff of which he had so long been a worker, gives a very feeling obituary, from which we take a few facts regarding his life.

Dr. Anstie was born at Devizes, on the 11th of December, 1833. He was the second son of a manufacturer in easy circumstances; and his family had been established in the locality for several generations. . . . Francis, after being educated at a private school at Devizes, which he left in 1849, was articled in the following year to his cousin, Mr. Thomas Anstie, a medical practitioner of the town. According to the

* [Here insert sex, aged, married or single, and occupation.]

† [Here insert facts upon which such opinion rests.]

‡ [Here insert the name of the Judge granting such certificate.]

custom of those days he remained with his cousin three years; and entered at King's College in 1853. He passed through the ordinary medical curriculum with credit, and gained the Gill prize for general proficiency at the end of his first winter session. He was a steady worker both at the college and in the hospital, where he was an enthusiastic disciple of Dr. Todd, under whom he served as clinical clerk, and whose teaching gave a manifest color to his whole professional life. In 1857, being as yet undecided with regard to his future line of practice, he took the post of resident physician-accoucheur's assistant in the hospital. In the autumn of the same year he took his M.B. degree at the University of London, and was for some time occupied in administering chloroform for Sir W. Ferguson. After this he lived for a short time in Stamford street; but in 1859 he moved to Ouslow square, and was appointed physician to the Chelsea Dispensary. By this time he had determined to practice medicine: and having been appointed pathologist to Westminster Hospital, he was elected assistant-physician and co-lecturer on Forensic Medicine in 1860, in the vacancy caused by the transference of Dr. Russell Reynolds to University College. He subsequently exchanged his lectureship for that on *Materia Medica*, which he held for many years, his course being devoted rather to the therapeutic action of drugs than to matters of mere detail. In 1862 he married, and from thenceforward devoted himself far more closely to the practical business of his calling, displaying a power of steady and sustained work that had previously lain in abeyance, and that rapidly brought him into the first rank of his contemporaries. In 1863 he removed to the house in Wimpole street, in which the rest of his life was spent; and in the following year published his well-known work on Stimulants and Narcotics, chiefly the results of experimental research conducted at the Westminster Hospital. His tenure of office as assistant physician was prolonged for thirteen years, during which he applied himself to the work of the out-patient department with an energy and solicitude that never flagged. About a year ago he succeeded to the post of physician, and was enabled to give full scope in the wards to those powers of clinical teaching which his long work among out-patients had cultivated to the utmost. For a short time he shared the lectureship on medicine with Dr. Basham, but had lately given the full course, in a manner which elicited the warm admiration of those who heard him. Besides his appointment at the Westminster Hospital, he was physician to the Belgrave Hospital for Children, and consulting physician to the Royal South London Ophthalmic Hospital. It need no longer be a secret that the most flattering overtures were made to him from New York, to settle there as a hospital physician and consultant, and a lecturer on the principles and practice of physic; but family reasons, and the feeling of growing success in England, prevented him from assenting to a proposal which was none the less gratifying that it came from those who knew him only by his professional reputation. His last work, and that on which his future fame will chiefly rest, was his admirable treatise on Neuralgia, on a second edition of which he was engaged at the time of his decease.

Besides his books, Dr. Anstie was a frequent writer of more fugitive literature. He contributed occasional articles on scientific subjects to various non-medical papers, and was for years a member of the editorial staff of *The Lancet*. In that capacity he was the chief member of The Lancet Commission to inquire into the state of the workhouses, and took a prin-

cipal part in conducting the inquiries and writing the reports.

In July, 1869, he became sole editor of *The Practitioner*, which, during the first year of its existence, he had edited in conjunction with Dr. Lawson, and which has ever since been indebted for its high position to his sound judgment, his constant industry, and his ready pen.

Dr. Anstie became a Fellow of the College of Physicians in 1865, and was now recognized as a power in that venerable institution, where his voice was raised in support of every proposal which was calculated to increase the dignity or to extend the usefulness of the College. He was much interested in the recent improvements in the manner of electing Fellows, as well as in the negotiations for the conjoint scheme of examination; and he was the prime mover of the Petition to the Premier on the subject of the overcrowded dwellings of the poor. In two directions, therefore, in the reform of workhouses and in the limitation of the power of railways to sweep away needful habitations, his efforts led immediately to legislation for the public good.

The circumstances of his death will form part of the history of the profession. The schools of the Patriotic Fund at Wadsworth had been visited by a somewhat strange succession of illnesses, and at last some of the children were attacked by a rapidly fatal form of peritonitis. Dr. Anstie was called in to the assistance of the medical officer, and he made a careful examination both of the premises and of the patients. He was at the time suffering from over-work and want of rest, and was, perhaps, hardly in a state to undertake the oftentimes dangerous duty of a medico-sanitary inspection; but after accomplishing it, he made, on Sunday, the 6th, a post-mortem examination of one of the children who had died from peritonitis. Whilst thus engaged, the middle finger of his right hand was accidentally punctured with a needle. He sucked and washed the wound immediately, and on Tuesday mentioned the occurrence to some of his friends, but expressed a hope that no harm would result from it. On Wednesday he felt ill, and complained of pain in his right arm-pit. During the afternoon he was so chilly that he sat before a fire wearing an overcoat. Dining with a friend in the evening, he spoke of having poisoned his hand, and said that he had much pain in the armpit, that he feared he would have an abscess there. On Thursday he was confined to his bed, and Dr. Brudenell Carter found him with a dry tongue, a dry, hot skin, and complaining of distressing headache, and of much pain over the right pectoral region. After a restless night the patient was worse on Friday, and the assistance of Dr. George Johnson was obtained. At three p.m. on Friday he was delirious, his tongue dry, and his temperature 105°. There was an erysipelatous blush about the size of the palm of the hand over the right pectoral muscle; there was excessive tenderness on pressure in the right axilla and over the front of the chest, on the right side. His condition at half-past nine the same evening remained unchanged. At half-past nine Saturday morning the breathing was very rapid; there was a distinct friction sound over the middle and lower lobe of the right lung, and dullness on percussion over the same space, the erysipelatous redness and tenderness remained the same. The urine was highly albuminous, and contained numerous epithelial casts. About the middle of the day symptoms of a blood-clot at the right side of the heart came on; the features were livid; the breathing rapid and shallow; consciousness was rapidly lost, and death occurred at half-past two p.m.

Medical Department of Life Insurance.

LIFE INSURANCE PRACTICALLY CONSIDERED.

By THEODORE PARKER, M.D.,

OF NEW YORK CITY.

LIFE INSURANCE has grown to such vast proportions, and its benefits are being so widely extended, that the public and its managers are equally interested in its prosperity, and the union of various companies, within a short period, for mutual consultation, interchange of opinion and experience, shows the newly awakened interest of its managers.

So far its mortality has been too great, and after ascertaining the cause, a new and early departure must be made.

It is to be regretted that hitherto, while treated and discussed fully in its business aspects, its medical relations, if not ignored, have escaped that attention which their first importance demands, and the opinions of its medical staff in its councils have been unheard, or deemed of minor importance. It is an earnest now of its progress, that the medical department, among several able officers, is receiving that attention which must result in general good.

It may not therefore be deemed inopportune to offer a few views of a practical character, which in the many interesting communications upon the subject have been but lightly touched upon, and which experience has demonstrated to the writer to be of vital importance, not only to the welfare of the companies, but of equal interest to their medical representatives. First, as to the

SELECTION OF EXAMINERS.

The company or home office must select, entirely independently of the agent and in advance of agencies, examiners who are men of character, strict integrity, and firmness; in other words, men who are thoroughly *reliable, competent, and prompt*; and when selected, no examinations should be received from others, unless in the absence or illness of the selected examiner, when an alternate, approved by himself and the company, might be temporarily employed. The examiner's certificate should be sent from and by the home office to the examiner for him to fill up, notifying him at the same time that he is the selected permanent medical representative of the company for his locality. Of the various plans by different companies of arriving at this object—the selection of proper examiners—some are faulty, others too expensive, and generally so far unsatisfactory. It may be asked here, How is the home office to accomplish this, and select proper examiners at a distance? Can they be certain they have made no mistake in the selection? The reply is, it has been and is being done daily; but to dwell upon or explain the best method would extend too far the limits of this article, and belongs more properly to business management. Now as to the

RELATION OF THE EXAMINER TO THE COMPANY.

The examiner should understand fully his true relation to the company. He should know that all selections and appointments are made by the *home office*, and not by the agent. He should understand that the company or home office pays him for every examination, whether favorable or not, though the agent, for convenience, may be allowed to hand him the regular fee

prescribed by the company; that a proposition from an agent or applicant to pay him an extra fee, or any commission upon cases examined by him, or any other than the company fee, is attempted bribery, and when an examiner so far forgets his self-respect, the dignity of his calling, and his true relation to the company as to listen to such a proposition, he is no longer a proper examiner.

In every case the examiner should consider himself as representing the company, and not the agent or applicant. In passing upon applicants he should know no friendship and should give the company the benefit of all doubts; that in cases where a necessarily rather hurried examination fails at the time to discover any organic disease, and yet the general appearance or complexion suggests to the experienced physician a doubt as to the safety of the risk (cases have been improperly recommended because as stated the examination shows no disease), such cases should never be recommended without an additional private note to the company, putting them in possession of those facts which could not otherwise be known, unless by an examination at the home office.

Again, the relation of the examiner to the applicant is often a very peculiar and delicate one. He is perhaps his regular physician, or that of his family and relatives. He knows of private matters, tendencies to disease, or evil habits—important information for the company—and yet obtained alone through this intimate and confidential relationship. His interests would all appear to be on the side of the applicant, but he feels that he cannot conscientiously recommend him. The agent allowed to select his own examiner finds another who will. Unless he passes the case, he expects to incur the ill-will of the agent, applicant, relatives, and friends. If he is a man of sufficient firmness to do his duty, he may brave all this and make the sacrifice. There are those who do not consider it expedient to make this sacrifice, and think they should be allowed to recommend any risk, while putting the company in possession of all the facts. These should send a private note with full explanations to the home office, for the company must depend upon their fidelity to its interests. Again, it is hardly just that the examiner should injure himself pecuniarily in the service of the company, unless the pay for his services should be in proportion to the injury sustained. Hence, while the system of having the application and examiner's reports upon the same sheet remains in force, the only remedy seems to be extra private correspondence in every case between the examiner and the medical department of the home office.

Under the present general system of paying solicitors or agents, their income being derived from the number of cases insured, good or bad, there is a strong inducement for them to sacrifice quality to quantity, and as self-interest warps the judgment with some, the effect is to forward any application which a pliable or ignorant physician will recommend: the agent reasoning with himself in this way: "I am not a doctor, and am not supposed to know a healthy from an unhealthy subject; the company must look to their examiner for this; it is his business not mine." This is true in cases where the company has selected its own examiner independently of the agent, and they will be safe in doing so; but where the agent has selected his own examiner, and made his own terms with him, and can discharge him at will, the company would be safer, or as safe, to dispense with the examination altogether, and accept the risk upon the recommendation of the agent, making him alone responsible.

A prominent insurance officer, several years ago, stated to the writer that from his experience he was beginning to believe that medical examinations were of little value in life insurance. The reply was: "Under the present system of selecting examiners I agree with you perfectly, and consider them worse than useless. But with the selection of proper examiners by the company, and not by the agent, examinations are of inestimable value, and indeed are the sheet-anchor of life insurance, the one great and only source of safety for the company." The results have since confirmed and proved beyond a doubt the views then expressed.

FOR SUCCESS,

the company must look to the honest, disinterested, and impartial judgment and report of the examiner to protect them against doubtful or bad risks. The honesty of the examiner is the first, and by far the most important point, next his professional skill; for the highest professional ability, without honesty and faithfulness to the company's interests, furnishes no protection whatever.

It is for this reason that an examiner of but moderate professional attainments, possessing this honesty, is often preferred to others of much greater reputations, who are easy, careless, or accommodating.

Those companies that succeed and continue to merit public confidence must secure both, viz.: the strictest integrity and the best medical talent. When these are added to a prompt discharge of duty, they may hope to do a safe business, and look for a greatly diminished mortality. Failure is only a question of time with any company that receives examinations from any physician who can fill up a readable examiner's certificate at the request of the agent, and of whom the home office knows nothing except the favorable reports furnished perhaps by his own references.

SOLICITORS NOT AGENTS.

Furthermore, the term agent is a misnomer, and calculated to mislead inexperienced examiners. The solicitor for life insurance is in no sense of the term an agent of the company, and the distinction should be clearly defined by the company, and should be fully understood by the examiner. Cases have occurred where the examiner felt some doubt as to the propriety of recommending certain risks. His doubts have been removed by the remark from the agent: "It is certainly not a first-class risk, but recommend it, and we will take it upon some plan or other." The examiner has been greatly chagrined to learn afterwards, when his reputation was at stake, that the term *we* did not represent the interests of the company, but those of the individual agent himself.

While there are agents who, if they fail to get an impaired life insured in one company, will have it "go the rounds," there are honorable exceptions who identify themselves with the company and guard its interests; but a few of the baser sort, with the aid of unreliable examiners, can do an incalculable amount of injury, and neutralize the best directed efforts of the others.

There should be full, free, confidential and constant correspondence between the examiner and the medical department of the home office. Confidential it must necessarily be, for the subject is one involving not alone length of life and pecuniary obligations, but in many instances reputation itself.

In reference to the professional attainments or qualifications of the examiner, or the proper method of

making examinations, it is not the design of this article to speak. As to the third point, however,

PROMPTNESS.

The necessity of this is sometimes overlooked. For instance, the company has selected an examiner of known integrity and thoroughly competent. When called upon by the agent to make an examination, he perhaps replies: "Bring the applicant to my office," or, "When convenient I will call and examine him." Either of these would be fatal to the business of an agency. Perhaps when in the presence of an applicant, he may discuss the subject of life insurance in a way to discourage him. This would also be doing great injury to the company employing him. He forgets for the moment that the whole matter has been fully discussed before he is called upon, and his duties are to examine and report the results of examination, with his opinion, to the company. He should reflect that he is not expected by the company to solicit; but, on the other hand, he should be careful to do nothing which could injure or embarrass the efforts of the solicitor. He should *act promptly*, give all the information to the company bearing upon the risk, as he alone has the applicant before him, then his opinion; for upon these facts and opinion the insurance committee must depend to decide upon acceptance or rejection. He should do this faithfully, and then concern himself no further as to the fate of the application, for there his responsibility ends. As long as he reports fully and truthfully though the risk may be rejected, he still enjoys the full confidence of the company, and what to many is more, the consciousness of a faithful discharge of duty.

THE CHAMBER OF LIFE INSURANCE.

BEFORE this reaches the eyes of the readers of the RECORD, the Chamber of Life Insurance will have held its quarterly meeting, and determined what course to pursue in regard to the question of medical examiners. From the very beginning this journal has strongly advocated the wisdom of placing the system of appointing medical examiners upon a more solid and independent basis, and has urged the plan of a single list of examiners, to be appointed by some central authority—be it a committee or an individual—who shall act solely in the interest of the companies, or, which is the same thing, of the great mass of policyholders. It has advocated this plan for two reasons: first, because it believes that it will prove better for the life insurance companies; and second, because it will certainly in the main prove a benefit to the medical profession. It is not necessary to discuss these points again, for they have already been fully discussed in previous issues of the RECORD, and besides, by the time this is made public, the opportunity for discussion will have passed by. Suffice it to say that the Committee, appointed by the Chamber to consider this subject, has brought in a report recommending the adoption of some plan of this kind, and the forthcoming meeting (already held on the 13th ult.) is to be devoted chiefly to the discussion of the Committee's report.

It is difficult to predict what will be the action taken by the Chamber upon the recommendations made by its Committee at the last quarterly meeting. The different medical directors are either strongly in favor of those recommendations, or else are indifferent about the whole question; none, so far as we are aware, are opposed to the carrying out of the plan

under discussion. It is doubtful, though, whether the influence of the medical directors upon their lay colleagues, the presidents and secretaries of the different companies, will be sufficient to overcome the objections which they will be likely to advance against such a change. What these objections will be, we only know in part. The agents, it is said, will be unwilling to submit to the new régime; business will be interrupted by the necessity of employing only the regularly-appointed examiners; the plan will cost more money than it is worth, etc.;—these, and many more, are the reasons brought forward by some against the change. The Chamber, however, is composed of a goodly number of sound, practical business men, who will not be likely to vote against any well-digested plan of reform, unless there is some serious and tangible reason why it should not be carried into effect.

THE SPIROMETER — ITS VALUE AND UTILITY TO LIFE COMPANIES.

By DR. W. GLEITSMANN,

OF BALTIMORE.*

LIFE INSURANCE is the fulfilment of a sacred duty. By its means a man provides that the weight of pecuniary care shall not be added to the sorrow of those who are called to mourn his death. That life insurance companies should employ all the means that they can command for securing their protection against loss, is but simple justice to those offering them *bona fide* risks.

The purpose of the present article is briefly to consider one of these means of protection—a careful medical examination. In comparing a table of questions of the present day with one of a few years ago, the progress made by life insurance companies in this respect will be readily recognized. But notwithstanding the guarantee against the admission of unsound risks afforded by a scrupulous examination, and by the greatly improved method of examination resulting from the advance of medical science, yet surely every aid to a still deeper insight into any conditions affecting the applicant's health should be attentively considered.

The enemy which life insurance companies most dread, and labor most earnestly to discern, is consumption, whether actually existing in a latent form, or merely threatening in the future. In the daily practice of a physician many cases occur where the most rigorous medical examination fails to trace the source of the malady which will but shortly after overwhelm its victim. This is very often the case with apparently healthy young persons, who, by reason of their social position, offer a large contingent for life insurance. In cases of this kind the spirometer is of especial value as a means of recognizing the threatened danger. Although it may not afford positive certainty, yet it challenges a renewed and more careful examination. This instrument is constructed to show the capacity of the lungs by the volume of air blown into it in one forced expiration. Such capacity is pretty nearly constant in one and the same person, varying only with the altered condition of the individual, as, for instance, change of bodily position, weariness after exertion, full or empty stomach, frequently repeated respirations, and the like. If these accidental circumstances are taken into consideration, the same person

will nearly always exhibit the same capacity on the spirometer. It must not be supposed, however, that it is enough to let the individual in question blow into the spirometer, and simply to read off the indicated number. It is necessary in the first instance to find the number appropriate to each person by calculation before comparing it with the actual figure presented; only when both correspond entirely, or at least in part, can the result be looked upon as satisfactory. The spirometer will be deprived of much of its value, if, in comparing the numbers indicated by two persons, we conclude the one to be less healthy and strong than the other, because their respective capacities differ. Frequently the question is addressed to me, whether the number represented is a proof of sound lungs; but the answer will only suit the individual case. One man, for instance, having a larger capacity than another, can carry the seed of the disease, whilst the other is sound. A great many points have to be taken into consideration in determining the capacity of the lungs on the spirometer, of which I will only mention the three leading ones:—size, sex, age. It must be left to the physician to sum up the capacity depending on these different influences. Provided the calculated number accords with that shown on the spirometer, and that no unusual symptoms manifest themselves, the applicant may be declared sound. Whenever the medical examination results in any suspicious observations, the spirometer will not fail to confirm them by falling short of the calculated number. A large number of cases comes under observation, to which I chiefly desire to draw the reader's attention, where an ordinary examination gives no indication of disease of the lungs, but where the spirometer shows a more or less palpable divergence from the calculated number. They are generally persons in their younger years, who either possess the medically so-called phthisical habits, or who have lost some relative by the disease. The affirmation of this is but too frequently met with in practice, and I could quote conclusive evidence from spirometrical data contained in hand-books, if my space permitted. When we meet such a case in practice, the proof on the spirometer will at once animate us to repeat our examination with unusual attention in order that we may perhaps succeed in discovering grounds for a definite opinion, that have hitherto escaped us. Should we fail in this, we have to base our judgment all the more cautiously on the remaining indications, in proportion to the difference existing between the actual and calculated spirometrical numbers.

In advocating the use of the spirometer for life insurance purposes, I desire, therefore, not to be understood to imply what is sometimes erroneously believed, that the spirometer is of itself sufficient to establish a diagnosis of a person's state of health. It is only proposed to corroborate the results of a medical examination, or, in case of deviation, to induce increased caution in passing judgment on the applicant's health. In order to prove how vastly important these facts are to life insurance companies, I will conclude by giving a few statistics. According to the reports of the Board of Health there occurred in the

City of Baltimore in 1872, of 1,000 inhabitants,	3.20	deaths by Phthisis.
" " " 1873, of 1,000 "	3.65	" "
" Philadelphia, 1872, of 1,000 "	1.10	" "
" San Francisco, 1873, of 1,000 "	2.57	" "
" St. Louis in 1872, of 1,000 "	1.29	" "

As the death-rate by phthisis is here only exhibited in its proportion to the total population, it might be anticipated that life insurers are more favorably circumstanced, owing to the fact that here we only deal

* From the Baltimore Underwriter, August 20, 1874.

with carefully selected lives; but such is not the case. According to a publication of the Royal Prussian Statistical Bureau, by Dr. Oldendorff—a compilation of nineteen annual reports of German life insurance companies for the year 1871—the number of deaths by phthisis amongst a thousand insured averaged 3.79, that is to say, a larger percentage than is exhibited by the total population of Baltimore, Philadelphia, San Francisco, and St. Louis. It is conceded that phthisis is, at any rate, not more frequent in Germany than in the United States. These short proofs may serve to support the views already expressed, that life insurance companies should carefully consider every mode of assistance for obtaining the most reliable opinion on the applicant's health. I have no doubt that they will urge the universal adoption of this additional method of examination as soon as they have learnt fully to appreciate its scientific value.

DISEASES CAUSED BY THE INHALATION OF DUST.

By DR. GOTTLIEB MERKEL,

OF NUERNBERG, GERMANY.

Translated by DR. HORATIO BRIDGE, of New York City.

(Continued from the August 15th Number of THE MEDICAL RECORD.)

III.

CROUPOUS PNEUMONIA.

THE entire mode of origin and the course of croupous pneumonia, according to my apprehension of this disease, are of such a nature that we cannot reckon the inhalation of dust among the immediate causes of croupous inflammation of the lungs. We can recognize an indirect connection only by considering that through other diseases of the organs of respiration previously incurred, the lungs become more sensitive to those injurious influences which are capable of inducing in them a croupous inflammation.

Hirt tells of a cotton-weaver, thirty-one years old, born of healthy parents, who, in his thirteenth year on leaving the school began to learn weaving. Four weeks after entering upon his dusty employment, without having suffered previously with catarrh, he was seized with croupous pneumonia in the left side. After complete recovery, having resumed his work only a few months, he was attacked by a fresh pneumonia, which in his nineteenth year was followed by a third attack. During the three following years of service in the army he continued well; but on resuming his trade again, after only six weeks of work, he was seized for the fourth time with pneumonia; he underwent a fifth attack in his twenty-ninth year, and Hirt treated him for a sixth in 1868.

It is, indeed, not to be denied that the repeated occurrence of pneumonia immediately on resumption of work is in the highest degree remarkable; still, we must not forget that, as Hirt states, a lung which has once undergone an attack of pneumonia, although it may have completely recovered, nevertheless remains very frequently a *locus minoris resistentiæ*, and that under such circumstances the pure air, and especially the obligatory exercise in the open air in military service, can and must exert only a beneficial influence, and that finally the return into the atmosphere of the little work-room (in his father's house) containing three spinning machines, where the air was at best only

very imperfectly renewed—this, I say, alone offered a predisposing cause for the occurrence of a fresh croupous pneumonia. Still, setting aside this consideration, this is only a single case, which, indeed, shows the urgent necessity for further investigation, but, of course, cannot be considered as affording any positive conclusion in reference to dust inhalation as a proximate cause of croupous pneumonia.

I have given special attention to this subject, of the inhalation of dust, for seven years, and out of 500 cases of croupous pneumonia, with seventy-five fatal cases (all of which underwent a post-mortem examination), I have not heard one ascribed to the inhalation of dust, nor seen a case where such a cause could be proved.

In one single case I observed in the cadaver, around a necrotic portion of a lung affected with iron rust, a narrow zone of lung tissue, which broke down easily, was deprived of air, and seemed to be infiltrated with the products of croupous pneumonia; and once I found in the lung of a man working upon the protoxide of iron exquisite gray hepatizations with clearly marked fibrous plugs in the bronchioles. In this last case, moreover, an injurious influence from without had produced its effect upon the lung. The patient—in whose case the dependence of the phthisis upon the inhalation of dust had already been diagnosed—was discharged at his own request, in order that he might arrange his business affairs, which absolutely demanded his attention. At the end of eight days, during which he had exposed himself to a very marked diminution of temperature, he returned to the hospital with a croupous pneumonia, acquired two days before, and died from the attack. Such a case, however, cannot properly, in our estimation, be cited here as an example.*

Hirt in his work endeavors to prove, by means of statistics, that workmen exposed to dust afford by far the largest contingent to the sum total of those affected with croupous pneumonia. In reference to my own judgment in the premises upon the worth and significance of statistics, I refer the reader to that which I shall introduce further on, and remark simply, what I have already stated in the beginning, that this increased frequency is sufficiently explained by the well-established fact that there are large bodies of men the parenchyma of whose lungs is exceedingly vulnerable and especially disposed to be affected with croupous pneumonia, and that to this class belong those men especially who live under conditions which make immoderate demands upon their organs of respiration, and which circumstances in and of themselves place them at once in an abnormal state. In this category, therefore, we must include, before all others, those who live in an atmosphere which obliges them to breathe in, along with the air necessary for respiration, substances irritating to their respiratory organs. Such an increased disposition to croupous inflammation of the lungs is not, then, to be ascribed to dust as such, but rather to its irritating effect upon the bronchial mucous membrane, which is thereby put into an abnormally vulnerable condition as regards inflammation.

In regard to the pathologico-anatomical condition, we do not, of course, expect to find anything different from the well-known lesions of croupous pneumonia, and the hepatized lung of the man working on protoxide of iron, whose case was mentioned above, perfectly justifies this supposition, since the usual ap-

* I wish to say here once again, with especial emphasis, that all that is here stated relates to the croupous, and not to the catarrhal or desquamative pneumonia.

pearance of gray hepatization appeared, modified only through black deposits in form of stripes and spots.

According to a remark in Hirt's work, Coetscm appears to have given in his work on "Pneumonie Cotonneuse" more exact statements concerning the course and symptoms of this disease. To my regret I have been unable to obtain possession of a copy of the original article by Coetscm, which would have enabled me to give more positive opinions on these points.

From all that has been stated, we may set it down as established that workers in dust are more disposed to suffer from croupous inflammation of the lungs than other men; only we must remember at the same time that inhalation of dust is not to be regarded as the immediate, but simply as the predisposing cause for this disease.

In like manner it is established as a fact that the symptoms of pneumonia among workers in dust are the same as those which may be observed in others sick with this disease, and that the pathological lesions found after death are precisely the same as those observed in ordinary cases.

Whether the prognosis of a pneumonia occurring in a workman exposed to dust will differ from that in other pneumonias, depends, according to my opinion, upon two things: first, whether the respiratory organs were already previously affected (through catarrh, emphysema, etc.), and whether thereby the constitution of the workman had already been somewhat undermined; and secondly, whether the inspired dust had already penetrated into the tissue of the lungs, and perchance already induced anatomical changes, which would naturally give to a fresh additional disease quite a different importance from what it would otherwise possess.

Now, with regard to the diagnosis of the disease, in so far as its connection with the inhalation of dust is concerned, we must insist upon the importance of an exact history of the case in all its details as the best means of directing our opinion to its real nature. It should, however, be added, that the inquiry in reference to occupation should extend back not only to the last few seasons, but into the past years; for we have seen cases in which serious trouble first declared itself years after the patient had quitted his dusty occupation.

The sputa will indeed throw light upon the diagnosis, but will only make it certain in those cases in which they are found to contain free dust particles together with portions of the lung (elastic fibres); in such cases, however, disintegration has already clearly begun its work. We shall have more to say on this point further on. Dust particles enclosed in cells will be found only among those workmen who have worked within the last two or three weeks in a dusty atmosphere. While the discovery of these elements will of course be of value as regards prognosis, I have already shown how the same information may be obtained through the history of the case.

The treatment cannot, of course, differ in anywise from that of the common croupous pneumonia. The occurrence of this disease in a workman exposed to dust naturally makes it the duty of the physician to inform his patient of the danger of his occupation, as well as of the increased danger of relapses.

IV.

CHRONIC PNEUMONIA—CIRRHOSIS OF THE LUNG— PHTHISIS PULMONALIS.

When one considers how utterly powerless therapeutic measures are in advanced stages of the diseases

mentioned in the title of this chapter, he will welcome every hint, however slight, which may throw light on the question, how to ward off the disease. But before we can with any propriety speak of the prophylaxis of specified diseases, we must understand exactly their causes. It is upon such methods of reasoning that those recent works are based which are designed to throw light upon the etiology of phthisis pulmonalis, that disease which, according to the report of mortality statistics, sacrifices relatively the greatest number of lives, and in our hospitals is answerable for nearly one-half the deaths.

After what has already been said concerning the action of dust upon the respiratory organs, it will not excite wonder when we state that the continued inhalation of dusty air affords one of the most frequent causes of these forms of lung disease.

In the first place, we must consider the direct irritation of the bronchial mucous membrane caused by the continued inhalation of fine, and often sharply cutting molecules. We have stated above that there are men whose respiratory organs possess so great a degree of resistance to injuries of this kind, that after they have successfully recovered from the first acute, or, perchance, second chronic catarrh of the bronchiae, they become completely acclimated to their dusty atmosphere, and continue to work in it up to extreme old age, without experiencing very much trouble from their more or less injured lungs.

If this were not so, the relative percentage of mortality from chronic lung affections would indeed be very much larger than it is in reality.

On the other hand, however, all are not so fortunate in escaping. To gain some idea of the extent to which the lungs of our laborers are subjected to injurious influences, we have but to call to mind the fact that in Nürnberg, according to a very rough estimate—one indeed that falls 33 per cent. below the truth—there are actually 5,000 workmen engaged in occupations which are extremely dusty. When we consider, furthermore, that these workmen came from families whose hygienic surroundings are unfavorable; that just in these classes hereditary influence plays a most important part; that they are paid wretchedly small wages, and are consequently poorly clothed and fed; that they are often very irregular and dissipated in their habits; that there is gross negligence on the part of the employer as well as of the workmen in the observance of certain precautionary measures; when we consider all these things, I say, we can readily appreciate how greatly increased is the danger to life in these particular occupations.

Whoever reads attentively the regularly published mortality lists of our city will not fail to observe that, for instance, all ultramarine workmen, all iron-founders, etc., die of "consumption."

On the other hand, the irritating action of dust, so apt as it is to produce catarrhs, is not the sole agent in inducing more serious disease of the lungs; we must also take into account the direct action of dust molecules upon the lung parenchyma itself, that is, the changes effected in the tissue of the lung by dust particles which have become deeply implanted in it.

In both cases, however, the long-continued irritation causes chronic diseases of the lung substance, which in turn threaten life. We must next consider the consequences of chronic catarrh, in so far as it gives rise to more serious affections of the bronchial mucous membrane, to ulcerations, through whose encroachments upon the neighboring lung tissue bronchiectatic cavities are produced, and later on, phthisis of the lungs. We must also consider those effects which

are due to the progressive action of the inflammatory process upon the peribronchial tissue, leading to peribronchitic infiltration, which in turn, through cheesy degeneration, can give rise partly in a direct way to suppuration in the lungs, and partly indirectly (through resorption) to true tubercle. It is not of less importance to remember that the termination in thickening and shrinking of the parenchyma, in cirrhosis of the lungs, not infrequently occurs in cases of long-continued chronic catarrhs and of uninterrupted irritation caused by the inspiration of deleterious wounding substances. We would again mention that in this section those diseases only are discussed which are favored by the inhalation of dust. We cannot, therefore, furnish here for these forms a separate and distinct pathologico-anatomical description; the picture is the same as that which can be found in any text-book treating of the subject. In novise will the course of the disease be changed; at the most it will become more chronic than in the ordinary cases. The treatment also remains the same.

STATISTICAL APPENDIX.

What we here introduce is taken from Hirt's work, already often quoted. Since statistical statements, as such, in matters of this nature, are very apt to mislead, they can only, in our estimation, serve as a reliable means of drawing conclusions when they fully include all workmen who are exposed to the common injurious influences; and that in turn is only possible in large factories, where, in the first place, the number of workmen is large enough to be of importance, where nearly all the workmen live under almost precisely the same circumstances, and where accurate lists are kept of their sicknesses and deaths. When lists of this description can be obtained, we acknowledge the great worth of the statistics; but they are still, however, very few in number, and unfortunately exclude those workmen who indeed are exposed to injurious agencies (those above mentioned), but who do not labor together in large numbers (as in factories). Cases of this kind, however, frequently come under the notice of the private practitioner.

In addition to this it should be said that it is not an easy matter to obtain from large factories the proper statistical material, for in many it is simply not to be found, and in others interested persons guard these results of factory work with as much anxiety as they would the private records of business. It has happened to me that, while in small factories the whole business was most willingly shown, I was politely requested not to express in the work-rooms any opinion concerning those things connected with the business which were dangerous to health. Hirt has also had the experience that in such factories he was not even admitted within the doors. I was promised a very complete statistical statement relating to the diseases and deaths in one of the largest factories in Nürnberg, in which dust in large amount was whirled about through the air, and this promise was again withdrawn because I had published in the feuilleton of one of the city journals an article upon diseases caused by the inhalation of dust, in which I spoke specially of a fatal case of lung disease caused by dust in that very factory. This publication was looked upon as a meddlesome investigation into the secret affairs of the business, as an attempt to make the workmen discontented.

A statistical statement concerning workmen as they are to be found here and there in different employments would be of great importance. Upon this point, of course, only the records of large hospitals

could give information, and in pursuance of this idea, knowing that in our city hospital (which was opened twenty-eight years ago) very accurate records and case-books were kept, I endeavored to collect statistics relating simply to consumption. But I soon quickly convinced myself that this task, requiring so much exertion and expenditure of time, would yield very insufficient returns, and I have at present wholly given it up. The first and most important obstacle is this, the impossibility of obtaining a correct representation of the number of workmen exposed to dust inhalation. A large machine factory, for instance, employs about 400 workmen, the half of whom perhaps are exposed to dust in very different degrees, the other half not at all, but all are of course classed as factory hands. Then, again, employments are so frequently changed. A woman who now serves as a domestic was perchance until within a year engaged from six to ten years in one of the most dangerous dust occupations (such cases we have repeatedly observed), and of this circumstance one can find no record in the journal or case-book. A second still more productive source of error lies in the circumstance that all those suffering with chronic lung diseases can be discharged even though not cured, and in consequence, after a longer or shorter time they return to the hospital. In one year they may return as often as two, three, or even four times, and each time they are inscribed in the journal with a fresh number, and this difficulty cannot possibly be rectified. Since large numbers are requisite to accuracy, the record of one year is insufficient; a large number of years must be taken together; but with an increased number of years the error of reckoning increases.*

On the other hand, we have the incontrovertible fact that each person can die but once, for the reason that only a single bill of mortality is published. But in the same it is above all important, if it is designed to be accurate, that the whole number of those engaged in the employments alluded to should be known, and to obtain this is exceedingly difficult, is especially so now—in fact almost impossible—since free-trade has gained so universal an ascendancy.

I am, therefore, unfortunately unable to present a complete statistical statement, which would establish the truth of so many principles above stated. Hirt has endeavored to collect statistics upon this subject. In dedicating his book to Professor von Bamberger, he says that the task which he originally proposed for himself presupposed long years of study and painstaking. He has nevertheless done his best. He has collected as far as possible numbers from the larger factories; on the 25th page of his book he gives the respectable number of 12,647 workmen exposed to dust, and obtains from the same the following deductions:

I.

The relative frequency of chronic bronchial catarrhs among workmen exposed to dust.

Out of one hundred patients chronic bronchial catarrh occurred in the following frequency:

Metallic Dust.	Mineral Dust.	Vegetable Dust.	Animal Dust.	Mixed Dust.
14.8	11.8	19.0	13.6	18.4

In our city hospital, according to an average (estimated) from the records of twenty years, 7.53% of

* According to our poor-laws, sick persons are cared for by the commonwealth in which they work only ninety days for one and the same sickness; after that time the patient has to look for further cure and assistance to his native town. The result of this is, that all strangers, after their ninety days have expired, must be taken to their native place, while those claiming a residence here appear again and again at the cost of our city.

all diseases were bronchial catarrhs due to dust inhalation.*

II.

The relative frequency of emphysema among workers in dust.

The percentage of emphysematous cases was as follows:

Metallic Dust.	Mineral Dust.	Vegetable Dust.	Animal Dust.	Mixed Dust.
3.1	9.0	4.7	3.0	5.1

In our hospital, according to an average for twenty years, 0.55% of all diseases.*

III.

Relative frequency of pneumonia among workmen exposed to dust.

The percentage of cases of pneumonia was as follows:

Metallic Dust.	Mineral Dust.	Vegetable Dust.	Animal Dust.	Mixed Dust.	No Dust.
7.4	5.9	9.4	7.7	6.0	4.6

In our hospital, according to an average for twenty years, 3.13% of all diseases.*

IV.

Relative frequency of phthisis among workmen exposed to dust.

The percentage of phthisical cases was as follows:

Metallic Dust.	Mineral Dust.	Vegetable Dust.	Animal Dust.	Mixed Dust.	No Dust.
28.0	25.2	13.3	20.8	22.6	11.1

In our hospital, according to an average for twenty years, 7.28% of all diseases.*

The principal works on dust-inhalation and the diseases caused by it, are the following:—

(To be continued.)

RATE OF MORTALITY IN DIFFERENT CITIES.

In the way of contribution to the records of the development of the rate of mortality in metropolitan life, the subjoined statistics, collated and tabulated in the form of a comparative exhibit of the death-rate of the principal cities of Europe and America during the year 1873, will be found interesting. It is a subject for congratulation that the registration of these cities is so carefully and faithfully conducted, though the fact that so little practical use has been made of their teachings is less cheering. The waste of life in our cities from preventable causes is enormous, so much so as to be discreditable to our civilization; yet with the perception and acknowledgment of the need of steps for checking it, the progress of sanitary reform has been slow. Efforts have been made, time and labor and money have been expended for the improvement of sanitary conditions and of the health of the population, yet the results are by no means satisfactory. In some cases the data show that while the general conditions of human life at the present day are more favorable to increased vitality, the actual experience has been discouraging.

The data showing the sanitary state of thirteen leading European and Asiatic cities are taken from quarterly reports, and are as follows:—

CITIES.	First Qr.		Second Qr.		Third Qr.		Fourth Qr.		Mean Rate.
	No. Deaths.	Rate per 1,000 living.	No. Deaths.	Rate per 1,000 living.	No. Deaths.	Rate per 1,000 living.	No. Deaths.	Rate per 1,000 living.	
London.....	18,970	22.7	16,690	20	18,234	21.8	20,898	25.0	22.4

LIFE INSURANCE AND SANITARY REGULATIONS.*

THE *Versicherungs Zeitung*, of Berlin, in a recent number, urges the claims of life insurance companies upon the state for the maintenance of proper sanitary regulations. A large proportion of the deaths which occur are the indirect result of unfavorable hygienic conditions, and have for their immediate cause the small-pox, scarlet fever, or some other disease originating in them belonging to that large class of diseases to which Dr. Farr has given the name zymotic—a name which has been adopted into general use. Our German contemporary argues that the mortuary records of the companies do not fairly represent the full number of deaths which are really due to diseases of this class. In these records a great many deaths are attributed to disorders such as consumption, acute or chronic inflammation of the lungs, inflammation of the kidneys, affections of the stomach or scalp, degeneration of the tissues when the origin of these disorders may be traced back to some disease of a zymotic character. The peculiarity of the zymotic diseases is, that they either directly produce degeneration in some tissue or organ, or leave behind them, after an apparent cure, a tendency to or predisposition for some other disease. It is frequently the case that inflammation of the lungs or of the kidneys can be traced back with certainty to some previous illness. Many instances must be within the recollection of every one, whether belonging to the medical profession or not, of difficulties of the chest or other complaints which have set in after a recovery from typhus or slow fever, an interval generally occurring between the original disease and the subsequent one. A careful consideration of the deaths which are ascribed to consumption, with reference to the remote cause of the disease which produced them, will help to elucidate the subject. In Germany, the medical examinations for the life insurance companies are made with the most anxious care, and yet it is astonishing to note the extent to which consumption figures in the mortality returns of the companies. This cannot possibly be explained unless reference is had to the effects left by zymotic diseases behind them. Family history is inquired into upon the examination, and in coming to a decision the facts in regard to it are duly weighed. The consumption, when death occurs from that cause, must either have already had its beginning at the time of the examination or it must have been developed during the period covered by the insurance. If in existence, its presence is ordinarily revealed at the examination by some external sign, or can be discovered, even by a tyro in medical art, through per-

cussion or auscultation. Medical examiners, besides, generally make use of the stethoscope or plessimeter. But, admitting that cases occasionally occur in which incipient consumption, whether inherited or not, through mistake, ignorance or otherwise, escapes detection, there will still remain a large proportion of the deaths attributed to consumption in which the tuberculosis must have originated during the period covered by the insurance. We think that it will be found, upon careful examination of these cases, that only a very few of them can be explained by the operation of external causes, such as the atmosphere, employment, climate, or voluntary exposure. Some other originating cause must be sought in order to account for a considerable part of that class of disorders popularly known under the general name of pulmonary complaints, and—*hic haeret aqua*—here come in the zymotic diseases as an explanation. It is obvious that if no insurance had ever been granted upon these lives, the companies would have avoided a number of losses. These deaths are returned under various heads, and probably form a considerable percentage of the whole number. In these observations we have not lost sight of the fact that large regions, and even whole continents, like that of North America, are peculiarly subject to consumption, and that particular callings are also peculiarly subject to it; the variations from the normal rate of mortality produced by these causes are rather apparent than real, because they are offset by the increased probability assigned to inheritance, and by the allowance made for extra exposure. The main point which we wish to urge is, that great importance belongs to zymotic diseases among the factors, of which the combined result is found in the aggregate mortality of the life insurance companies. The opinion is gradually gaining ground among insurers that the probable duration of life does not depend solely on the quantity of vital force originally possessed, but rather upon the final balance struck in the account always kept between the vital force on the one side and the unfavorable influences to which the individual is exposed on the other. It is a problem in mathematics, in which the sum of vital force is represented by a number of units, from which are to be subtracted successively numbers corresponding to the influences of climate, employment, occupation, zymotic disease, etc., which tend to destroy human life. The problem cannot be stated in actual figures, but the illustration serves to show that when any of the quantities of the subtrahend can be diminished or eliminated, the result will be favorably affected. Hence the importance of taking up arms to combat these influences. When deaths which might have been prevented are caused directly by zymotic disease, the insurance companies suffer an immediate loss, which might have been saved. But the companies suffer a heavy loss no less when these diseases, after having been apparently cured, are succeeded, after a time, by other diseases, which terminate fatally, and the terms during which the stipulated premiums are paid are thereby cut short. The premiums were based upon the assumption that the payments would continue in accordance with the mortality tables. In comparison with the loss of future premiums, the agents' commissions, physicians' fees, and other expenses of procuring new business, sink into insignificance. The very existence of a company may be imperiled by the loss of them. We agree with the *Versicherungs Zeitung*, that the time has arrived for government intervention, and that the interests of life insurance urgently demand that proper hygienic regulations should be enacted and rigidly enforced.

Original Lectures.

A CLINICAL LECTURE

ON THE

TREATMENT OF POPLITEAL ANEURISM

ACCORDING TO THE

METHODS OF FLEXION AND COMPRESSION.

By H. B. SANDS, M.D.,

SURGEON TO THE ROOSEVELT HOSPITAL.

GENTLEMEN:—During my present term of service in this hospital two cases of popliteal aneurism have been treated with success. One of these was cured by compression of the femoral artery, and the other by flexion of the leg. As these methods of treatment have hardly yet obtained among us the preference to which they are perhaps entitled, I may profitably occupy your time in presenting to you, in the first place, a brief history of each of the cases referred to; and, in the second place, in setting before you the principles of both plans of treatment, in order that you may be enabled to estimate their relative value as surgical expedients.*

CASE I. *Popliteal Aneurism cured by Digital and Instrumental Pressure.*—Alfred Barnes, a native of England, aged 31, entered the Roosevelt Hospital April 4th, 1874, for the treatment of a popliteal aneurism, the symptoms of which had first been noticed six months previous to admission. The patient had been treated for rheumatism, and was somewhat pale and anæmic. The aneurism affected the right limb, and formed a large tumor which, longitudinally, slightly exceeded the limits of the popliteal space, and extended laterally beneath the hamstring. The circumference of the diseased limb at the upper border of the patella was 16½ inches, while the corresponding measurement of the opposite side was 13½ inches. Pulsation could be felt over the entire surface of the tumor, but was most distinct on its external aspect along the edge of the biceps tendon. The aneurismal thrill and murmur were both well marked. The tumor was tender on pressure, and the patient complained of severe pain at night. Within forty-eight hours after his admission the aneurismal tumor became more prominent, and the integument covering it somewhat discolored; the temperature in the axilla also rose to 102°, and the patient complained of feverishness and loss of appetite. Fearing that the aneurism was on the point of becoming diffused, and regarding the patient's constitutional disturbance as a contra-indication to the operation of ligation, I determined to try the effect of digital compression of the femoral artery against the horizontal ramus of the pubes. This was begun on the evening of April 8th, the pressure being made either by the patient himself or by some one of the patients in the hospital ward.

April 9th. Digital compression was continued last night from 6 to 11 o'clock, and resumed at 5 A.M. to-day. The patient bears the pressure well. The skin beneath the compressing finger is kept dusted with a powder composed of lycopodium and oxide of zinc. At 6 P.M. pressure was resumed, it having been remitted during the afternoon on account of pain, to relieve which morphine was administered.

April 11th, 12 M. Up to the present time, pressure

has accomplished nothing; but it has been very ineffectually made by hospital patients. It was now recommended by relays of medical students, twelve of my pupils having kindly volunteered their services for the occasion. Digital pressure was maintained continually until 10 P.M., when a modified Carte's compressor was applied, and the pressure of the two pads alternated every hour during the night. The force employed was just sufficient to arrest the pulsation of the aneurism.

April 12th, 10 A.M. Instrumental pressure having caused considerable soreness, the compressor was removed, and digital pressure maintained until 10 P.M. Patient complains of pain in the leg and foot, and the pulsation of the tumor is growing indistinct.

April 13th. Instrumental pressure was continued during the night and until 2 P.M. to-day; then digital pressure until 10 P.M. At 3 P.M. the tumor was examined, when it was discovered that it had become quite firm, and that pulsation, murmur, and thrill had entirely disappeared. The skin covering the tumor, however, still remaining hot and red, the application of an ice-bag was ordered.

April 16th. Since last date pressure has been continued, with the alternation of manual and instrumental compression every twelve hours. At 3 P.M. the treatment by pressure was discontinued.

June 1st. The cure effected seems to be permanent, and the tumor has nearly disappeared. The flexor muscles of the foot, which have been paralyzed, are slowly regaining their power; and the leg which, at the time of the patient's admission, was immovably flexed upon the thigh at an angle of 120°, has now, by the aid of a weight and pulley, become nearly straight.

CASE II. *Popliteal Aneurism cured by Flexion.*—Edward P., aged 31, entered the Roosevelt Hospital on the 23d of May, 1874. Habits somewhat intemperate. Patient first felt pain in the right popliteal region a month previous to admission, and a fortnight afterward discovered a swelling behind the knee-joint. Five days before admission, after a long drive, he suffered so severely from pain in the foot and leg that he went to bed and remained there until he came to the hospital. Meanwhile he noticed an increase in the size of the tumor. He is still deprived of sleep by pain, and is unable to take morphine, which is said to cause convulsions. On examination a soft, pulsating tumor, presenting all the characters of an aneurism, is found high up in the ham, extending from the upper third of the popliteal space upward for a distance of 4½ inches. Laterally it extends through the whole thickness of the thigh, but is most prominent on its inner aspect. The following measurements indicate the comparative dimensions of the opposite limbs:

	Right.	Left.
Circumference of calf of leg	14 in.	12½ in.
“ over tubercle of tibia.	13½ “	12½ “
“ over middle of knee.	16½ “	14½ “
“ over most prominent part of tumor, 1 inch above patella	16½ “	13½ “
“ of thigh, 2 inches above patella.	16½ “	13½ “

* I am indebted to my House-Surgeon, Dr. Blauvelt, and to his Assistant, Dr. Fewsmith, for the notes of the above cases.

It is found that flexion of the leg at a right angle

arrests the pulsation of the tumor. Ordered 3ss. of chloral at bedtime.

May 24th. Patient has had a comfortable night. At 2 p.m. he was put upon a water-bed and the treatment by flexion was begun. The leg, having been bandaged from the toes to the knee, was bent upon the thigh at a right angle, and retained in that position by an additional roller bandage. This degree of flexion stopped pulsation and caused hardly any pain. Twenty grains of chloral were given at bedtime.

May 25th. Patient has passed a good night and does not complain of pain. At 2.30 p.m.—twenty-four and a half hours after the treatment by flexion was begun—the limb was examined by Drs. Sands and Peters, and when extended no pulsation could be perceived in the tumor, which, however, was not very firm. Flexion was now resumed, and chloral prescribed, in scruple doses, whenever necessary, to relieve pain.

May 26th. Tumor becoming firm. Patient has had less pain than before the leg was flexed. Same treatment continued.

May 31st. Bandages removed and patient allowed to gradually extend the leg. The following measurements exhibit the diminution which has taken place in the size of the diseased limb since the treatment was begun:

	May 24.	May 31.
Over calf of leg.....	14 in.	13 in.
" tubercle of tibia.....	13½ "	12½ "
" centre of knee.....	16½ "	15½ "
" most prominent part of tumor.	16½ "	15½ "
" thigh, 2 inches above patella...	16½ "	15½ "

June 16th. Since the last date the tumor has rapidly diminished in size, and can now no longer be discovered. Measurements, such as those taken previous to treatment, show that the dimensions of the opposite limbs are alike. Patient discharged cured.

Such, gentlemen, is the narrative of these two interesting cases of a formidable surgical disease, both, happily, cured by methods of treatment at once safe and simple. Let me briefly refer to the history of each of these methods, and endeavor to point out to you the circumstances in which they are applicable.

The compression-method of treating aneurism is not new, although its success is of recent date. An allusion to the subject is made by Avicenna, but the earliest cases that possess any interest are those recorded during the latter half of the seventeenth century by Rivière, Bourdelot, Tulpin, and Brommelius, whose results were published as successful. The aneurisms treated were generally those of the brachial artery, and were of traumatic origin, having been occasioned by an accidental wound of the artery at the bend of the elbow, during the operation of venesection. In these early attempts, also, the compression was made by means of a bandage applied directly over the aneurismal tumor; and pressure of the afferent artery was carefully avoided, as it was believed by the surgeons of that period that such pressure might cause the obliteration of the artery, and that gangrene would then inevitably follow. About the middle of the eighteenth century Guattani had recourse to this method for the cure of popliteal aneurism. Of eleven reported cases, four are said to have been successful. Such a degree of success would not be deemed flattering at the present day; but at the

period referred to, when the old and cruel practice of opening the aneurismal sac was the alternative, it was calculated to afford encouragement, and indicated an advance in surgical art. The introduction of the Hunterian operation, a few years later, and the remarkable success which attended the ligation of the femoral artery in cases of popliteal aneurism, eclipsed, for the time, the treatment by pressure; and it was subsequently proved that pressure, to be effectual, should be applied, not to the tumor itself, but to the artery leading to it. The direct compression of the aneurismal tumor having been abandoned in favor of better methods, I need not consider it at any length; yet, as it has been shown to be successful, we may, perhaps, speculate briefly upon the *rationale* of its operation. Viewed in the light of our present knowledge, such treatment would, at first sight, appear to be irrational. As you are doubtless aware, the various methods for the cure of aneurism have this feature in common, namely, that they aim at causing a coagulation, either slow or rapid, of the blood contained within the sac. Now, the effect of the application of a tight bandage to the aneurism would be to empty the sac of its contents, and thus prevent a cure; for the adhesion of the opposite walls of the sac, and the consequent obliteration of the latter, can rarely if ever happen. It is highly probable that where direct compression proves successful, it does so by causing the formation of a coagulum, and that its *modus operandi* does not, therefore, differ essentially from that of the more approved methods. If the sac is already partly filled with coagula, the application of external pressure may, by retarding the passage of the blood through it, determine the completion of the coagulating process; and it may, also, favor the contraction of the sac itself. Or it may cause a clot, already existing, to be displaced in such a manner as to obstruct the distal orifice of the sac; in which event the circulation through the latter will be arrested and coagulation thereby rendered probable. An interesting example of the cure of an aneurism by the impaction of a coagulum in its distal orifice, is afforded by a patient now in Ward 5, whose case many of you have watched with interest during the past month. This man entered the hospital with a well-marked aneurism of the upper third of the left axillary artery; the tumor could be felt both above and below the clavicle. The patient stated that shortly before his admission, and after a very hard day's work, he suddenly felt an intense pain in his left arm, and on examination found that his radial pulse had stopped. When he came under my care I could detect no pulsation either in the radial, the ulnar, or the brachial artery, whereas each of these vessels pulsed strongly upon the opposite side. Inferring that on the occasion just alluded to, the passage of the blood through the sac had been suddenly arrested by the impaction of a clot in the axillary artery, I predicted the possible occurrence of a spontaneous cure, and I was gratified to observe that the tumor steadily diminished in volume, and that six weeks after his admission it had entirely disappeared.

There is yet another way in which direct compression may prove curative, and that is, by causing inflammation of the sac. Inflammation thus excited, however, is apt to prove unmanageable, and to terminate in suppuration of the sac, with its attendant danger of fatal hemorrhage. If the pressure is not evenly distributed, or if it is too great, an eschar may be produced; and when this separates uncontrollable hemorrhage may ensue. Again, the walls of an aneurismal sac are sometimes weak, and have occasionally ruptured under the influence of external pressure. In

a word, then, the treatment of aneurism by direct pressure must be regarded as nearly obsolete, and as applicable only to aneurisms of small size, and of traumatic origin. In idiopathic aneurisms, and especially in those affecting the popliteal artery, the method is inferior to many others, and is attended with risks which should be avoided.

Far otherwise is it with the method of compression called *indirect*, to which I now invite your attention. We shall find that this method of treatment, while less dangerous than that of direct compression, is far more successful in its results; and that it is especially adapted for the management of that form of aneurism now under consideration. It consists, as you are perhaps aware, in making pressure upon the artery leading to the sac. Now, the principle of this method of treatment so nearly resembles that of the ligature, that you will not be surprised when I tell you that these two methods were conceived at about the same period. The compression of an artery had for a long time been practised for the arrest of hemorrhage; but the date of its adoption as a mode of curing aneurism coincides almost exactly with that of John Hunter's first operation by the ligature. In fact, it is recorded that in 1785, only a few months prior to Hunter's operation, this celebrated surgeon held consultation with seven of his colleagues upon a case of popliteal aneurism; and that they decided to resort to compression of the femoral artery in the groin. The treatment was discontinued on account of pain; but six months afterward the aneurism disappeared spontaneously. During many subsequent years the compression-treatment made little progress; it was seldom tried, and when tried, was rarely successful. Bruckner, a German surgeon, is said to have had the first successful case. He began by employing the ordinary tourniquet, which, however, could not be borne by the patient. He then adapted a sort of horseshoe tourniquet, and alternated the pressure between two points along the course of the artery. The treatment seems to have been intermittent, and to have extended over a period of two years. In other successful cases, reported at this early period, the cure was often very tardily accomplished, and many months of treatment were found necessary to bring about the desired result. This fact was due partly to the use of imperfect instruments, and partly to an unfounded apprehension of gangrene, as the probable result of a complete arrest of the circulation through the artery compressed. Meanwhile, the ligature of the femoral artery in Scarpa's space was proved, by experience, to be so well adapted for the cure of popliteal aneurism, that both patients and surgeons preferred the cutting operation, even with its risks, to the tedious, painful, and uncertain method of compression, as then practised. But it has happened in this case, as in many others, that an old method has been so perfected as to acquire almost the claim of an original invention; and the merit of reviving the compression-treatment of aneurism, and of placing it upon an established basis, unquestionably belongs to the surgeons of Dublin. Prior to their investigations the method had few advocates; while now, hardly any one can be found to dispute its value.

Before proceeding further, let me state to you certain changes of opinion respecting the *modus operandi* of the pressure treatment, which took place before the Irish surgeons so completely demonstrated its success. As I have already mentioned, in the earlier trials of this method, the compression exerted upon the afferent artery was only slight, as it was generally believed that gangrene of the limb would ensue unless

this precaution were taken. To this circumstance we may doubtless attribute the rarity of success, and the length of time required, in favorable cases, to effect a cure. So soon, however, as the safety of the ligature was established, professional opinion ran to the opposite extreme; and many surgeons maintained that the obliteration of the artery, and the consequent permanent interruption of the circulation through it, were indispensable elements of success. As we shall see hereafter, this opinion was erroneous; and it naturally led to the employment of extreme pressure, which often proved intolerable, and sometimes injurious. In several cases treated by Boyer, early in the present century, the compressing instrument caused sloughing of the soft parts, which, in at least one instance, was followed by fatal hemorrhage from the femoral artery.

During the course of these trials it was ascertained that, in some of the successful cases, the artery which had been compressed remained pervious after the completion of the cure. This led to a recognition of the fact that the cure of an aneurism depended not necessarily upon the occlusion of the afferent artery, but upon the consolidation of the contents of the sac.

In 1820, Dr. Todd, of Dublin, advocated the employment of compression, with the object, not of obliterating the artery, but of simply retarding the current of blood through it, so as to favor the coagulation of that contained in the sac. His practice, however, was not very successful, and found but few imitators; and it was only after the lapse of twenty years that the correctness of his theory was attested by the experience of the Dublin surgeons. In 1843, Mr. Hulton, of the Richmond Hospital, effected the cure of a popliteal aneurism by instrumental pressure kept up for only six days. In the same year three other cases were cured, by compression, in the Dublin hospitals; and in one of these the pressure was continued for only two days. From that time onward the utility of the practice has been generally admitted; and in an interesting paper published by Mr. Bellingham, in the thirty-fourth vol. of the *Medico-Chirurgical Transactions*, that surgeon has reported all the cases of popliteal or femoral aneurism that had been treated in Dublin by compression during a period of seven years—from 1843 to 1850. Of 26 tabulated cases of popliteal aneurism, 21 are said to have been entirely cured, and no death had occurred which could be ascribed to the use of pressure. One patient died of erysipelas; but as galvanopuncture was here employed in combination with pressure, it is to this fact that we must attribute the intercurrent disease which proved fatal. When the results of the compression-treatment, as above described, are contrasted with those obtained by the use of the ligature, the value of the former method becomes still more striking; for statistics show that the ligature of the femoral artery has proved fatal in about fifteen per cent. of the published cases; and the actual ratio of mortality must be considerably higher, as it is well known that many unsuccessful cases are never reported. You naturally inquire, then, why the compression-treatment has not entirely superseded that by ligation, and the answer is twofold. In the first place, compression has succeeded better in the hands of the Dublin surgeons than elsewhere; and, in the second place, the operation of ligation is less troublesome, and when skillfully performed, is reasonably sure to succeed. The late Mr. Syme stated, some years ago, that up to that time he had tied the femoral artery in thirty-three cases, without a single failure. Whether the subsequent experience of that distinguished surgeon was equally fortu-

nate, I am not aware; but, doubtless, the unexampled success which he recorded was due, in no slight degree, to his acknowledged skill as an operator. You see, then, of how little value surgical statistics may be, in deciding upon the merits of a particular method of treatment, since a method which in itself leaves little or nothing to be desired, may, in the hands of the average practitioner, meet with very indifferent success. Bearing this fact in mind, let us examine the details of the compression-treatment, and endeavor to ascertain the best mode of conducting it. My remarks will be confined to the subject of popliteal aneurism. Now, compression of the femoral artery may be made either by the fingers alone or by means of an instrument; and I shall first speak of instrumental compression. The instruments which have been employed are various. Todd used an apparatus almost identical with an ordinary hernia-truss—the spring, however, being stronger. Such an instrument is inadequate for its object. A favorite plan with Bellingham, and other Dublin surgeons, consists in the employment of a weight of lead, of a conical shape; this is supported at the sides, and made to bear directly upon a compress placed over the course of the artery. I cannot show you this kind of instrument; but there is one at St. Luke's Hospital, which has been used without success, it having been found impossible to prevent the displacement of the weight, during the movements of the patient. Several modifications of Signorini's horseshoe tourniquet have been recommended; but I shall not detain you with a description of them, as I can occupy your time more profitably by exhibiting to you the apparatus which was used in the case I have narrated, and which fulfils all the indications better than any other one I have seen. It

was made by Mattliien, of Paris, and bears, if I am not mistaken, the name of the French surgeon Broca; it is evidently, however, only a modification of the compressor invented many years ago by Carte, of Dublin. It consists in the first place of a padded steel trough, which receives the thigh, and which serves for mak-

ing counter-pressure. Attached to the outer side of the principal piece are two jointed steel rods, which are curved above the patient's thigh, and carry the screws that make pressure upon the pads. The latter are made of India-rubber, and are of various shapes and sizes. The several joints, you see, which give to the apparatus a complicated appearance, enable the surgeon to alter the position of the screws carrying the pads, so that the latter may be made to press in any desired direction. Lastly, the curved steel rods can be moved longitudinally upon a metallic bar, thus permitting the pressure to be made, from time to time, at various points in the course of the artery, as circumstances may require. The instrument referred to has the following advantages. It is light, and, although somewhat complicated, is easily managed. It permits the alternation of pressure between the two pads, and the application of pressure at any point in the course of the artery, and at any desired angle of incidence. Moreover, the pressure, although effected by means of a screw, is elastic, from the presence of the steel arch which carries it, and of the rubber pad upon which it acts.

Being provided, then, with a suitable instrument—and it is idle to undertake the treatment with an imperfect one—you adjust it, having previously placed the patient upon a good, firm bed. This latter point is important; for unless the patient is so placed the apparatus is liable to get deranged. Moreover, as the treatment is irksome, and often extends over a considerable period, nothing should be neglected that is calculated to promote the patient's comfort. The apparatus having been applied, the treatment is begun by screwing one of the pads against the artery. The point usually at first selected is where the vessel passes out of the pelvis, as here it can be easily compressed against the horizontal ramus of the pubic bone; while in Hunter's canal, also, the artery may be pretty effectually compressed against the femur, but in Scarpa's space the circulation is with difficulty controlled, owing to the yielding nature of the soft parts upon which the artery rests. Between these two points, then, the pressure is alternated—such alternation being necessary to relieve pain, and to guard against excoriation or sloughing of the skin. The latter should be dusted with some fine powder, such as lycopodium or pulverized French chalk, which will lessen the tendency to abrasion. The administration of anodynes at night is often necessary to induce sleep, and I have found nothing that answers this purpose better than the hydrate of chloral.

Two important questions present themselves in the treatment of aneurism by compression. Shall the pressure be continual or intermittent; and shall it be partial, so as to retard the current of blood through the artery; or total, so as to arrest it? Upon both these points a considerable difference of opinion has prevailed; and I am not myself prepared to speak dogmatically. In regard to the first question, whether the pressure shall be continued or intermittent, I think it is one the decision of which rests rather with the patient than with the surgeon. Provided the former can bear it, there appears to be no reason why the pressure should be remitted. But you must not forget that long-continued pressure is very painful, and that it may be followed by sloughing of the soft parts. Your duty, then, is to ascertain the degree of toleration of the patient, and to regulate your treatment accordingly. It is gratifying to know, however, that intermittent pressure often suffices for a cure; and in a paper read before the British Medical Association in 1871, by Dr. Macnamara, of Dublin, it is stated that

in that city the mode of treatment then in vogue was to make compression only during the night, this plan having been found to work well.

The second question, namely, whether the compression of the artery should be partial or total, is one that is not easily answered; and the answer will depend not so much upon the recorded experience of surgeons as upon the theoretical views which you may be led to entertain respecting the process by which an aneurism is cured. When the cure is spontaneous, as it sometimes is in aortic aneurism, the sac is found to be filled with a firm, fibrinous mass, which is generally distinctly laminated; and there is some reason to believe that these layers of fibrine have been gradually deposited from the circulating blood. Now it is generally admitted that to promote the formation of such a deposit it is only necessary to retard the passage of the blood through the sac, and not to cause its stagnation; nay, it is even affirmed by Broca and others that the complete arrest of the circulation through the sac will be followed by the simple formation of a soft, spongy clot; and that this clot, being incapable of organization, will probably act as a foreign body, and set up suppuration of the sac, with all its evil consequences. With the first part of this statement I fully agree, and therefore I have nothing to say in condemnation of those who resort to partial compression. That such compression is adequate to effect a cure is shown, not only by theory, but by abundant experience; and the difficult point to determine will be, I think, the precise degree of retardation of the circulating fluid which may be necessary in a given case. Provided the right amount of pressure has been made, and a deposit of fibrine has taken place, the aneurismal tumor will become firmer, and its pulsation will gradually cease. The cure by this method will rarely be rapid, and may result only after the lapse of weeks or months. Partial compression is, of course, less painful than total compression, and is attended with less danger of excoriation or sloughing. But it not infrequently fails to cure the aneurism, and the alternative of the ligature is presented.

Total compression has been condemned by eminent surgeons, but, I think, upon insufficient grounds. Experience has clearly shown that the gradual deposit of stratified fibrine is not requisite for the consolidation of an aneurism, and that a cure may result equally from the rapid or even sudden formation of a coagulum. This must happen, for instance, where a ligature is applied to the common carotid artery for an aneurism affecting that vessel above the point of ligature. In this case, as there are no collateral branches between the ligature and the sac, there can be no circulation through the latter, and the blood which it contains must speedily coagulate. The clot, it is true, may soften, and act as a foreign body; yet this accident is possibly too rare to affect the general result. Moreover, in popliteal aneurism, the anastomotic channels are sufficiently numerous to insure the passage of a certain quantity of blood through the sac, even when the main artery is entirely obstructed; and that this circulation may be very free is shown by the fact that ligature of the femoral sometimes fails to cure—the pulsation of the sac being only temporarily arrested, and consolidation never taking place. On the other hand, it should be borne in mind that where rapid coagulation results from compression before the anastomotic vessels have had time to enlarge, the danger of gangrene must be greater than where partial compression is employed; and this consideration may perhaps determine our practice, if the patient is advanced in life, or has ossified arteries or a feeble circulation.

It is surprising how rapidly an aneurism may sometimes be cured by total compression. Many examples are on record in which consolidation has taken place within twenty-four hours; and Mr. Cooper Forster* has reported a case in which pressure for three and a half hours sufficed for a permanent cure. But the most remarkable instance which has come to my knowledge is one reported quite recently in London.† The patient, a man aged 78, had an aneurism of the femoral artery of the size of an orange, situated six inches below Poupart's ligament. It had resulted from a kick. It was cured by compression in ninety minutes. The efficacy of total compression is further shown in cases which have been treated by this method after an unsuccessful trial of partial compression. Mr. Prescott Hewitt applied partial compression for five months in a case of popliteal aneurism. The result being unsuccessful, total compression was tried, and brought about consolidation in forty-eight hours. I might easily multiply these examples, which prove not only that total compression may be successful, but that this method, in many instances, will succeed where the other one fails. I do not wish to be understood, however, as being the partisan of either method. One method need not exclude the other; and further experience is necessary to teach us their relative safety and value, and to enable us to select the cases to which they are respectively best adapted. So far as we now know, total compression is the more certain and speedy method, while partial compression is the safer one. In a case of popliteal aneurism, if the symptoms were not threatening, I should proceed cautiously, and resort to total compression only when the other method, after a fair trial, had failed. In the case you have lately seen, however, I feared that the aneurism was about to rupture, and therefore lost no time in resorting to total compression, which caused consolidation on the fifth day. The pressure was continued for another twenty-four hours, as the patient did not complain of it.

Digital compression for the cure of aneurism was first practised by the late Prof. Knight, of New Haven, who in 1848 treated a mulatto, the subject of popliteal aneurism, by this means alone. The tumor became firm at the end of forty hours, and the cure was permanent. Since the period referred to this method has been extensively practised, both at home and abroad; and there seems to be no doubt of its superiority to instrumental compression. It consists simply in the substitution of one or more fingers for the pad, and in the employment of muscular force to determine the degree of pressure. Digital is preferable to instrumental compression, because it can be more accurately made and more readily varied; it is therefore less painful and less liable to cause sloughing. You will often be surprised to learn how slight an amount of pressure will arrest the flow of blood through a large artery, provided the force is properly directed. A number of examples have been recorded where patients have succeeded in curing themselves of popliteal aneurism by digital compression of the femoral artery against the innominate bone. But manual compression is very fatiguing to those who undertake it, and cannot be thoroughly practised without a large number of intelligent assistants. It is because digital compression is so troublesome that we cannot generally hope to avail ourselves of it. In the case before us, manual compression was employed during the daytime, and instrumental compression during the night; and to some of the gentlemen whom I am now addressing

* *London Lancet*, 1872, vol. i. p. 187.

† *London Lancet*, 1874, vol. i. p. 586.

the patient is indebted, in no slight degree, for his recovery.

I am unable to present you with any record of the experience of New York surgeons in the treatment of popliteal aneurism by compression; but, although many cases have been cured by this method, I think I am right in stating that we have hitherto given the preference to the ligature. That the latter is an admirable remedy, no one can deny; and the operation, when skillfully performed, is generally successful. It must be acknowledged, however, that the method of compression, although not absolutely, is yet relatively free from danger; and that, when practicable, it should always be fairly tried by the surgeon before resorting to the knife. Should compression fail, the ligature can then be applied, without any disadvantage from the previous treatment, provided pains have been taken to avoid making pressure upon the artery in the lower part of Scarpa's space; and I have already explained to you that this spot is not well adapted for the application of the compressing force.

Before quitting this part of our subject I desire to call your attention to certain forms of treatment which are allied both to compression and to the ligature, but which lack the merits of either. I refer to *direct* compression of the afferent artery, after its exposure by dissection. Such compression may be made, either by the finger, by instruments, or by the application of a temporary ligature.

The idea of using a temporary ligature was first conceived by the late Mr. Travers, who, after having performed a number of experiments upon animals, was led to believe that all of the advantages of the ligature might be obtained, and its inconveniences and dangers avoided, by removing it from the vessel a short time after it had been applied, and before the establishment of suppuration. He imagined that the application of a temporary ligature might cause a permanent obliteration of the artery, and that its early removal would determine the union of the wound by primary adhesion. But in both these respects his hopes were disappointed in the only case of popliteal aneurism in which he put this matter to the test. The ligature was applied at the usual place, and was removed after an interval of twenty-seven hours. Pulsation returned in the sac three hours later, and the disease remained unchecked. Six weeks after the first operation the artery was tied in the usual manner, at a little higher point, and the patient was cured. It was evident, therefore, that a ligature applied to the femoral artery could not be removed, after the lapse of so short a period as twenty-seven hours, without the danger of an almost immediate return of the current of blood through the constricted vessel. But, it was further noticed, that the wound from which the ligature had been removed at this early period, not only failed to unite by adhesion, but healed very tardily by granulation. Thus the operation proved a double failure; it did not permanently arrest the current through the artery, nor did it promote the healing of the wound.

In stating his case, Mr. Travers announced his intention to abandon the use of the temporary ligature, and congratulated himself that his trial of it had not been attended with loss of either life or limb. A few years later, Mr. Roberts repeated Mr. Travers's operation and obtained a success.* Notwithstanding this, however, such was the cogency of Mr. Travers's arguments against it, that the operation of temporary ligature fell for a time into disuse. Unluckily it was revived some years ago in this city, and the results were such

as to make the operation, I think, unjustifiable in the future. The following is a brief summary of such cases as have attracted my notice:

CASE I.—On September 28th, 1868, at St. Luke's Hospital,* Dr. Buck treated a man with popliteal aneurism, by exposing the femoral artery at the seat of election, and twisting around it a silver wire. Two days afterward the wire was removed. The wound suppurated; and on October 19th, secondary hemorrhage occurred, which was controlled by pressure. The aneurismal tumor diminished in size, but did not disappear; and in the following April the patient was readmitted into the hospital, the tumor having attained such formidable dimensions that amputation was deemed necessary. This was performed, and the case terminated fatally.

CASE II.—Dr. Markoe,† in a case of popliteal aneurism, passed a fine iron wire around the femoral artery, and secured it by twisting. He removed the wire seventy-two hours afterward, and, as in the case last described, considerable difficulty was encountered in this step of the operation. Gangrene followed, and proved fatal. At the autopsy, the artery was found pervious; but a slender clot, three inches in length, extended on either side of the point of constriction. The operation was performed September 29th, 1868.

CASE III.—In the same year, at the New York Hospital,‡ Dr. Peters applied a temporary ligature to the femoral artery for a popliteal aneurism. It consisted of a piece of hempen twine, the ends of which were passed through a double canula. The ligature was removed after an interval of forty-seven hours. Gangrene of the foot followed, and was ascribed partly to a loss of blood which the patient had sustained before he entered the hospital—the aneurism having been opened upon the supposition that it was an abscess. Dr. Peters amputated at the knee-joint, and the patient recovered.

CASE IV.—In July, 1869, at St. Luke's Hospital,§ Dr. Hull exposed the femoral artery, and surrounded it with a ligature which was tightened by means of a miniature tourniquet, contrived for this purpose by Dr. Buck. Two days afterward the ligature was with some difficulty removed. Pulsation returned in the tumor on the same day, and compression of the artery was made above the wound. On the next day, arterial hemorrhage occurred, and a ligature was applied on either side of the bleeding point. Gangrene of the limb set in and proved fatal.

Here is a dismal record, which hardly needs any comment. It shows that the use of a temporary ligature, while failing to accomplish its object, is an exceedingly hazardous procedure; and, in the opinion of my friend Dr. Markoe, the great liability to gangrene is probably due to some disturbance of the femoral vein, which occurs at the time when the ligature is removed. Whatever be the cause, however, there is no doubt that, in the light of our present knowledge, the operation should be consigned to oblivion. And I may take occasion here to remark, that the presence of a ligature in a wound is by no means so injurious as many persons imagine. If the ordinary operation is done with care, and the parts are brought into accurate apposition, the suppuration is often hardly perceptible—the wound uniting almost wholly by the first intention. I can recall several instances in which I have tied the femoral artery for aneurism, where only one or two dressings were required before the separa-

tion of the ligature. The presence of the latter, therefore, is not so objectionable as to warrant any risk to the patient in the endeavor to prematurely remove it.

Temporary acupressure of the femoral artery has been tried lately in three cases in this city.* In one case, the operation cured the disease; in the second, pulsation returned in the aneurism soon after the removal of the needle, and the surgeon resorted to the ligature; and in the third, gangrene supervened, and, I believe, proved fatal. I think it may safely be predicted that this form of operation, which closely resembles that of temporary ligature, will, like the latter, prove to be a step in the wrong direction; and I conceive it my duty to warn you against any such dangerous and uncertain experiments, especially as the disease for which they are undertaken can be controlled by milder means.†

My time will permit me to say but few words in regard to the cure of popliteal aneurism by flexion of the leg; yet the subject is full of interest, and deserving of your careful study. The merit of demonstrating the value of this plan of treatment belongs to Mr. Ernest Hart, of London, who, in 1858, succeeded in curing a patient of popliteal aneurism by simply bending the leg upon the thigh, and confining it in the flexed position by the application of a roller bandage. Consolidation seems to have been effected on the fifth day; but the treatment was continued until the twelfth day, when the patient was allowed to extend the limb, and to go about. Three weeks afterward, the tumor was hardly perceptible. Mr. Hart's example was soon followed by other surgeons, and the flexion method has ever since retained its place as a simple and valuable surgical resource. Like compression, flexion is uncertain in its results, and sometimes fails after thorough trial. Several cases, in which it was tried without success, you will find reported in THE MEDICAL RECORD. In 1864, at the New York Hospital, Prof. Markoe treated a colored man, aged sixty-two, for a recurrent popliteal aneurism—the ligature having been employed with success ten years previously. Flexion to a right angle, which arrested pulsation, was kept up for seventeen days without benefit; and at the end of this time Dr. Markoe tied the femoral artery in Hunter's canal, and the patient was cured.

In THE MEDICAL RECORD for 1866 two cases are reported as having been treated at the same hospital by the flexion method, but with a negative result. In one of these cases flexion was continued for seven, and in the other for fourteen days. The treatment was stopped on account of pain; and the artery was tied by Dr. Buck, the attending surgeon. Both patients were cured by the ligature.

Contrasting with these cases, in which a fair trial of the flexion method proved unavailing, are those in which this treatment causes a rapid consolidation of the aneurism. In the case of the patient now before you, coagulation doubtless took place in less than twenty-four hours; and in one reported by Penherton, of Birmingham, it occurred in less than twelve hours. The most remarkable example of this kind, however, that has come to my knowledge, is one quite recently recorded in the *London Lancet*.‡ The patient was an inmate of the Leicester Infirmary, and was cured by flexion in six hours. It is further stated that he had previously been cured of a popliteal aneurism, affect-

ing the opposite limb, by flexion lasting only seven hours.

Sometimes this plan succeeds when other plans fail. About six years ago I treated a man with popliteal aneurism, at the Bellevue Hospital, by tying the femoral artery in the usual manner. The patient recovered from the operation, and the aneurism diminished in size. Recurrent pulsation was soon detected, however, and in the following year the man entered the Strangers' Hospital, where he was treated by simultaneous flexion of the leg and the thigh. The contents of the aneurism soon consolidated, and a permanent cure was effected—the patient having remained entirely well up to the present date. A case analogous to this one has been reported by Spence, of Edinburgh. The ligature of the artery having failed to cure, compression of the common femoral was tried for no less than five months without success. Ligature of the artery in Hunter's canal was then proposed; but—the patient refusing to submit to the operation—flexion was resorted to, and accomplished a cure at the end of a month.

The flexion method, although tolerably safe, is not quite free from risk. In a case lately treated in St. Thomas's Hospital,* London, flexion during four days caused gangrene of the foot—the gangrene extending to the knee on the following day. The surgeon, Mr. Wagstaffe, performed amputation at the lower third of the thigh, and the patient recovered. It is stated that the circulation was completely arrested only during the first two hours of flexion.

The method is exceedingly simple, and hardly needs to be described. A roller bandage having been applied from the foot to the knee, the leg should be flexed until pulsation of the aneurism ceases. The roller must then be carried around the thigh and leg, to maintain the bent position. Sometimes acute flexion is required to produce the desired result, and, in this event, the patient is apt to suffer from pain, which may prove intolerable. In other cases, as in the one before you, the treatment is easily borne, and produces little or no inconvenience. In many instances the patient has been permitted to get up and walk about during the treatment, with the aid of a pair of crutches. It is preferable, I think, to confine him to the bed; and, if a water-mattress can be provided, it will add greatly to his comfort.

It is not easy to offer a satisfactory explanation of the manner in which an aneurism is cured by flexion; and it is probable, I think, that the *modus operandi* varies in different cases. Of course, the current of blood through the sac must be retarded; but the question that arises is, How is this retardation brought about? By some it is thought that the pressure to which the sac is subjected is the main element of cure, and that, consequently, the flexion method resembles that of direct compression, which I described to you at the beginning of the lecture. This mode of explanation does not commend itself to my judgment, and would fail, I think, to account for the large number of cures which have taken place. Another theory is, that the pressure made upon the sac by the flexion of the leg is—especially if the former already contains coagula—communicated to the artery above the sac, and that thus the circulation through the latter is arrested. This explanation will apply, perhaps, to those cases in which the aneurism has attained a considerable size, or in which flexion is carried to an extreme degree. But it would not apply to the case of the patient now in the hospital, whose aneurism was of

* St. Luke's Hospital Records.

† In the New York MEDICAL RECORD of April 26th, 1871, a case of popliteal aneurism is reported as having been cured by the application of Dr. Spier's "artery constrictor" to the femoral artery. Very slight asphyxiation occurred, and the wound healed in fifteen days. A perusal of this report has not led me to change the views above expressed.

‡ *London Lancet*, 1874, vol. i. p. 765.

* *Med. Times and Gazette*, 1874, vol., - p. 207.

moderate size, and situated high up in the popliteal region. In this instance, I think, the lower edge of the aneurism was, in the act of flexion, forced against the artery on the distal side of the sac, and an effect was produced similar to that which would follow the application of a distal ligature. At all events, the main body of the sac was not compressed; and certainly no pressure could have been exerted upon the afferent artery, so as to arrest pulsation below. That the explanation just offered is probable, will appear from the fact that extreme flexion of the leg will, even in healthy subjects, either greatly retard or else arrest the flow of blood through the main artery. In my own person I have ascertained that extreme flexion of the leg arrests the pulsation of the anterior and the posterior tibial arteries; and that a corresponding movement of the forearm arrests that of the radial and the ulnar. In the case of the patient cured by flexion at the Strangers' Hospital, I mentioned, as you may remember, that he was treated by simultaneous flexion of the leg and of the thigh. Now, this modification of the flexion method was the result of experience; for it was ascertained that although simple flexion of the leg, when carried as far as the patient would bear it, did not stop, but only diminished the pulsation of the aneurism, the pulsation ceased entirely when rectangular flexion was made, both of the leg and the thigh. It was further observed that the same result could be produced, even when the leg was extended, by making extreme flexion of the thigh. In most instances, as I imagine, a cure is effected by a combination of the causes I have mentioned, and not by any one of them alone.

To sum up, then, both the compression and the flexion methods of treating popliteal aneurism have yielded excellent results, and are, perhaps, capable of still further development. They are to be tried, in suitable cases, as a substitute for the ligature; and, in the event of failure, the latter can be resorted to with the usual chances of success.

TREATMENT OF CHANCRE.

SYNOPSIS OF A LECTURE DELIVERED

By T. F. MAURY, M.D.,

LECTURER UPON VENEREAL DISEASES IN JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

(Phonographically reported for THE MEDICAL RECORD.)

GENTLEMEN: The treatment of chancre is divided into local and constitutional.

Constitutional treatment is *invariably* necessary when the chancre is *hard*, but is not necessarily instituted when the chancre is soft.

Local Treatment.—Local treatment should be adopted for *all suspicious* sores in and about the genitals, and the *invariable* line of topical treatment is *escharotic*. The agents by preference to be employed for that purpose are acid nitrate of mercury, nitric acid, muriatic acid, and chloride of zinc. If treatment of chancre can be instituted within five days after exposure, the chances are very good that the patient may escape from constitutional symptoms; but after five days have elapsed it is not safe to predict a perfect cure under any circumstances whatever. By way of illustration, if a patient should present himself with a chancre eight or ten days after exposure, local application should be made as soon as possible in the way of cauterization, and constitutional treatment at once

adopted if the chancre is hard; but guarantee of perfect cure cannot be made with safety.

In such cases it becomes necessary to first determine whether the chancre has been previously cauterized or not, for the inflammatory action induced by the cautery may have produced an induration which has changed a soft sore into one closely resembling the true *hard* chancre. Cauterization can be too frequently resorted to. You must be governed in the application of caustics, from time to time, by the effects produced. It not unfrequently happens that an inflammatory chancre is produced by repeated cauterization.

After the cautery has been applied, the sore will require some local dressing. For this purpose citrine ointment, diluted eight times with simple cerate or benzoylated lard, is perhaps as elegant a dressing as can be employed for either the hard or soft chancre. A twenty-grain solution of nitrate of silver is sometimes employed. Black wash is a most excellent dressing. Labarraque's solution is very serviceable in many cases. A very cleanly and agreeable dressing consists of equal parts of aromatic wine and glycerine. The wine contains some twenty or more ingredients, all of which are useful in the treatment of this class of sores. Tannic acid $\mathfrak{z}$ i. and glycerine $\mathfrak{z}$ ii. also forms an excellent dressing.

Whatever dressing may be employed it is important to keep in mind the fact that the ulceration remaining after the cauterization should be treated in the same manner as an ordinary ulceration, and one of the most essential elements is *thorough and perfect cleanliness*. To wrap these sores up with a cloth saturated with some form of ointment, as is sometimes seen, is exceedingly pernicious; and this is especially true with regard to the soft sore, for the reason that there is a very great liability of transmitting the poison to surrounding parts. This fact is particularly to be borne in mind in the treatment of females. Always keep the edges of the sores isolated. To this end the proper method of carrying out your local treatment is to dress each sore *separately*. Cover each individual sore with a separate piece of plain scraped lint wet with the dressing employed. The lint absorbs all discharge from the sore, and it should be removed as often as may be necessary to insure perfect cleanliness and comfort. Whenever the discharge of pus is abundant, it will be necessary to change the dressing quite often.

These directions are not so specially important in the local treatment of the hard chancre, although they can be observed with advantage even there.

When the sore is under the prepuce a liquid dressing is preferable to an unguent, especially in the summer season.

These, gentlemen, are some of the essentials, or if you choose you may call them "necities," in the successful management of this class of diseases.

Constitutional Treatment.—There is one condition in which the administration of mercury may be justifiable in the treatment of *soft* chancre. This is the condition which is present when you have utterly failed to restore the parts to a healthy condition by local applications. Under such circumstances the administration of mercury may be resorted to with good results. The mercury is given simply for the purpose of assisting the healing process. It is administered for the same purpose that it is sometimes administered to assist in healing an indolent ulcer upon some other part of the body—it is because of the so-called power which the remedy has to stimulate the vessels to remove the material that has been deposited in and about the sore. Salivation and purgation are not to be resorted

to, but it is a tonic and alterative influence which is desired, and for that purpose mercury seems to exert the best influence of any drug we at present possess.

When the chancre is *hard*, constitutional treatment by the use of mercury is *invariably* to be adopted. Under no circumstances whatever should you endeavor to heal the sore and cure the patient by simply using ordinary antiphlogistic or ordinary topical means. The sheet-anchor is constitutional treatment, and constitutional treatment by the judicious use of mercury until its effects are produced primarily upon the sore, and secondarily upon the constitution, as evidenced by tenderness of the gums.

Never administer iodide of potassium in the treatment of primary syphilis. The constitutional treatment to be adopted for the soft chancre consists chiefly in regulating the diet and giving proper attention to the alimentary tract. If the grade of inflammatory action is high, as evidenced by the condition of the pulse, heat of skin, and general constitutional disturbance, it may be necessary to modify such action by the administration of aconite, or antimonial mixtures, or saline mixtures, or antimonial and saline mixtures combined. An occasional laxative is usually serviceable, even though no marked constitutional symptoms are present.

The general outline of constitutional treatment for the soft chancre is embraced in abstaining from stimulants and avoiding all agents which have a tendency to excite inflammatory action.

In general terms, then, the treatment of chancre may be summarized as follows: For the *hard* chancre, *invariably* cauterization and the internal use of mercury; the mercury being administered for the purpose of establishing resolution of the sore, and not solely for its constitutional effects. For the *soft* chancre, *invariably* cauterization, and the adoption of a constitutional treatment chiefly embraced in a regulation of the diet, habits, and general constitutional condition. Mercury is to be resorted to *only in exceptional cases*.

In both instances cauterization of the sore is to be repeated or not according to the condition of the sore when it first comes under observation.

In both instances the local treatment which should follow cauterization is such as may be employed in the treatment of an ordinary ulcer.

These rules closely observed will give you the key to successful treatment of the primary, secondary, and tertiary forms of syphilis. We will now take up the consideration of the treatment of special forms of chancre. First, of the

Inflammatory Chancre.—The inflammatory chancre is a soft chancre attended with a great degree of inflammatory action. It has for its causes position, confinement of the poison beneath a long prepuce, constriction, want of cleanliness and attention, excessive cauterization, etc.

In the inflammatory chancre there is present a high degree of inflammatory action, which must be abated before any further treatment is adopted. *Never apply the cautery to an inflamed chancre until the inflammatory action has been subdued.*

The inflammatory action is to be subdued by the use of ordinary antiphlogistic means, such as purgatives, diaphoretics, alteratives, emollient poultices, anodyne and saturnine lotions; and, when all inflammatory action has subsided, apply the caustic. It is always well, as a matter of protection to yourselves, to state to the patient, if he has had the sore for eight or ten days or more, that the value of the caustic application has been very much diminished by the delay.

PHAGEDENIC CHANCRE.

In the phagedenic sore we have an entirely different condition from that which is present in the inflammatory sore.

Phagedæna in the soft tissues corresponds to necrosis in the osseous structures.

It has for its causes: a low condition of system; a scorbutic condition; the same conditions which give rise to inflammatory chancre may give rise to the phagedenic sore, the one being the first step of the other.

It is simply a mortification of the soft parts. *The phagedenic chancre occurs only as the result of neglect.* The treatment consists in the prompt, repeated, active, but judicious application of caustics. Control the phagedæna by cutting off all the dead tissues. There is no time for parley or consultation of books; for within a few hours, perhaps twelve or twenty-four, the penis is gone. The strongest caustic possible must be employed, and, in many cases, time can be saved by removing the phagedenic tissues with the scissors or knife, and then applying the caustic.

The best caustic, probably, which can be employed in these cases is the acid-nitrate of mercury.

Cut down until, when the slough comes away, a healthy surface presents itself. For farther topical application in these cases, there is none more excellent than the ordinary cracker poultice and tr. opium. Take the common water-crackers, pound or roll them fine, and mix with boiling water, and add tr. opii as may be necessary. Starch, slippery-elm, or bread-and-milk poultices may be used; and, in brief, all agents which will control inflammatory action. At first, you should lose entire sight of the specific nature of the disease, and treat the local condition. The treatment in such cases must be energetic and undelayed.

MASKED CHANCRE.

Under this head belong the so-called urethral chancres, etc.; the term "*masked*" indicating what is understood by masked chancre. It is a common subterfuge employed by medical men, when constitutional symptoms become developed in consequence of errors in diagnosis, improper treatment, or neglect in treatment instituted for the cure of the primary lesion. For instance, a patient presents himself or herself with a suspicious-looking sore about or upon the genitals; it may be cauterized even; but subsequently constitutional symptoms are developed, and, when the doctor is asked for an explanation, he consoles the patient by saying that he had a "*masked chancre*." I believe, however, that it is a thing almost unknown.

It is true that a chancre may occur in the urethra, as far back as the fossa navicularis; it may occur as the result of improper use of instruments, even deeper in the urethra than this; but ordinarily, and as a rule, I believe that chancre never occurs in the deeper portions of the urethra, and that it is only in very exceptional instances that it occurs as far back as the fossa navicularis. The treatment must be according to the character of the chancre.

MIXED CHANCRE.

This is simply a mixture of the two kinds of chancre, the *hard* and the *soft*; that is, a soft and a hard chancre existing upon the genitals at the same time. It is now a well-established fact that this may occur. It is quite probable that it is just here that all the trouble has existed with regard to the nature of syphilitic poison. The treatment consists in cauterization, and the constitutional treatment adapted to the two conditions. Cauterization is important, for it may insure a prevention or modification of constitutional symptoms.

CHANCRES OF THE ANUS AND RECTUM.

These are extremely common, especially in the female. Uncleanliness is the great cause. Intercourse in the rectum is a very common cause. Chancres in the mouth and other parts of the body may be developed in the same manner. When found they are to be treated in accordance with the general rules already laid down.

Original Communications.

PERITYPHLITIS; ABSCESS; OPERATION ON EIGHTH DAY; RECOVERY.

By SAMUEL B. WARD, M.D.,

ONE OF THE SURGEONS TO THE PRESBYTERIAN HOSPITAL, ETC.

J. B., age 18 years, single. Nativity, United States. Occupation, driver.

May 15th, 1872. Was first called to see him, and found that on the 9th instant (six days previous) he had returned from work not feeling well; feverish, bowels constipated, slight nausea, and pain and swelling in right iliac fossa. His mother, a professional nurse, had given him something to move his bowels, and had applied a poultice over the swelling. From the 10th to the 14th he gradually improved. During the day of the 15th he became rapidly worse, and I found him in the evening with pulse of 106, temp. 103.6°, skin hot and dry, and tongue thickly coated in the middle, and red and cracked at the edges. In the right iliac fossa was a tumor larger than a hen's egg, hard, attached, and very tender, but not painful while he lay quiet. The rest of the abdomen appeared natural.

The diagnosis was made of impending abscess in and about the appendix vermiformis. As the bowels had not moved for several days, and the patient complained a good deal on that account, a gentle laxative was ordered, with perfect rest in bed, and hot poultices.

16th. Dr. J. W. Wright saw the case with me, and confirmed the diagnosis. Pulse, 96; temp., 103.3°. Tongue better, and feels better every way. Thought that we detected slight fluctuation.

17th. Drs. D. M. Stimson and Wright saw the patient in consultation with me. There being no change in the symptoms, and all agreeing as to the diagnosis and proper course of treatment, I proceeded—either having been administered by my student, Mr. E. L. Partridge—to open the abscess by an operation very similar to that for ligating the external iliac artery. The incision commenced about three-fourths of an inch internal to, and a little above, the anterior superior spinous process of the ilium, and curved downwards and inwards nearly parallel to Poupart's ligament, terminating at a point nearly over the external iliac artery. The skin incision being so far external and so low down, I was obliged, in order to reach the tumor, to carry the division of the deeper tissues obliquely upward and inward, and this caused some little difficulty in completing the operation. When we reached the peritoneum the tumor was distinctly felt; but the peritoneum did not appear to be adherent to its surface, and we could not satisfy ourselves as to any fluctuation being perceptible. For these reasons it was considered expedient to stuff the wound with lint and leave it for the present. Poultices reapplied. Patient bore the operation perfectly well.

18th. Patient slept only about two hours last night,

but is much improved. Early this morning, about sixteen hours after the operation, there escaped from the bottom of the wound about two ounces of pus, having a dirty brown color and fecal odor, but in which no foreign body was to be found. Careful probing showed the cavity of the abscess to measure about one inch by two. At 11 A. M. pulse 69; temp. 99.2°. Considerable tenderness in region of wound; swelling less than yesterday.

19th. Much better; pulse 66; temp. 99°. Wound healthy, not yet suppurating. Abscess discharged about two ounces in last twenty-four hours.

20th. Suppuration established in the wound, so as to render it impossible to say how much of the pus discharges from it, and how much from the abscess. Odor much less marked than yesterday. Wound dressed with lint and carbolic acid, and syringed out with an aqueous solution of carbolic acid every day.

21th. Patient has done uninterruptedly well since last date, and wound has filled up from the bottom until it is only about half its original size and depth. Bowels moved on the 23d for the first time; no measures having been adopted either to promote or retard their action. They have moved every day since. Appetite very good, spirits excellent, sleeps well. A record of the temperature and pulse shows nothing of interest. Since the operation the former has not exceeded 100.2°, nor the latter 80.

June 14th. Patient discharged to-day cured. Wound entirely healed, and general health as good as could be expected after so long confinement to the house.

September 26th, 1874. Examined the patient to-day—two years and four months after the operation—and find the scar resulting from the operation to be soft, pliable, non-adherent, and perfect in every respect. It has changed its position however, so as to lie below Poupart's ligament. That portion of the abdominal wall incised in the operation seems to be as strong as any other, and the patient states that he has never had any kind of trouble that could be referred to the operation.

Dr. Willard Parker deserves the credit of having called our attention to the diagnosis of abscesses in and around the appendix vermiformis, and also of recommending early operation in suitable cases, in an article which may be found at p. 25 of vol. ii. of the *NEW YORK MEDICAL RECORD*.

A few weeks ago Dr. Gurdon Buck read a paper on this subject before the New York Academy of Medicine, founded on ten cases which he had collected, and from which it would appear that an English surgeon, Mr. Hancock, as long ago as 1848, recommended the same operation and reported a case. This paper seems to have escaped the notice of all subsequent writers on the subject.

OFFICERS ELECTED BY THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK FOR THE ENSUING YEAR.—*President*, H. B. Sands; *Vice-President*, Thomas A. Emmet; *Recording Secretary*, A. E. M. Purdy; *Corresponding Secretary*, F. A. Castle; *Treasurer*, F. P. Farnham; *Censors*, Ellsworth Eliot, J. E. Janvrin, A. Jacobi, H. T. Hanks, J. C. Peters; *Delegates to State Medical Society* (to serve four years): John C. Dalton, A. E. M. Purdy, J. E. Janvrin, G. M. Smith, H. B. Sands, E. Krackowizer, F. A. Castle, A. H. Buck, A. B. Crosby, A. Jacobi, T. R. Pooley, C. M. Allin, F. P. Foster, H. P. Farnham, J. H. Emerson, L. de F. Woodruff, H. G. Piffard, H. T. Hanks, C. W. Packard, G. Bayles, Mary Putnam Jacobi.

Progress of Medical Science.

HEMORRHAGIC MALARIAL FEVER.—Dr. W. A. B. Norcom, in an address as President of the Medical Society of North Carolina (Transactions of the Twenty-first Annual Meeting), gave a very valuable and practical description of this form of disease, which is not well understood in this section of the country. Alluding to the various views entertained, he expressed his opinion that the disease did not, as was claimed by some, appear for the first time a few years ago, but that it had long been recognized. The clinical history of the fever is very well given by the author. It either begins *de novo*, or as the result of long or frequent attacks of intermittent fever. In its whole course it seems to resemble what we see here as severe forms of remittent fever, to which there are such complications as hemorrhages of severe form from the nose, mouth, stomach, bowels, kidneys, and womb. It begins usually, but not invariably, with a chill of about two hours' duration, attended with intense internal heat, which causes the patient to demand cooling drinks. Almost coincidentally a severe nausea is experienced, which leads to vomiting, at first of food, then bile, and then, in bad cases, of blood—the latter sometimes resembling the black vomit. There is a sighing respiration, insomnia, great restlessness, anxiety, and an almost unquenchable thirst. The pulse rarely exceeds 100, but after severe hemorrhages it goes up to 150, and is very feeble. The temperature ranges between the normal point and 105° Fahr. The skin assumes a yellowish, even a bronze color, and the eyes become sunken. The tongue does not become very much coated. The bowels are usually costive. In one instance blindness was observed by Dr. Norcom, which he thinks was due to hemorrhage of the retinal vessels. This symptom is very rare. Remissions do not occur, or at least cannot be noticed. The urine may simply contain large quantities of degenerated red-corpuscles, or in severe cases blood and albumen. Urea and the mineral acids are not increased, but are retained in the blood, thus poisoning it. The hemorrhages occur most frequently from the kidneys, next in order of frequency from the nose, and rarely from the other sources. The duration is from four to twelve days. The fact of the hemorrhage from the kidneys leads to the disease being termed in some quarters malarial hæmaturia. Pathological anatomy shows defibrinization of the blood and destruction of the red globules, enlargement and softening of the spleen, enlargement and bronzing of the liver, softening and injection of the alimentary canal. In the hæmaturic form the kidneys are enlarged and congested, and there is a casting off of the epithelial lining of the uriniferous tubes. The greater or less implication of the kidneys causes the proportionate intensity of the uræmic symptoms. Under favorable circumstances in a few days the fever subsides, the nausea ceases, and the patient becomes convalescent. In severe forms he dies, either conscious and from asthenia, or unconscious from uræmia; heart clot and cholesteræmia may also cause death. The directions for treatment, as given by Dr. Norcom, are noticeable for their valuable practical character. He shows the necessity of active early interference. He advises the usual warming applications for the cold stage; hot, stimulating drinks being given even if rejected; morphine, in good doses, is to be injected under the skin. This has a tendency to control the vomiting, which, being relieved, ten grains of quinine are to be administered, if rejected to be given hypodermically. This dose is to be repeated

every hour until four or six doses are given; at this time another injection of morphia is necessary. During this time stimulants and meat broths are to be given, and cooling drinks are allowed. Hemorrhagic complications are to be combated with astringents, and he suggests ergotine hypodermically. Enemas may be necessary for constipation. The continuance of the administration of the quinine and morphine depends on the progress of the case. By this treatment Norcom claims that the mortality, which is usually set down as 50 per cent., is rendered much less. The paper, which also treats of causation and prophylaxis, is a valuable contribution to literature, and gives evidence of extended study and clinical perspicuity of the author.

RELIEF OF INTESTINAL OBSTRUCTION BY INFLATION OF THE BOWELS WITH AIR.—Though a number of cases have recently been reported in which air has been successfully used to overcome intestinal obstruction, it is not claimed that this treatment is new, for it is well known that Hippocrates recommended it for intussusception and obstructive difficulties over two thousand years ago. Rokitsansky made some experiments in this direction by producing volvulus artificially, and he found that air introduced per rectum would restore the parts to their proper position. Osborne published twenty-eight cases of obstruction, in which seven recoveries took place, and three of them were ascribed to the inflation of air. Since then other cases have been reported. The treatment consists in placing the patient in the knee-elbow position, and then injecting air per rectum with an ordinary syringe or pump, of which the Davidson apparatus is one of the best. Sufficient air must be introduced to distend the bowels completely, and give the patient a slight feeling of uneasiness. The symptoms are said to yield rapidly. Dr. Boettger, of Dessau, has added three successful cases to the list, two of which are good tests of the method advocated. One was a young man, twenty-four years of age, who was suffering from a strangulated scrotal hernia, and refused to allow any operation to be performed on him. Efforts were made from time to time to replace the gut, but they were ineffectual, and other remedies that were tried were equally unsuccessful. On the fifth day it was decided, as a *dernier resort*, to try inflation of the bowels with air. The operation was performed in the usual way. Shortly afterwards offensive gases began to be discharged, and they were followed by thin feces. It was then observed that the hernial tumor had disappeared. The whole time occupied was not over half an hour. Eight days later the patient was so well that he had resumed his work. In another case a woman, forty years of age, was found to have had a strangulated femoral hernia for three days. She had suffered from the hernia for years, but had always succeeded in replacing it when it prolapsed. When the patient was first seen she was suffering from nausea. An attempt was then made to replace the hernia by taxis, but it failed. The next morning a second attempt was made with a like result. On the following afternoon inflation with air was resorted to. Some thin passages, possibly from the intestine below the obstruction, were evacuated, but the symptoms were somewhat relieved. For several days the same procedure was adopted, and the tumor diminished gradually in size. About this time a dose of oil was given, and the patient had copious fecal discharges. A small tumor still remained, which seemed to be due to the adhesion of some of the abdominal contents to the wall of the sac, while the intestine had returned to the abdominal cavity. The patient continued to do

well from this date. In the third case there was obstinate constipation for eight days, which was presumed to be due to some internal obstruction of the intestines. It was relieved by the same treatment.—*Memorabilien*, 5, 1874.

MALFORMATIONS OF THE LUNGS.—Klebs says that we meet with the following anomalies of the lungs: 1. Absence of both lungs. 2. Complete development of one lung and rudimentary development of the other. 3. Rudimentary development of both lungs. A lung arrested in its development shows no signs of lobes, and may possibly be unconnected with the bronchi. A further anomaly is the abnormal insertion of such a rudimentary lung. He alludes to a specimen which he had seen, where the right lung was represented by a body not larger than a hazel-nut, and was attached to the esophagus, just above the diaphragm, and proved on careful examination to be made up of lung tissue. Generally a rudimentary lung is inserted like the normal lung. The results of his observations had been that where a single lung was deficient it was the right one, in eight out of ten cases, and the pleural cavity was then occupied, on the right side, by the heart and a certain amount of connective tissue.

The causes that produce such deficiencies may be due to a mechanical arrest of growth. The anterior end of the body, during the first four weeks of foetal life, is turned from right to left by the development of the amnion. Consequently the tension of the amniotic membrane will exert its influence on the organs of the right side anteriorly, and will retard their development. The absence of the kidney, in the same instances, on the opposite side, is explained on the same hypothesis; for while the anterior end is turned to the left, the posterior end is turned to the right, and there must be tension of the parts on the left side posteriorly, which accounts for the atrophy or absence of the kidney.—*Lerztl. Corr.-Blatt*, 13, 1874.

DEATH FROM RUPTURE OF A CASEOUS BRONCHIAL GLAND.—Kjerner reports the sudden death of a boy, seven years of age, who was not known to have any organic disease, and had merely suffered from a hacking cough. Without previous warning he was attacked with vomiting, followed by a violent paroxysm of coughing and a feeling of extreme pain in the chest. In a short time his face became cyanotic, and he died with symptoms of suffocation. At the post-mortem examination the trachea was found filled with an ashy, white mass, which extended downwards below the bifurcation. On the posterior wall of the right bronchus an opening about five millimetres in diameter was found; it led directly into the cavity formed by the cheesy degeneration of a bronchial gland, which rested on the bronchus, partly surrounding it. The material found in the trachea corresponded exactly with the cheesy contents of the diseased gland. The other bronchial glands were in a similar state of degeneration. The lungs were hyperemic, but the larynx and heart were normal.—*Hygieia und Nord. Med. Ark.*, 2, 1874.

TYPHOID FEVER PROPAGATED BY MILK.—In April, 1872, typhoid fever broke out in the village of Arnley, near Leeds. The disease continued to prevail until the following September, and there were 107 cases in 68 houses. Sometimes only a single case occurred in a house, at other times several. Persons of all ages and of all classes were attacked, and the males and females in about equal proportions. Children, however, were more frequently the victims than adults. It was thought that the cause might be defective drainage in the village; but there seemed to be no particular reason why these

houses should be any worse in this respect than the others. It was suggested that the milk might be the medium of infection, as, at one time, nearly all the families that were attacked obtained their supply of milk from the same dealer, and he himself had the disease in May. It was found on inquiry that of the 68 families, 51 bought their milk of this one man. He supplied milk to 132 houses out of 449 in the village, and about 37 per cent. of these families had typhoid fever, while of the remaining 317 houses, who were supplied by 18 other dealers, 17, or about 5 per cent. only were attacked. The disease also occurred later in the 17 instances, and the causes may have been secondary, as may be the case in any such epidemic. When attention was directed to the milk, it was found that the excreta of the milk-man, who had been sick, were deposited in a vault near the well, and during the rainy weather these foul matters found their way into the well, from which water was taken to dilute the cows' milk. On the 10th of July the use of the well was prohibited, and on the 27th the epidemic suddenly abated.—*The Lancet*.—*Rundschau*, August, 1874.

THE SPIRILLA IN THE BLOOD OF RELAPSING-FEVER PATIENTS.—The minute parasitic organisms that Obermeier found so abundant in the blood during relapsing fever, and which he supposed to be peculiar to the disease, have been observed again by Birch-Hirschfeld, in a typical case of the same disease. The blood was examined microscopically during the second febrile exacerbation, and when the temperature in the axilla stood at 103° Fahr. Every field of the microscope showed from three to eight of these organisms, whose length was from five to ten times the diameter of a red-blood globule; they appeared like delicate threads, and exhibited active spiral movements, as a rule, but occasionally were quite motionless, appearing then to be nearly or quite linear in form; often they would remain at rest for a considerable time, and would then suddenly assume the most active spiral motions. During the continuance of the fever the spirilla were always found, but they decreased in numbers during its subsidence. One of the chief points brought out by this case was, that two days after the end of the fever, and when the temperature had fallen to the normal, or even below, spirilla were still found in the blood, a fact which is opposed to the statements of previous writers, who assert that the spirilla disappear with the last vestiges of the fever. The urine was repeatedly examined, but no spirilla were found, nor could any be produced by cultivation in Pasteur's fluid. After three days had elapsed, there were numerous bacteria, but no spirilla.—*Deutsches Arch. f. klin. Med., Allg. Med. Central Ztg.*, 75, 1874.

PERIOSTEAL FLAPS IN AMPUTATIONS.—Tizzoni believes that the results of numerous operations on animals and occasional examinations of the stumps of patients, justify him in making the following statements as to the advantage of periosteal flaps:—

1. The operation is easily performed. At the present day, when pain and blood is spared the patient, it is a matter of small consequence if a little more time is consumed than usual.
2. The periosteal flaps retract considerably, but equally and without wrinkles.
3. These flaps will remain spread over the cut surface of the bone.
4. In twenty-four hours there will be a firm adhesion between the medulla and the flaps. Later, they consolidate with the bone. This early adhesion is of the greatest practical significance. It protects the medulla from the influence of the pus that may possibly form about the end of the bone.—*Riv. Clin. d. Bologna, Allg. Med. Central Ztg.*, 74, 1874.

THE USE OF OUR CODE OF ETHICS.

Our relations to each other and to the public are of such a nature as to render it imperative that some rules should exist for governing our actions. It is certainly a reflection upon our moral perceptions as individuals, and our obligations to each other, that there should be any code of ethics; but the longer we live, and the more we become acquainted with the motives and actions of medical men, the more are we impressed with the necessity for its existence. A strictly honorable physician needs no rules to govern his conduct towards his professional brethren. His standard of right and justice is high enough to make it impossible for him to do an intentional wrong to his associates. He has the same pride in being considered a high-toned, honest medical man as he has in being known as a gentleman. In fact, he is ever straining a point to leave nothing undone that would entitle him to the honor of being considered as such. His sensitiveness upon this point, in view of the interests at stake with him, makes a desire to please, to act justly and honorably with all, almost a morbid propensity. Such a man no more requires a code of ethics than does the gentleman require a set of rules which should govern his conversation and action in the drawing-room, or guide his conduct at a dinner party. If all of our medical brethren could be numbered with this class, it would certainly be a cause for congratulation. That such, however, is not the case, is a mortifying and melancholy fact.

There are two classes of medical men for which the code of ethics is of special use. First, for such as are deficient in their education as gentlemen, and who are in need of instruction; and secondly, for those who know better, but who persist in doing wrong intentionally and defiantly. With the first of these classes there is usually very little trouble, for when once they

are impressed with the importance of behaving properly they are anxious to supply deficiencies in their earlier education, and seldom are, as far as intentions go at least, subjects for discipline. Although they may not understand the reasons for their action, or appreciate the spirit of the law, they are nevertheless ready to obey its letter, and, like ordinary men of their class, become law-abiding citizens. They thus benefit themselves at the same time that they benefit the communities of which they are part.

The class which, knowing better, yet is constantly and intentionally transgressing the law, is, in the medical profession, very large. For the government of this class it is for the benefit and credit of medicine that we have a code, that we have a standard by which in some way or other all their wrong-doings, quibbling, dodging, and cunning can be judged. The intentional transgressors are not confined by any means to the lower walks of professional life, but, on the contrary, are to be found among men of position and influence in medical circles. It would seem that their very position grants them immunity from discipline. So much does this appear to be the case, that it is often asserted that the code was only made for the government of the little ones, to impress them with the privileges of those who have gained position. Very few, it is true, of this latter class are ever brought to trial; but that is an argument in favor of strict justice. One would suppose, judging from the medical men who are tried for wrong-doing—for transgressions against the code—that none but obscure individuals commit any sin. We are not willing to believe this, and we imagine that the profession in general are of the same way of thinking. How often is a certain prominent man pointed to as an example of wrong-doing, and his actions quoted in extenuation of similar acts in a lesser light. The trouble is, however, that committees of ethics and individuals are not so ready to enforce discipline upon a great man as they are to bring to account a small one. If the latter is expelled from a society, or virtually banished from the profession in consequence of an adverse judgment, no particular interests but his own suffer, and we quiet our consciences by imagining that we have vindicated the law. But if we have laws, and wish them to be respected, we should be ready to understand that they were made for the great as well as the small.

We contend that the men who hold positions are, by virtue of their example, really more responsible for violations of the code than their less fortunate associates. We are not of those who think that because a man is a professor, a president of a college, an officer of a society, that he is incapable of doing a wrong act; in fact we, in common with the majority of the rank and file, know that such a state of things comes very often within the range of possibility. Such acts, in comparison with those of lesser men, are tenfold

more culpable, and are only to be explained upon the presumption that they are purely intentional. We are not willing to account for it on any other ground.

It would be amusing, if it were not outrageous, to see how much artful dodging there is among these wrong-doers; how near they can come to the line of conventional propriety and not overstep it; and how righteous is their indignation when their motives are honestly questioned. They have always some ingenious explanation for their conduct, and manage by some hook or crook to cover up their tracks, and make themselves safe against what they choose to denominate meddling impertinence. But behind the code, behind the law, there is a moral sentiment in the profession which cannot be tricked into any false interpretation, and which measures their actions blindfolded to any other interest than strict justice.

We have often heard it said that there are as many quacks in the profession as out of it; but while we would be ashamed to acknowledge the whole truth of this, we are nevertheless compelled to admit that there is need for a good deal of sifting, and that in some of the so-called higher ranks the coarser the sieve the better. We are looked upon by outsiders as a jealous profession; but this jealousy centres itself into a desire to see fair play to its respective members. We do not envy the success of the charlatan, when we consider the meanness and knavery to which he stoops. When any member of our fraternity so far forgets his sacred and professional obligations as to show an inclination to go over to quackery, his associates are outraged at this violation of a principle rather than jealous of the pecuniary gains which are oftentimes the result of such actions. Every honest medical man is ready to acknowledge superior merit in his confrère; but he rightly despises that trickery which of late in many quarters is taking the place of legitimate and honorable competition for the coveted prize.

In view of this state of things we have need in the first place to thank the American Medical Association for our code of ethics, and in the second place to prepare ourselves to enforce it in letter and spirit. In the latter respect there is a good deal to be done by the different county societies, for never before was there a more urgent need for drawing in the lines of discipline and defining the limits of professional propriety. The county societies are the accepted expounders of the law, and the profession at large have reason at present to look to them for an outspoken and honest interpretation of its views. If the right disposition is shown by the Medical Society of our own county, its Committee of Ethics will have a pressure of business during its present winter session.

VIVISECTION AND THE COUNTY SOCIETIES.

THE threatened prevention of vivisection by law is still discussed with a good deal of earnestness by the profession. Several very able articles on the subject

have appeared in the daily press, and altogether it must be acknowledged that medical men have the best of the argument. There does not seem to be any doubt that during the next State Legislature the President of the Society for the Prevention of Cruelty to Animals will leave nothing undone to accomplish his purpose of preventing vivisection in future. Absurd as it may seem, there is a possibility that he may in the end succeed, unless some definite stand is taken against him by the profession as a body. The Medical Society of this County has taken the proper initiative in the matter, and its example should be followed by every similar organization throughout the State. Let suitable resolutions be passed protesting against any legal interference with our rights as experimentalists and investigators. If that be done and such protests be communicated to the parent Society, the profession can speak to our legislators in a manner not to be misunderstood.

Reports of Hospitals.

PHILADELPHIA HOSPITAL, PHILADELPHIA.

REPORTS OF PRACTICE AND PECULIARITIES IN TREATMENT.

THE TREATMENT OF CHRONIC BRIGHT'S DISEASE.

THE endeavor in treatment is to restore the kidney to the normal condition. The condition of the blood is, therefore, of the first importance. The remedies regarded as pre-eminently serviceable for the general constitutional treatment of this disease, are iron and quinine. Basham's mixture, or liq. ferri per acetatis, uniformly is used, and Dr. Tyson is of the opinion that the addition of strychnia in $\frac{1}{4}$ gr. doses adds very much to its efficacy. The mixture is administered in tablespoonful doses three or four times a day. Ten grains of quinine are given daily in divided doses.

Milk diet is regarded as specially useful, and a due proportion of meat may not be improper.

In the treatment of the dropsy incident to this affection, it is thought that digitalis will not help so much as in the dropsy developed in the acute form of the disease.

The salines are regarded as better for overcoming the dropsy. Digitalis is not to be discarded, but such remedies as bitartrate of potassa or acetate of potassa are decidedly preferable. When dropsy is present the diuretic treatment, which is chiefly relied upon, is combined with the general constitutional treatment. The idea is to improve the condition of the blood, and hope through this improvement to affect the dropsy. Hence, diuretics form no part of the general plan of treatment, except the diuretic effects obtained by administering the ferruginous mixture referred to. The formula for Basham's mixture can be found in connection with the report from the Pennsylvania Hospital.

ACUTE BRIGHT'S DISEASE.

Dry cupping over the loins and digitalis. The digitalis increases the blood pressure, causing more water to pass through the kidneys, so as to flood them. If

symptoms of incipient uræmia are present, or perhaps the patient has had one or more convulsions before admission, hydragogue cathartics, diuretics, and dry cupping to the loins are the chief measures adopted for the relief of the convulsions or symptoms of convulsions. Hot-air baths are occasionally employed. Acetate of potass, in thirty-grain doses, is a diuretic very commonly employed.

Hypodermic injection of morphine, as recommended by Prof. Loomis of New York, had been resorted to in one case for the purpose of controlling such convulsions. In that single case the convulsions were completely controlled. Two cases of acute Bright's disease had been treated with ergot. The symptoms were at once relieved, and the treatment regarded with favor.

CHRONIC CYSTITIS.

A case of this kind was doing very well under the following treatment. Injections three times a day of a tablespoonful of the following mixture to a pint of water:

R. Borax	$\frac{z}{i}$.
Glycerine.....	$\frac{3}{4}$ vi.
M.	

The patient was also drinking a simple infusion of triticum repens and buchu.

CHRONIC ORCHITIS.

When the patient was admitted the testicle was very much enlarged, and exceedingly hard.

A local application of hydrochlorate of ammonia of the strength of an ounce or ounce and a half to the pint of water had been kept continually applied, and the testicle at the end of a week or ten days was quite soft and natural to the touch. It was next ordered to be strapped.

CHRONIC ULCERS.

In general, these cases are treated by strapping with adhesive plaster. Three or four cases of large ulcers upon the legs, having heavy indurated edges, were doing very nicely under the local influence of tr. iodine applied to the indurated parts. The ordinary tincture is painted freely over the induration, and then covered with adhesive straps in the usual manner. Dr. Housekeeper instituted the plan of treatment and had obtained results eminently satisfactory.

BED SORE.

One was healing kindly under the influence of the compound resin ointment.

GNORRHOEA.

In both acute and chronic gonorrhœa, injections of sulphate of zinc are employed, varying in strength from one grain and upwards to the ounce of water; and in acute cases the injections are used from the beginning.

Internally, oil of sandal wood is the favorite remedy, administered in doses of gtt. xv. t. i. d.

SOFT CHANCRE.

Caustics first. Acid nitrate of mercury is the favorite caustic, and a very favorite dressing to follow the cauterization is aromatic wine applied upon scraped lint, being careful to dress each sore separately.

INDURATED BUBO.

Cover the part freely with mercurial ointment, and keep up constant pressure by means of a hot brick. Better results were claimed for this method of treatment than any other that had been adopted.

PHAGEDENIC CHANCER.

One of these was seen, which had been met with the more than equally energetic treatment of having all the dead tissues removed by the knife, and the operation followed by cauterization with acid nitrate of mercury. The phagedenic process was at once arrested, and the sore now presented a healthy appearance—the slough having been removed—under the influence of aromatic wine dressing.

SUPPURATING BUBO.

Free incision, and pack the cavity with lint wet in a lotion composed of one drop of sat. sol. of carbolic acid and six drops of sweet oil.

SYPHILITIC LICHEN.

The case was exceedingly well marked, and was at the 43d day from the exposure.

The treatment which the patient was under was as follows:

Good food and porter; vapor bath not lasting more than ten minutes, once or twice a day; and the following drugs:

R. Potassio tartrate of iron.....	$\frac{3}{4}$ vi.
Aque.....	$\frac{7}{8}$ viii.
M.	

Teaspoonful of this mixture with from $\frac{1}{4}$ to $\frac{1}{8}$ of a grain of bichloride of mercury, t. i. d.

The mercury is combined, not for the purpose of producing its specific effect, but simply for its tonic and alterative influence. Salivation is not desirable.

In connection with the above, the patient was also receiving Fowler's solution, gtt. xxv. t. i. d., administered in milk and after meals.

The arsenic was commenced in doses of five or six drops, and increased to ten as soon as possible, and from that the remedy was to be carried on until *some nausea* was produced. The twenty-five drops were being taken without inconvenience.

The idea entertained was that arsenic is not specially serviceable in the treatment of this class of affections unless carried up to the point of producing *some nausea*. Prognosis guarded with regard to perfect cure in this case.

ANTE-SCROTAL FISTULE.

Introduce a sound into the urethra; determine the track which the fistule take to reach the urethra, by introducing a small probe. When this is determined, melt a small quantity of nitrate of silver in a test-tube over a spirit lamp, and coat the end of a probe with the silver by simply immersing it in the molten mass. When sufficiently coated, introduce it into the fistule, and repeat every third day. On the days between, throw into the fistule by means of a hypodermic syringe a concentrated tincture of cantharides.

The concentrated tincture can be obtained by evaporating the ordinary tincture to one-third or one-fourth its natural bulk.

TONIC PRESCRIPTION.

The following prescription is regarded specially beneficial as a general tonic in syphilitic patients, and has been found to act exceedingly well in those cases in which the functions of the stomach have been almost destroyed by the use of alcoholics.

R. Quinia sulph.....	gr. xxx.
Tr. ferri chlorid.....	$\frac{3}{4}$ iii.
Strychnia sulph.....	gr. $\frac{1}{4}$.
Syr. zingiberis et	
Aque ad.....	$\frac{3}{4}$ iii.

Teaspoonful every four hours.

PHAGEDENA.

The case was one of sloughing upon the foot, dependent upon syphilis. Bristow's solution of bromine was employed in this case to destroy the phagedena, and the applications followed by yeast and charcoal poultice. The solution is made as follows:

R. Bromine.....	℥i.
Bromide of potassium.....	℥ii.
Aque.....	℥ii.

M.

It is claimed for this solution that the appetite is almost invariably improved within twelve or twenty-four hours after its application to the affected part. This was said to be the peculiar effect produced by the application.

REMOVAL OF BRACHIAL PLEXUS.

The patient was a man 71 years of age, who had a painful neuroma of the skin for ten years. Dr. Maury had dissected and removed the entire brachial plexus of nerves, and the operation was attended with complete recovery so far as pain was concerned. Motion and sensation were lost. A more perfect report of the case can be found in the *Am. Journal of Med. Science* for Oct. 1873.

SPRAINS.

Foot bath, hot as can be borne, for half an hour, followed immediately by free rubbing with liniment composed of soap liniment with a small quantity of aqua ammonia and oil of rosemary, and then a snugly applied bandage.

ACUTE SYNOVITIS.

Treatment, general antiphlogistic, associated with local counter-irritation in the form of tr. iodine or blisters.

CHRONIC SYNOVITIS.

The aspirator has been used somewhat frequently, and with very good results.

ESMARCH'S APPARATUS

The tourniquet is preferred to the rubber tubing, for the reason that all danger of the tubing getting loose is avoided, and the tourniquet can be easily loosened to facilitate finding the arteries for purposes of ligation.

FRACTURE OF THE FOREARM AND COLLES FRACTURE.

For the treatment of these fractures Bond's splint and Nélaton's pistol-shaped splint are the ones chiefly employed.

FRACTURE OF THIGH.

The wire-gauze splint of Dr. Nathan R. Smith is usually used.

FRACTURE OF THE LEG.

The book-back splint is the favorite.

The idea is to nearly enclose the limb in some unyielding material, and yet leave the posterior portion sufficiently flexible to permit of easy removal. This can be easily accomplished by reinforcing a light plaster dressing with lateral strips of cloth, pasteboard, leaving the back of the splint more or less flexible.

"Permanent," or "immobile," or "mobile immobile" dressings are but little employed in the treatment of fractures in this hospital.

ACUTE ARTICULAR RHEUMATISM

The full alkaline treatment is commonly adopted in the treatment of this affection. Dry cotton is the most commonly used local application. Hop poultices are occasionally employed.

If the temperature becomes high, demanding active

measures for its reduction, the patient is placed in a bath of the temperature of 60° F., and permitted to remain there until the temperature of the body has fallen within reasonable limits. Dover's powder is given to relieve pain; and, as soon as the acute stage has passed, quinine gr. xv. per diem.

PNEUMONIA.

In the main, the treatment of this disease is expectant. Rarely is local blood-letting resorted to. It is occasionally employed for the purpose of relieving local pain. Sometimes digitalis is used; sometimes veratrum viride; but these remedies are administered only in a small proportion of cases. Quinine, ten grains a day, is quite commonly administered with a nourishing liquid diet. What is called the "jacket-poultice" is, as a rule, applied. The jacket-poultice is simply a linseed meal poultice sufficiently large to cover the whole chest, and usually has a little powdered mustard sprinkled over the surface, or mixed with it. Most of the patients recover. The application of cold to the chest has never been adopted. Quinine in large doses has been used for the purpose of reducing high temperature, but it does not enter into the plan ordinarily adopted in the treatment of the disease. Carbonate of ammonia is used when an active stimulant expectorant is desired, or its general stimulating effect.

SUB-ACUTE PLEURISY.

Diuretics (iodide of potassium, acetate of potash); tonics and good food; and moderate counter-irritation. Paracentesis thoracis is performed rather late in the progress of the case, remedies having first been faithfully tried. To relieve the pain of the more acute form of pleurisy, and also of this form, the local application of cold has been resorted to with good success.

DELIRIUM TREMENS.

Bromide of potassium and hydrate of chloral are the remedies commonly employed. The potassium is administered in doses varying from 20 to 60 grains, and the chloral may be given perhaps twice during one night in doses varying from 15 to 20 grains.

In one case, chloral, bromide of potassium, and morphine has failed to produce sleep, but whiskey, in half ounce doses every half hour, accomplished the desired effect. When nervous symptoms dependent upon alcohol are present, a dose of whiskey is ordinarily administered before resorting to any medical treatment whatever. The hospital staff are about equally divided upon the question of bromide of potassium being able to produce sleep.

ACUTE PERITONITIS.

Opium is the chief remedy employed.

NIGHT SWEATS OF PHTHISIS.

Sulphate of atropia is regarded as an excellent remedy for their arrest. It is usually administered in a simple dose at bedtime of $\frac{1}{16}$ of a grain.

Aromatic sulphuric acid.

Niemeyer's pill. Niemeyer's pill and atropia used in conjunction. Oxide of zinc and hyoscyamus were said to be efficient with their cases.

The pill called Niemeyer's, or the one he ordinarily prescribed, properly known by the name of Heim's pills, is in general prescription. The formula for the pill is as follows:

R. Pulv. herb. digitalis.....	℥ss.
Pulv. rad. ipecac.	
Pulv. opii puri, aa.....	gr. v.
Ext. bellad. q. s. u. f. pl.....	℥o. xx.
Comp. pulv. rad. irid. flor.	

S. A pill three times daily. The addition of a scruple of quinine to the above prescription constitutes Niemeyer's modification, and is added for its antipyretic effect. This pill of Niemeyer's is one very commonly prescribed in this hospital in cases of phthisis, and is regarded as a very valuable combination of remedies.

HEMPTYSIS.

Hypodermic injections of ergotine were mentioned with special favor. The solution used is of such strength that $\mathbb{M}\text{xv}$. contain one grain of the ergotine. Inhalations of the oil turpentine are frequently employed.

As good success has attended the use of the above remedies to which have been employed.

DIARRHŒA OF PHTHISIS.

Among the many remedies and combinations of remedies that have been used, the following prescriptions have obtained some reputation for good:

R. Opium..... $\frac{1}{2}$ to 1 grain.
Bismuth subnit..... gr. xv.
Ipecac..... $\frac{1}{2}$ grain.
M.

Taken p. r. n.

R. Nitrate of silver..... $\frac{1}{2}$ gr. to $\frac{1}{2}$ gr.
Opium..... $\frac{1}{2}$ gr. to 1 gr.
M.

Ft. pil.

To be taken p. r. n.

R. Strychnia sulph..... $\frac{1}{4}$ gr.
Bismuth subnit..... 15 to 20 gr.
M.

Taken p. r. n.

TYPHOID FEVER.

Treatment, in the main, expectant. Some of the visiting physicians prefer to have administered about 18 gr. of quinine daily for the purpose of preventing tissue waste. The acid treatment is also regarded with favor; that is, the administration of some one of the mineral acids in moderate doses from the beginning.

Glycerine and water has been employed for the purpose of reducing the temperature when it becomes moderately high, and it was thought with more satisfactory results than sponging with simple water. The proportions used are—

R. Glycerine..... $\mathbb{I}\text{iv}$.
Water..... $\mathbb{O}\text{i}$.

When *hemorrhage from the bowels* occurs, the chief reliance is upon cold applications and the use of suppositories containing various astringent remedies, but especially opium. All necessary measures also must be adopted to sustain the patient until the crisis has passed.

ERYSIPELAS.

The case was an ordinary one, in which the disease affected the head and face.

Tr. iron and quinine were being used as internal remedies.

These remedies are uniformly employed in these cases.

For external applications the lead-water with tr. opium is a favorite, although not especially new.

Oxide of zinc ointment is sometimes used. Hypo-sulphite of soda, combined with some mucilaginous mixture, is a favorite application with some of the visiting physicians.

SCARLET FEVER.

Treatment of the fever is mainly expectant. Stimulants are of benefit in the class of cases seen in this institution.

For the dropsy which sometimes appears, diuretics are used, and if the children have some age, purgatives are administered. When throat symptoms are prominent, a very common prescription is a saturated solution of chlorate of potash in tr. of iron and well sweetened with honey. The dose is to be regulated according to the size of the dose of iron proper for the age of the child. The rates of mortality are low.

DIPHTHERIA.

Constitutional treatment by means of quinine and iron.

Local application, most commonly of dilute muriatic acid, sometimes of tincture of iron. The resident physician had but little faith in the power of lime-water to dissolve the membrane, for the reason that he had kept for a long time a specimen of membrane that had been preserved in lime-water.

Alcoholics are not administered until the system needs them. It is believed that this is the better plan, for the reason that, if commenced early, they are liable to produce more or less nausea, perhaps vomiting, which may prevent their use at the time when they are most needed. Local applications are made to the throat if the throat is very much inflamed.

Treatment with calomel and bicarbonate of soda had just been adopted in a couple of cases, but the results were undetermined.

WHOOPIING-COUGH.

Hydrate of chloral is the common remedy, and gives very satisfactory results. Sometimes belladonna is combined with it.

The remedy is pushed as much as possible; commencing, in a child from one to two years old, with one to two or three grains t. i. d.

Sugar had been found in the urine of all these patients.

The co. tr. benzoin is sometimes added to the chloral to stimulate the kidneys to increased action, when the chloral has rendered them somewhat inactive.

FACIAL ERYSIPELAS IN PREGNANT WOMEN.

Erysipelas was developed in three pregnant women a few days before confinement. Their labors were easy and they recovered without a single bad symptom. The erysipelas passed away with the most favorable termination. Every other woman, however, who was in the same ward was affected by something which caused the temperature to rise upon an average to 103° the day after confinement. Many other symptoms of equally unfavorable import were developed in connection with the rise in temperature. After the second case opium and quinine were administered for a few days previous to confinement in anticipation of serious puerperal trouble. There were no deaths.

PUERPERAL FEVER.

Opium in sufficient quantities to calm all local irritation; quinine in tonic doses; sometimes in large doses, gr. xxx. a day, to reduce the temperature; veratrum to control the pulse; fair amount of liquid nourishing diet; and alcoholics if necessary. If veratrum produces vomiting, aconite is substituted for it. Care must be exercised in the administration of aconite lest its depressing effects be too markedly produced. It is much easier to bring up from the depression of

veratrum than from the depression of aconite. Turpentine stupes are applied to the abdomen if tympanites is present.

One case, probably puerperal septicæmia, was treated by giving nitro-muriatic acid dilute in doses of twenty drops every two hours; lead and opium lotion to the abdomen; opium simply to quiet; quinine grs. xxx. daily for three days. The bowels moved several times each day, and the discharges were exceedingly offensive. No measures were taken to arrest the discharges, and they did not produce exhaustion. The patient recovered.

QUININE AND MORPHINE.

It had been noticed in several cases that, when one-quarter of a grain of morphine would not produce sleep, if ten grains quinine were administered a short time previous to administering the morphine, the morphine would almost invariably act efficiently. This fact was noticed in connection with puerperal cases.

MAMMARY ABSCESS.

Quinine in full doses as soon as chill occurs. Cease nursing at once, and remove the milk by hand rubbing, covering the parts with warm lard, and rubbing from the base of the gland towards the nipple.

QUININE OF GLYCYRRHIZA.

To disguise the taste of quinine administer it in fld. ext. of glycyrrhiza. If fld. ext. is not at hand, the powder can be used with nearly the same result.

INJECTION OF PULMONARY CAVITIES.

In two cases in which there were well marked signs of cavities in the lungs, from 15 to 20 drops of a 15 per cent. sol. in water of Trousel's solution were thrown into these cavities by means of a hypodermic syringe plunged directly through the walls of the chest. This was done with the result of producing an improvement in the general symptoms, and very much less expectoration. The measure was suggested for the relief of hemorrhages.

DECLINE OF THE UNIVERSITY OF BERLIN.—The diminution in the number of students at the University of Berlin, which had already been noticed during the last three months of the summer of 1873, has again been observed during the six winter months of 1873-74. The *Gazette de Cologne*, commenting on this falling off, remarks that hitherto as a rule the University medical courses were more numerously attended than the other ones. It seems, however, certain that the number of students of medicine has sensibly diminished; one professor having 100 fewer students in his class than he had in the preceding year. In short, the number of students has reached its lowest point in comparison with former years. The University is now outstripped in numbers, not only by that of Leipzig, but also by the University of Göttingen, which now contains 1,000 students. It appears that in Germany the salary of the professors, which, inclusive of the students' fees, is considerable, is only increased if they be requested to transfer their services to other seats of learning, and if their departure be considered injurious to the interests of the University which they have hitherto taught. Thus distinguished professors have been drafted to the University of Berlin, but this has not been accomplished without promising them double the salary offered some years since. This increase of salary is rendered imperative by the continually increasing price of the necessities of life in Berlin, as in other parts of Germany.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 7, 1874.

DR. J. LEWIS SMITH, VICE-PRESIDENT, in the Chair.

FRACTURE OF ILIUM.

DR. SAYRE presented a specimen of fracture of the ilium produced, by a runaway accident, in a boy eighteen years of age, a resident of Jamaica, Long Island. On Sunday night of Sept. 27, Dr. S. was sent for by Dr. Wood of that place to see the patient, the statement of the messenger being to the effect that the injury was a very severe one, that the fracture was a compound one in the neighborhood of the hip, and was evidently caused by being thrown upon the stump of a tree. When it was stated that the boy had walked two or three steps after the injury the conclusion at once was that the thigh had not been fractured. Dr. Sayre found the patient lying on his back, and bleeding quite profusely from two wounds, each about an inch and a half long, situated just above the trochanter major. The isthmus between the openings was cut through in order to facilitate a thorough examination. Introducing the finger into the wound a fracture of the crest of the ilium was at once detected, and the loose pieces of bone were removed through the external opening. The specimen consisted of the summit of the crest of the ilium, and was about four inches in length. It was supposed that the external wound was produced by the lower edge of the upper fragment being tilted and tearing its way through the integument. Dr. Sayre believed such accidents very rare, unconnected with railroad collisions and gunshot injuries.

There was considerable hemorrhage at first, but this was fortunately checked by twisting the divided ends of a small artery, which proved to be a branch of the middle gluteal.

RUPTURE OF GALL-BLADDER FROM FALL.

DR. JANEWAY exhibited a specimen of rupture of the gall-bladder removed from a patient of Bellevue Hospital, who was admitted a few days before his death, and who had received an injury from a fall from a mast striking the deck flatwise. He soon after showed signs of peritonitis, from which disease he died at the end of a very few days.

At the autopsy there was found a transverse fracture of the sternum at its point of junction with the third costal cartilage, attended with bloody effusion in the anterior mediastinum, and in the pericardium. In the cavity of the abdomen there was discovered serous effusion with fibrinous flocculi and also in the pelvic cavity. The effusion was more or less bile-stained, in the pelvis, and in the neighborhood of the liver. In the folds of the mesentery there was a good deal of bile effused, as was also the case all along the ascending colon around and in the fat capsules of the kidney. The peritoneum around the gall bladder was uninjured, the rupture in the viscous being through the mucous membrane, thus allowing the infiltration of bile to take place underneath the peritoneum and in the manner already described. The gall bladder itself was distended with bile and adherent to the transverse colon, at which point there was a small amount of supuration. It appeared to be evident that the adhesion, together with the distended condition of the organ, were the principal reasons why rupture had occurred.

FALLOPIAN ABSCESS, ETC.

DR. JANEWAY presented a second specimen, for the following ante-mortem history of which he was indebted to Dr Rankin, of Bellevue Hospital:

"I saw the patient for the first time on the 29th of September. She had then been confined to her bed four days. Her condition was as follows:—Face very much suffused; tongue heavily coated; she had intense thirst; was unable to retain anything on her stomach; had nausea even when no food had been taken for some time; pain on somewhat firm pressure in the right iliac fossa, and also over the bladder. Two or three times a day she would have a sudden chill, and with the chill, intense pain deep in the pelvic cavity. And at the same time there would be a sudden profuse watery diarrhoea, coming on sometimes so suddenly, that she would not have time to get out of bed. This would be followed by extreme prostration and a very rapid pulse. Temperature $102\frac{1}{2}^{\circ}$. Pulse 125. Ordered opium and quinine, bismuth and pepsin, and put her on a milk diet and beef-teen.

"September 30.—Feeling somewhat better. On making a vaginal examination (digital), I was unable to find the os uteri, or make out the anterior or posterior lip. There appeared to be a tumefied condition of the parts, prohibiting the mapping out of the organ. I was able to press the uterus upwards without any or with very little pain. There was a bloody discharge, which was quite offensive.

"October 1, A.M.—Passed a more comfortable night. Temperature 100° . Pulse 100. P.M.—Since morning has had two quite severe paroxysms of pain. Considerable pain on pressure over the whole of the lower part of the abdomen. Temperature $102\frac{1}{2}^{\circ}$. Pulse 130. Tongue heavily coated—is troubled considerably with hicough.

"October 2, A.M.—Temperature 102° . Pulse 120. Very much prostrated, not much pain except on pressure—has had no vomiting or diarrhoea for the past two days. P.M.—Dr. H. T. Hanks saw the patient with me. Temperature 102° . Pulse 120.

"October 3, A.M.—Patient slept all last night; is in a state of collapse. Temperature 105° . No pulse. Died at 2 P.M.

"*Previous History.*—Ten months ago, during her menstrual period, she went out wearing slippers, on an intensely cold day. She was immediately laid up with peritonitis, and was confined to her bed for two weeks. Since then, at every menstrual period, she has had a more or less severe attack of peritonitis. Three months ago had a miscarriage."

DR. JANEWAY remarked that the reason why Dr. Rankin could not map out the os was quite apparent when the parts were examined at the autopsy. The posterior cul-de-sac was obliterated by a cicatrix, and the os was almost entirely closed. The cavity of the uterus was somewhat distended. Posterior to the uterus there was found an abscess, formed by a distended Fallopian tube, and bounded on one side by the posterior layer of the broad ligament, and on the other by the cul-de-sac of the rectum. Fatal peritonitis was produced by an ulceration through the right Fallopian tube, at a point two inches from its entrance into the uterus.

The primary origin of the abscess was supposed to be metritis.

OBSCURE CASE OF CANCER OF STOMACH.

DR. DELAFIELD presented a kidney and heart, taken from a patient who died at the Roosevelt Hospital the day previous. The patient was fifty-five

years of age, a 'longshoreman' by occupation, and was admitted July 29. He then gave a history, that he had been suffering for nine months with pain and vomiting after eating; the pain coming on half an hour after eating, and the vomiting an hour after. These attacks of pain and vomiting, which occurred only from time to time, became more frequent, until shortly before his admission every meal was attended with these symptoms. When admitted he was much emaciated, and presented a cachectic appearance. There was no tumor in the epigastrium, nor was there any particular tenderness. His liver was somewhat enlarged, but his chest organs were normal, and there was no sign of disease in his urine.

After being in the hospital for a while the pain and vomiting ceased, not to return until he died. In fact, during his stay in the institution he was in a condition which rendered a diagnosis very difficult, not making any complaint. There was nothing to draw attention to any particular organ, and nothing occurred except two attacks of diarrhoea, one of these lasting ten days, and the other two weeks. These attacks were very severe—were rebellious to all the usual remedies—and ceased, apparently, of their own accord. He grew steadily weaker, and died Oct. 6.

At the autopsy a cancerous growth was found at the pyloric orifice of the stomach, nearly surrounding and closing it. The kidneys were pretty far advanced in chronic nephritis, and the upper lobe of the left lung was the seat of red hepatization. The intestines were normal. The urine was examined repeatedly during life, and nothing abnormal was found, except a few days before death when it became scanty; at the same time the legs became cedematous.

The interest of the case centred in the obscurity of the symptoms.

DR. SELL referred to two cases then under his observation, in which the symptoms markedly resembled those in Dr. Delafield's case, and in which he expected to find the same autopsical lesions.

PERFORATION OF APPENDIX VERMIFORMIS.

DR. WEISS presented an appendix vermiformis, which he had removed that afternoon from a gentleman, aged fifty, whom he saw, in consultation with Dr. Purdy, the Friday evening previous. The patient was then suffering most intense agony, with vomiting, retraction of the testicle, and frequent passage of scalding urine. The pain which had been felt in the right flank had shifted somewhat downwards and inwards. The abdomen was rigid and no thorough examination could be made. In the supposition that a renal calculus was passing, the pressing indication was to relieve distress, and a hypodermic injection of morphine was accordingly administered. He had some fever the day following, some chills, and a small amount of pain.

The next evening an examination was allowed, and the diagnosis of perforation of the appendix vermiformis was made. Dr. Sands, who was present at the time, confirmed this conclusion.

The patient subsequently died of peritonitis.

At the autopsy the posterior margin of the appendix was found perforated, and through the perforation a hardened calcareous mass had been found.

DR. SELL asked if the surface thermometer had been used over the appendix, and being informed that it had not, referred to an instance in which the surface showed a difference of three degrees over the seat of such an inflammation.

DR. SANDS remarked that the case presented none of those physical signs in the shape of circumscribed

abscess, which were considered as sufficient to call for operative interference. It was also a curious fact that this very severe peritonitis should have occurred without any perceptible escape of feces in the peritoneal cavity.

DR. DELAFIELD remarked that in many instances the appendix would become inflamed independent of any apparent exciting cause external or internal to it, and in those cases the inflamed organ seemed to be a sufficient exciting cause for the fatal peritonitis.

DR. SANDS had no doubt that such was frequently the case; that in some instances the simple inflammation of the appendix might result in gangrene and then give rise to peritonitis; still he believed that there were many other cases in which there was a very small escape of feces—so small as to escape notice except by its odor, and the quantity being never so small was almost always enough to excite fatal peritonitis. The peritoneum was very intolerant of a mere drop of urine or the slightest amount of fecal matter.

The Society then went into executive session.

NEW YORK JOURNAL AND LIBRARY ASSOCIATION.

Stated Meeting, Oct. 2, 1874.

DR. J. C. PETERS, PRESIDENT, in the Chair.

CONTRACTIONS OF THE PALMAR FASCIA.

The paper for the evening was read by Dr. A. C. Post, and entitled, "Contractions of the Palmar Fascia." A brief allusion was first made to the anatomical relations of this fascia, and then the author of the paper passed to the consideration of the causes which may give rise to this morbid condition. These were set down as being chiefly of traumatic origin, such as handling of ours, driving chisels with the palm, and other injuries of like character. This morbid condition is to be diagnosed from persistent flexion of the fingers from other causes, such as the result of sloughing wounds; from the cicatricial contractions of burns; from paralysis of the extensor muscles; and from rheumatic and gouty affections. It affects the ring finger most, and the little more than the index-finger. These flexions are accompanied by arched folds and arrangements of the skin which have their *concavities* towards the fingers.

A careful consideration of the history of the cases of contraction affecting the palm is usually sufficient to enable the surgeon to make a correct diagnosis.

The disease was first described by Dupuytren, but has not been generally recognized by authors; and, on the contrary, it has been regarded as being due to some other condition, such as has been enumerated.

As regards prognosis, if the disease is left to itself it undergoes no amelioration, and the change which takes place is from bad to worse. If the contracted bands be divided, the hand and fingers secured upon a splint, and passive motion be vigorously and persistently applied, a good degree of motion may reasonably be expected to be obtained.

The treatment at the outset must be operative. The patient should always be anesthetized. The incisions should be made as nearly subcutaneous as possible, at points wherever capable of relieving tension, and without wounding the skin more than is absolutely necessary.

The subsequent treatment is both tedious and painful. The wounds are to be immediately covered with

adhesive plaster. The hand should at once be placed upon a metallic splint which should cover the posterior surface of fingers and hand, and extend somewhat upon the forearm. The splints must be well padded with woollen batting and lint, each finger secured to its own portion of the splint by means of adhesive plaster, and the splint secured to the hand and forearm by means of a roller bandage. The dressing should be changed daily, the wounds kept well cleaned, and passive motion persistently and regularly practised.

The histories of four cases were read, and in all of them the curious fact was noticed that flexion in the latter stages of the treatment produced more pain than extension, although flexion was the original deformity. The ability to flex the fingers fully is very slowly gained.

DR. WEISSE remarked, with reference to the pathology of the affection in question, that the reason why this peculiar contraction of the palmar fascia was produced, leading to flexion of the fingers, with inability of extension, rested probably in the peculiar anatomical arrangement of the palmar aponeurosis itself. This aponeurosis, as it passes down to the centre of the palm, between the hyperthenar and thenar eminences, presents us with transverse fibres, and also longitudinal ones, which are attached to the skin of the fingers at its deeper portions. It is in these straight fibres that we have to look for the explanation of the contraction of the fingers, independent of the tendons within the theca.

DR. POST reported a case of lumbar colotomy, in which the operation had been performed upon a child three and one-half days old. There was absence of both anus and rectum. There had been a minute discharge of fecal matter with the urine. All the distressing symptoms were relieved by the operation, and then, six days after the operation, the child was doing well, and bids fair to recover.

DR. PETERS exhibited a specimen of what has been called "sneeze-weed" (*Helenium Autumnale*), which is said to be the cause of what is known as "hay catarrh."

DR. BUCK exhibited an instrument which he had devised for conducting the chain-saw around deep-seated bones, excision was intended.

The Association then adjourned.

MEDICAL ATHLETES.—Two of the finest athletes in Washington are members of the medical profession, Dr. W. V. Marmion and Dr. I. C. Rosse. The former gentleman lifts 1,000 pounds with his hands, and puts up a dumb-bell of 130 pounds. Dr. Rosse is probably the strongest man in Washington for his size. He lifts 400 pounds with one hand; is equally as good as Marmion with the dumb-bells, and suspends 63 pounds at arm's length on his little finger.—*Washington Chronicle*.

KJEVULF.—Died, on the 7th September last, Chr. T. Kjevulf, M.D., etc., etc., Chief of the Medical Department of the Interior, Norway. He was born in 1823, served as surgeon in the Danish army during the war of 1848-49; was appointed chief in 1857, and was an industrious writer in the "Norsk Magazin for Lægevidenskaben."

LEPERS.—According to Dr. Hansen, in the *Bergens Post*, the number of lepers in Norway, in 1870, was 2,350, or 500 less than fifteen years previously. The Doctor very reasonably congratulates his countrymen on the fact, adding the hope that the disease may be ultimately eradicated.

Correspondence.

HYDROPHOBIA ON THE DECLINE.

PINE RIDGE PAPERS.

IV.

I AM sorry to say that any continued discussion of hydrophobia is getting out of season. This, however, is no fault of mine, as I have endeavored to make the most of my opportunities and have striven to keep alive an interest in the subject not only for the good of science, and the stimulation of experimental research, but for my own personal benefit. There is a time, however, when the most enthusiastic and disinterested worker must make the unwelcome acknowledgment that his labors no longer claim that amount of attention which he naturally desires. The newspapers find it impossible, on account of the cool weather, to develop any fear of the disease in their readers, and dogs command no more notice than if hydrophobia did not sometimes exist and was not to be dreaded.

I had some hopes of creating a little excitement by the spread of the malady through the dogs of my neighborhood, which I had clandestinely inoculated, but my friend, the reporter, who promised me at the time to work up the cases for his paper, became so much engaged in attendance upon political meetings that he has entirely neglected me. Notwithstanding this, however, one of the dogs has "gone through" one of the most influential families of the place, and I have had six consultations and three post-mortems in consequence. While speaking of these cases I may mention in passing that I had considerable trouble in convincing my consultants that I was right in my diagnosis. They all contended that the time for the disease had passed, that there was no epidemic, and that the symptoms were the results of imagination. In fact, so strenuous was their opposition to my views that I was forced to detail to some of them the reasons why I was sure of my opinion, and to demonstrate to the others the Kanine under the microscope. Two or three of these rather significantly and concisely expressed their doubts of what they saw. The results of my revelations in regard to my inoculation have been somewhat damaging to my professional reputation and have called down upon me the malignant enmity of several of my brethren. But as I expected this would be the case from the beginning, I have prepared several elaborate replies to their attacks which I hope may have the effect of prolonging a discussion upon a subject which naturally is of a great deal of interest to me.

It would be strange, indeed, taking into account the great publicity which my experiments and their results have gained, if I, in common with other investigators, had not suffered from the persecutions of the Humane Society for Animals. The President of this Society happened upon me at a very inopportune moment, when I was applying the aspirator and explaining its mode of operation to a few dog-fanciers. He made no objection to the muzzle, but was vehemently opposed to the lever under the jaw as being uncomfortable, and most of all objected to the aspirator, claiming that the latter caused needless suffering, that God never made aspirators, that on that account they should not be used, and, consequently, that they were cruel. The worthy functionary was willing to strain a point by permitting the aspirator to be worn, but would not allow the skin to be pricked. My mucoid assistant was quite offended

at this interference, and triumphantly showed the instrument which he has "worn in his shirt collar for six months without change, and without the slightest inconvenience," but the President quoted a few appropriate texts and settled the argument at once. The result has been, that my establishment has been closed, my aspirators confiscated, and threats have been made to forbid me experimenting with the Kanine, principally on the ground that I have no legal right to use any substance obtained through the instrumentality of vivisection. Our county society has, however, taken up the subject, and declared its intention to pass resolutions against the interference with rights of professional property. I may say in passing, that I have prepared this substance in suitable vials, which are for sale at all the principal drug-stores. Sausage makers supplied at wholesale rates. It is unnecessary to state here that all my dogs have recovered, and have been discharged cured.

After the closing of the establishment, I was visited by a health inspector, who had been ordered by his head(s)-center "to examine and report." He discovered to his satisfaction that none of my animals had been vaccinated, and that the new cases of rabies had not been promptly reported, that the beds had not been properly aired and were developing zymotics; and that the urinals had not been sufficiently disinfected. In his report he condemned the establishment "as a disgrace to civilization, sanitary science, professional integrity, discrimination, and knowledge." I should have been very much discouraged in the hope of making my hospital popular had I not thought of the expediency of an interview with one of the Health Wardens. I told him my story, showed him the report and presented him with a vial of Kanine. He smiled, was much interested in my discoveries, and told me to pay no attention to the report, that the profession must stand by each other, and that he would use his influence in my favor. At his suggestion and with the promise of his protection I have had my institution reconstructed, built upon the pavilion plan, have laid four drains for every kennel, placed two extra ventilators in each ward, a piece of carbolic soap in each urinal, constructed new traps for the water closets and have entirely done away with a large sewer, the roots of my pine-trees serving such a purpose. In addition to this, I have also established telegraphic communication with headquarters so that I may report any new case the moment I find the Kanine in the laryngeal mucus. It is necessary that these facts should be borne in mind in anticipation of another epidemic of rabies, and their importance impressed upon those who desire to favor original research.

But now I wish to speak more particularly of the merits of the Pine Ridge aspirator. Of all the patients whom I saw in consultation, and who died, none would use the instrument. If this does not explain the mortality, I am willing that it "shall be put on record" as a curious, if not remarkable, coincidence. The main objection to its use was urged by the patients' friends, who persisted in declaring that the wound which it occasioned in the neck would spoil the looks of the corpse. This objection was made in the very face of my mucoid assistant, who showed that all unsightly marks could be concealed by the shirt collar, and that even the aspirator itself could be worn, if necessary, by a dead body without being seen. As further proofs of his correct views in the matter, he submitted certificates to that effect from several undertakers who had had a large experience with the hydrophobic patients of my brother-practitioners. It was to no purpose, however, and I only desire by referring to the circum-

stance to place the responsibility of the mortality where it rightly belongs.

Another point bearing upon the great utility of the aspirator may be mentioned in connection with my first assistant, who was bitten in the buttocks and died asphyxiated. In that case death occurred before the aspirator was perfected. The conclusions to be arrived at in this case are quite obviously in favor of the instrument. While speaking of this Pine Ridge aspirator, I am compelled to state that it cannot be used second-handed without some danger of infection. An enthusiastic medical student who happened to be present when the instrument was removed from the throat of one of my dog patients (who had by the way recovered) was curious to see how the instrument would act upon his own person, and inserted the needle in his throat, playfully remarking at the time that he could swallow tobacco juice with impunity. It is needless to say that he became infected, and that he is compelled to wear the instrument constantly. Instead of tucking it in his shirt collar, he has had another pin made for it, and wears the instrument as an elaborate scarf-pin.

I have examined very carefully into the cause of infection in these cases, and find that it is altogether due to the collection of the Kanine around the end of the needle. These granules are apt to lie dormant for a very long time when bathed in laryngeal mucus, and in this respect are very like the spermatozoons which lurk around the Fallopian passages for months ready to pounce upon any stray ovum that may come within their reach, and make it the prey of protoplasmic influences. I have already referred to the tenacity which this granule has upon life when I likened it to the syphilitic corpuscle of which we know so much. In view of the danger of using second-handed aspirators, I take occasion not only to advise my readers not to run any risk, but also to state that I have made arrangements with my instrument maker for supplying any quantity of entirely new ones.

Bearing upon the question of the pathology of the disease and at the same time affording me another opportunity for referring to my instrument, I may mention a very interesting fact. My present assistant, whose many narrow escapes have made him a little cautious, on one occasion tickled the nose of one of the hydrophobic dogs by means of a straw through a knot-hole in the fence. Almost immediately afterwards the animal sneezed, then rolled over in a hydrophobic convulsion and very soon expired. I explained the cause of death as reflex action, simply remarking at the time, that the animal was so saturated with Kanine that the least excitement in the shape of peripheral irritation was sufficient to disturb the relation of the granular hydrophobic elements, to cause the secretion of more laryngeal mucus, and to set up that promiscuous interchange of nervous forces which is known under the generic term of convulsion. At the time I expressed the suspicion also that the aspirator had become clogged.

In this accounting for the phenomena, I am happy to say in behalf of my theory that the principle established was correct, although it was proved in a different manner from what I at first expected.

At the autopsy of this dog the aspirator was kept *in situ* with the determination of entering the base of the brain through the throat. It was then discovered that the needle of the aspirator had really become clogged by perforating the root of the hypoglossal nerve, the accident being evidently occasioned by the efforts at sneezing during life. No one can deny that there was irritation at the root of this nerve, and

that the Kanine granules at that point must have been sufficiently disturbed to have reflected the convulsion to the extremities. I claim that a slighter amount of irritation would have accomplished death with equal certainty, provided the tube aspirator had not become impervious.

In order to prevent a similar accident from sneezing in future, I have made the needle of the aspirator jointed, after the manner of the catheters in use, so that its movements can be accommodated to the constant change of the relative positions of the parts above the larynx. A detailed account of this modification, with a wood-cut, will appear in my forthcoming work.

PINE RIDGE-ON-THE-HUDSON.

MEDICAL MATTERS IN PHILADELPHIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—The season of activity is again upon us, and the faces of hundreds of strangers to our city are visible in our lecture-room. We are just now giving these new-comers the cordial welcome as our future *confrères*, who are to follow in our footsteps and improve on our own achievements, whatever such may be, and however modestly we may speak of them. It is too early yet to estimate these gentlemen numerically, although an anticipation of large classes are indulged in by the sanguine among us. The interesting problem is, whether the removal of the University of Pennsylvania to its permanent and beautiful quarters on the western side of the Schuylkill, will or will not seriously affect it for a while in the dimensions of its classes, and its consequent pecuniary profits. With all the advantages of splendid buildings, ample accommodation for pupil and patient, with hospital teaching and practice at their very elbow,—for the cluster of University halls and edifices includes every available method of regular didactic and clinical instruction, and luxurious arrangements for professional comfort, for I am told that each teacher has his own well-furnished office, with all the modern improvements attached,—there is but one drawback to success, and that is peculiarly Philadelphian, and consists in the fact that this time-honored institution is now two miles distant from its ancient hallowed vantage-ground, having emigrated to a region scarcely yet invaded by students' boarding-houses and the usual accompaniments of elderly spinsters, widows, and mediocre diet, including hash, which forms an integral portion of the bill of fare reserved for them in all the large cities where these gentlemen most do congregate. My own impression is that at first the students will not take kindly to the change; but this can be but a temporary check to the continuously prosperous career of that school. It would be absurd to suppose that for any lengthy period young men coming to our city for medical instruction would be afflicted with the morbid Philadelphia epidemic weakness or delusion, that, within a few blocks of the business centres of the city, there is and should be concentrated the united medical wisdom of the whole community, and that more than a mile or so to the north or south of this restricted area is positively suburban. In such a view I scarcely know how Bellevue Hospital Medical College, distant as it is from the busy haunts of down-town trade, would appear to us, if similarly located here. In the parlance of relationship, we should consider it as a medical cousin, very far removed.

While wishing the University all the success it

richly deserves, I cannot help thinking that the Jefferson Medical College has done wisely to remain at its old battle-field of medical instruction. Its natural interests would be, now that its older neighbor has deserted it, to stay where it is, and when pecuniary resources become available in better times, when panic-stricken contributors to charitable funds become more cordial and fearless, to build for itself a hospital commensurate with its importance and merits, and then extend its facilities for clinical teaching and its area of illimitable usefulness. The University has, thus far, by efforts made a year or two in advance of the other school, secured a large share of legislative, municipal, and private assistance, and when the panic came there were not more than the crumbs left for its younger rival, though the full loaf must be its portion in due time. The University was forced into a false position last winter by the purchase of its old ground by the National Government as the site of the new post-office, and the subsequent action of its trustees in the rental of the building occupied in former days by the Pennsylvania Medical College, now, I believe, corporately defunct, but latterly by those who almost took the University name in vain, and whose course of instruction was not recognized by either of the other colleges. The latter party contends that the occupation was obtained by fraud, and that they have driven their venerable neighbor out; but the latter may be congratulated that it has now its own abiding-place, with its halo of respectability untarnished by any mere temporary surroundings.

There is scarcely a ripple on the surface of the medical world here at this moment. We have not even a libel suit on hand to stir us up to more than our usual animation, and it seems almost too late in the season to report any hydrophobic cases for microscopic examination. Our medical journals float along on the tide in the same old-fashioned way as of old, each differing widely in its aims and objects; one or two of them treading on the toes of sensitive subjects, with different degrees, however, of roughness or delicacy. When the "Ishmaelite of the Philadelphia Medical Times," as your friend Dr. Hammond called its editor, who is also the author of a recent excellent work on "Therapeutics," assumed the charge of that journal last year, it soon became controversial and aggressive, evidently under the impression that the true way to awaken a public professional interest in it—for it had been a slightly soporific periodical in the days of its infancy—was to wage an unceasing warfare on every salient point of obnoxious attack in the medical world, including its various respectable and other offshoots, even if sensibilities were wounded, and delicate nerves of individuals and corporations ruthlessly exposed. But there is a point beyond which the patient reader feels ill at ease; he doesn't care to see the scalpel always in use when more delicate instruments are available, and the writhings of the victim are not always pleasant to behold. On this account it is doubtful whether the *Medical Times* is morally more popular from these rude dissections, although I have no data on which to found an estimate as to its business successes. The *Medical and Surgical Reporter* has been, during the European absence of its editor, in the hands of the worthy secretary of the American Medical Association. It was pleasant, in the correspondence between the publishers of *THE RECORD* and the gentleman who has brought suit against it for libel, to find so much delicate consideration shown to the editor of that journal in all the arrangements for conducting it, so that, even in a matter which might peculiarly involve them, he continued to be the re-

cipient of their confidence, undisturbed by any interference on their part.

A new hospital for the treatment of the diseases of women and children has just been opened here. It will be, for a time, chiefly a dispensary for the relief of the walking subjects of these affections, but may be the nucleus of an important institution in the future. Its sponsors have christened it the "Gynecological Hospital," but the patients who are likely to resort to it will be sure to puzzle over the *Gyneco* portion of the name before they come to the logical conclusion as to its objects. These high-sounding titles do not promote the popularity of such institutions, however useful and meritorious the latter may be; and doubtless many a poor fellow will go there for treatment to learn that he is not classifiable in the ranks of the gynecologicals, when he would unblushingly absent himself from a woman's hospital. The women themselves have, by the way, such an institution in progress of construction, and have sensibly given it the simple Saxon name which suggests the sex to be benefited in its path of usefulness, so that it is hardly fair, although strictly true, for the hospital first-mentioned to say that there is no similar institution (to its own) yet established in Philadelphia.

Imagine the intense feeling of satisfaction experienced recently by a modest member of our profession, unskilled in the arts of puffing himself into prominent notice in the medical or lay journals by full details of surgical operations innocently dropped where ubiquitous reporters may pick them up; or by advertising in the daily papers his residence, and at the same time the fact that he is a hospital surgeon; or even by investigations into nervous or other phenomena (illustrated with medico-popular unintelligible diagrams);—imagine such a man's satisfaction, I repeat, as, skimming through the pages of the new "Medical Register and Directory of the United States," with its 70,000 names, etc., of physicians—just issued from the *M. J. and Surg. Reporter* office (the Register, I mean, not the physicians)—he finds about fifty lines of small type (more or less) following after his own name, giving his numerous titles of distinction (at least half of them he avers are omitted), the various learned papers he has contributed to a wondering world of science and literature, even mentioning the highest degree of M. T. which had been conferred upon him as an evidence of the quality of his intellectual development and of his preliminary education. What a satisfaction to him to find that men of so little distinction as Professor Samuel D. Gross and Joseph Pancoast, of this city, are, in the same volume, dismissed with the simple remark in the one case that he is "Professor of Institutes and Practice of Surgery in Jefferson Medical College, and Member of the Medical Society of Pennsylvania;" and in the other this last membership is the sole fact mentioned, "only this and nothing more." Among New Yorkers mentioned in it I notice the names of Drs. Sims, Emmet, and Peaslee, with their residences alone appended, while Dr. A. Flint is announced simply as Professor, and thirteen lines are devoted to Dr. A. Flint, Jr. But then these gentlemen did not furnish the facts for the preparation of the articles, when the editor kindly sent them the blanks for that very purpose, and how, therefore, was it possible for the latter to know that they were distinguished professors, members of numerous learned societies, or popular authors? How was he to know, indeed, that they had attained any eminence at all, unless they themselves should tell him so; and does not the preface to the work expressly state, in regard to the errors and omissions, that "those only

who have neglected to reply to the circulars are responsible for them?" The question naturally arises, however, Why should not a literary bantling, like the offspring of human kind, be at once dressed in the long clothes of extreme infancy, instead of being sent on its way through the world in scanty skirts?

Our city has been honored with the presence of Professor Erichsen, of London, for a few days past. It was certainly a gratification to the few members of the profession who had the opportunity of seeing him to give him a cordial welcome here; but his reception fell into the hands of a very select number, and as a consequence some of the best representatives of the professional and literary talent of our city were debarred the pleasure of sharing in it. Had the invitations been more general, the welcome would have been quite as sincere, and even more enthusiastic. It was certainly an oversight in the programme, if I am correctly informed, that he was allowed to leave the city without being invited to an inspection of the University and its new hospital. I was told to-day by a gentleman whose tendencies incline strongly towards the latter institution, that the professor's whole time was so completely blocked out by his Jefferson College entertainers, that there was no chance for the faculty or friends of the rival institution to lionize him, except as invited guests, themselves. Such may, however, be only the jealousy of competing interests; but yet the feeling of dissatisfaction has been repeated to me by others. Dr. Robert McDonnell, of Dublin, well known as a contributor to various medical journals abroad, and a gentleman of ability and culture, has also received the cordial greetings of a welcome guest.

Medical book publishers are so identified with the interests of the profession that it is only appropriate that I should mention the death of that estimable gentleman, Mr. William A. Blanchard, of the former firm of Lea & Blanchard, and Blanchard & Lea, which occurred in this city last evening. *

Medical Items and News.

DR. A. D. ROCKWELL writes to inform us that the use of his name upon a placard, advertising a patent galvanic apparatus at the Fair of the American Institute, was without his sanction or knowledge.

THE undersigned Censors of the Medical Society of the County of New York, direct the attention of all practitioners of medicine or surgery in the County of New York to the following:

Act to Regulate the Practice of Medicine and Surgery in the State of New York, passed May 11th, 1874.

CHAPTER 436.

The People of the State of New York, represented in Senate and Assembly, do enact as follows:

SECTION 1. Every practitioner of medicine or surgery in this State, excepting licentiates or graduates of some medical society or chartered school, shall be required, and they are hereby commanded to obtain a certificate from the censors of some one of the several medical societies of this State, either from the county, district, or State society; which certificate shall set forth that said censors have found the person to whom it was issued qualified to practise all of the branches of the medical art mentioned in it. And such certificate must be recorded in a book provided and kept for the purpose by the county clerk of each county in the State.

§ 2. The censors of each medical society aforesaid shall notify all practitioners of medicine and surgery of the terms and requirements of this act, and shall request such persons, so notified, to comply with these requirements within thirty days after such notification; and if such persons shall not, within the time specified in the notice, or within such further time as may be allowed by special arrangement with said censors, not exceeding ninety days, comply with the requirement herein made, of physicians or surgeons, as the case may be, such persons shall thereafter be subject to all the provisions and penalties prescribed by this act for any violation of the same, and the president of the society making such request shall, and he is hereby required to, at once commence the proceedings authorized by this act against such person.

§ 3. It is hereby declared a misdemeanor for any person to practise medicine or surgery in this State, unless authorized so to do by a license or diploma from some chartered school, State board of medical examiners, or medical society, or who shall practise under cover of a medical diploma illegally obtained; and any person found guilty of such misdemeanor shall, for the first offence, be fined not less than fifty nor more than two hundred dollars. For any subsequent offence, not less than one hundred nor more than five hundred dollars, or by imprisonment not less than thirty days, or by both imprisonment and fine; and all such fines shall go into the county treasury of the county bringing such action.

STATE OF NEW YORK, }
Office of the Secretary of State, } ss.:

I have compared the preceding with the original law on file in this office, and do hereby certify that the same is a correct transcript therefrom, and of the whole of said original law.

DIEDRICH WILLERS, JR.,
Secretary of State.

In accordance with the above, every person practising medicine or surgery in the County of New York, who is not a licentiate or graduate "of some medical society or chartered school," and who desires to obtain a license from the Medical Society of the County of New York, is requested to make application within thirty days to the undersigned Secretary of the Board of Censors.

To aid the Censors in the discharge of the duty imposed upon them by the above law, every practitioner who is in possession of a license or diploma is hereby requested to fill out the annexed blank, giving full name and residence, place and date of graduation, or name of society granting license, with date of same, and forward it promptly to the Secretary of the Board of Censors.

(Signed)

JOHN C. PETERS, M.D.,	} Censors.

MR. ERICHSEN.—During the brief sojourn of this distinguished surgeon in this city, the Faculty of the University Medical College gave him a complimentary dinner at Delmonico's.

Original Lectures.

A CLINICAL LECTURE ON FISSURE OF THE ANUS.

By ERSKINE MASON, M.D.

ADJUNCT PROF. OF SURGERY IN THE UNIVERSITY MEDICAL COLLEGE.
(Delivered at Charity Hospital.)

TO-DAY, gentlemen, I propose to show you some cases of fissure of the anus, and a case of ulceration within the sphincter, giving you, as in my former lectures, a brief description of these affections as regards their general history, symptoms, diagnosis and treatment.

First.—I show you in the person of this young woman a case of fissure of the anus, or, as it is called by some, irritable ulcer of the anus or rectum. Though in many cases the term irritable ulcer is a proper one to be applied to this affection, I prefer to-day to speak to you of it simply by the name of fissure, so that you will not be liable to confound it with that affection which I shall at another time speak to you about, namely, ulceration of the rectum, which, though as you shall see, exists in connection with fissure, yet at times is present entirely independent of a fissure of the anus.

I think I am safe in telling you that no disease to which this portion of the bowel is liable (except it be cancer) at times, causes a more distressing or painful train of symptoms; and yet when I show you the fissure in the anus of this patient before you, if you knew nothing of its symptoms, but judged of it only from its appearance, you might regard it as a very trivial affair, no more perhaps than you would a chap on the back of your hand in winter-time. The symptoms, however, are most tormenting, and the agony at times endured excruciating. The symptoms of which the patient complains are usually these:—Great pain on movement of the bowels, and this often lasts for a considerable time after an action of the bowels. The character of the pain is often compared to the passage of molten lead, or a hot knife cutting or tearing the bowel. Indeed, in aggravated cases the pain is so severe at this time as to compel a patient to lie down and rest. As a result of all this, a movement of the bowel is constantly dreaded, and in some instances is postponed for days, which sooner or later brings about dyspeptic symptoms, and renders the patient's condition truly miserable. Nor is pain only an attendant upon going to stool; while exercising or even when sitting down, they may be subjected to sharp lancing and bearing-down pains. You will also read, if you do not meet with cases, where the uterus and bladder are so affected that the source of trouble is supposed to be located in these organs: pains in the back and limbs are also a very frequent accompaniment of fissure. If you will carefully study the anatomy of the nerves supplying this region, you at once see why these symptoms are present. A spasmodic contraction of the sphincter muscle is very often present; and a slight discharge of blood may be noticed at times, especially white at stool, which leads the patient to believe is the source of his hemorrhoids; the pain experienced from this affection has often led people to suppose they had cancer. The cause of this severe pain is due no doubt to exposure of some nerve filament to pressure of the faeces, and into such a state of irritation or inflammation does it pass, that the slightest touch, or the pressure of the opposite side of the bowel, is sufficient to bring about these distressing symptoms.

All this suffering, if long continued, will often under-

mine the health and make one appear a confirmed invalid. You will be surprised to hear patients relate the agony which they have so long endured, either from their dread of an operation, or because the true source of their trouble was never made out. If fissure is so easily detected, as you have seen by our examination of this patient, you will naturally ask, why have some patients gone so long and often consulted many physicians, and used a variety of remedies, as has this girl, and yet obtained no relief?

The reason, gentlemen, is simply this: we do not often enough examine the anus or rectum, either from a foolish fastidiousness on our part, or because not wishing to annoy sensitive patients; therefore we too often content ourselves by believing the statement often made by patients that they are suffering from piles, and accordingly prescribe some medicine, which often does our patient no good, and certainly reflects no credit upon us as diagnosticians. Again, sufficient attention is not paid to these affections by general practitioners, so their patients, as the result, often drift into the hands of charlatans.

The cause of fissure you will often find due to constipation; the passage of hardened faeces tearing the delicate mucous membrane. A not unfrequent cause in the female will be found due to the acrid discharges which at times are observed from the vagina, which produce excavations around the verge of the anus. In this hospital we meet with great numbers of these fissures, a result of venereal disease. These, with the want of cleanliness on the part of some, will constitute the enumeration of causes. Not unfrequently we meet with several fissures in the same individual, again only one, and its location is often posteriorly towards the coccyx, though you will meet with them on either side of the anus; again directly in front, and we then call it perineal. This latter variety I think is most frequent in women. These fissures may be so small and be hid by the folds of mucous membrane, or covered by a small pile, that you have to search carefully for them. In examining patients who have suffered from fissure for some time, you will observe as a rule that the sphincter is well developed and the anus tightly closed, and perhaps the slightest touch will be sufficient to produce a spasmodic contraction of the muscle, and so great may be the pain that the patient shrinks from further examination. The whole length of the fissure is not always equally painful. Thus in the case before us I can touch the fissure lightly with the probe here and there without very great pain to her, but when this point is touched you see she recoils at once from the touch, and cries out with pain. At these very sensitive points some little filament of nerve is exposed, and you perhaps from this examination can appreciate how such a patient would suffer when the anus becomes distended, and the fissure is pressed against in the process of defecation.

These fissures at times resemble a mere crack or cut, again they are ulcerated, and at their termination within the bowel, yet within the embrace of the sphincter, we may find a distinct ulcer; indeed, you may at times find an ulcer here without a well-defined fissure involving the verge of the anus. Then it is appropriately termed *irritable ulcer*.

I have told you that this affection is met with at all ages. It is very common in females, and especially in young girls, whose constipated habits render them peculiarly prone to it, and who often, through a sense of delicacy, suffer for years before seeking proper relief, and from this cause you may see quite a train of anomalous symptoms presenting themselves, which may all have their starting-point from a fissure of the

anus. Now, with reference to treatment, and this may be divided into both medical and surgical; the latter, however, is by far the most satisfactory in every way, and we might say almost in a moment cures the patient. Before speaking of the means employed for its relief, let us ask the question: Does this affection ever get well of itself; is nature sufficient, without the aid of art, to cure this trouble? We cannot answer this question positively. Yet I feel sure if it ever is the case, it must be extremely rare. Under the head of medical treatment, we place first the use of mild cathartics, so as to render the feces more soluble; this, however, but mitigates suffering for a time. Second, the application of astringents and sedatives, as belladonna, zinc, or tannic acid, or any other astringent, as nitrate of silver, to the fissure itself. This certainly will greatly relieve the pain at times, and in young children, and at times even in adults, has been known to cure; but you should not place too much dependence upon it, nor waste time by a prolonged use of these means if you can avoid it. When they act as curative agents, they do so by destroying the exposed filaments of nerve in the ulcer or fissure, and the parts are then put in a state of rest, and then the fissure takes on healthy action and heals.

Our surgical treatment acts just in this way, viz., by putting the parts at rest. This is accomplished by either of two methods: over-distending the sphincter, paralyzing it for a time by means of the fingers; or else dividing the muscle with the knife. I will put in practice on these two patients both these methods, so you will see exactly how it is done, after I have given you a slight description of them.

Both these methods I believe we owe to French surgeons; the division of the sphincter to Boyer, the over-distention to Récamier. Over-distention is now perhaps more frequently done in this city, certainly in this hospital. In doing this we may make use of an instrument that has been devised for this purpose, which is very much like a bivalve speculum, the blades of which are caused to separate either by closing the handles, or by means of a screw. When you use the fingers, which I think are far better, you place your two thumbs well into the rectum so as to include the whole of the sphincter, then, grasping the buttocks with the fingers, you forcibly distend the sphincter as you bring the thumbs against the tuberosity of the ischium. This at first sight may appear a very rough and harsh mode of operating, and is so regarded by some, who, I believe, for this reason denounce it, and again because it has been said to have given rise to undue laceration of the tissues, and troublesome hemorrhage. I have resorted to this means a great number of times, and have never seen any but good results follow. It is true, I have heard of considerable bleeding taking place after its use, and of one case where cellulitis followed. When we use the knife we draw the blade through the centre of the ulcer or fissure, so as to divide the mucous membrane (if it has not already disappeared under ulceration) and some or all the underlying muscular fibre of the sphincter. Whether to divide all or only a portion of the muscle, is a disputed point. That a superficial incision will suffice, in many cases, in relieving pain and curing the disease, I know from personal experience, and it does so just in the same way that a caustic may act, viz., in dividing an irritable or inflamed nerve. Should you desire to be more certain of the result of the operation, a free division of the muscle, thus securing a longer period of rest to the parts, is best, and by many this is always done. Even after either of these methods, in a few days the normal action of the muscle is restored as

a rule. I have heard of cases where its normal condition did not return after forcible distention, and patients as a result suffered from incontinence of feces; they must be extremely rare, else we should have heard more of them. Some have seen fit to combine both these methods, and in some instances it may be of service; thus a few weeks ago, after stretching a muscle as far as I deemed safe, and yet on withdrawing the thumbs it did not appear as if distention had accomplished enough to paralyze or impair its tone, I drew my knife through the fissure, and the result was most gratifying. Both these methods have their strong advocates; they are both excellent and will accomplish a cure. If you operate without either, the knife is the least painful, and if the fissure is but slight and superficial, a slight incision is all that will be required; should the patient (as some always do) have a great dread of the knife, we can effectually relieve them by means of our fingers. Though myself practising over-distention more than incision at present, I am not quite prepared to recommend one method as much superior to the other. In those cases which, for want of a better name, we call neuralgic affections of the rectum, and which often is accompanied by spasmodic contraction of the sphincter, we have a group of symptoms very like those caused by fissure. Yet no ulcer or fissure is detected. In these cases, over-distention of the sphincter is the operation to be practised. With reference to the after-treatment, there is but little to be said. As a rule it is but necessary to keep the patient in bed; but for a few days you had better keep him quiet, preventing him from taking exercise, as walking or standing for any length of time. I have had patients after the operation of incision, or over-distention of the sphincter, resume their ordinary occupation on the following day and no trouble follow. I do not advise you, however, to allow your patient to do so in cases where you can as well prevent it. After the operation, patients as a rule are at once relieved of pain, and are rapidly restored to health. In weak, nervous patients, who have long been sufferers, some little interval will at times elapse before all symptoms which they formerly suffered from will cease; and here you must pay attention to their general condition, such as the use of tonics, proper diet, and out-door exercise. In speaking of the operation by incision, or dividing the sphincter, I omitted to tell you that even if there be more than one fissure present, one incision will suffice, that being sufficient to place the parts at rest. In those cases of perineal fissure in the female, do not be too free with your incision in that direction, else we might have incontinence of feces follow. This, no doubt, is due to the action of the transverse perineal muscles as well as the other muscles around the vagina which take origin from the perineal centre or body, by their traction keeping the parts from healing. Again, by a too free incision in this locality we may weaken the part which is known in the female, by anatomists, as the perineal body, and upon which the integrity of the female perineum depends.

A NEW DIAPHORETIC.—At a meeting of the Société de Biologie, on the 12th of April last, Rabuteau and Conthino made a communication on the subject of *Jaborandi*, a Brazilian plant of the order Rubiaceæ, which has remarkable diaphoretic properties. Rabuteau took forty-eight grains, and fifteen minutes afterwards began to sweat freely, and had copious discharges of saliva. A bitter principle seemed to be the essential chemical constituent of the leaves.—*Berlin. klin. Week.*, 30, 1874.

NOTES UPON CASES PRESENTED AT THE
CLINIQUE

OF

S. D. GROSS, M.D., LL.D.,

PROFESSOR OF SURGERY IN THE JEFFERSON MEDICAL COLLEGE,
PHILADELPHIA.

(Phonographically reported for THE MEDICAL RECORD.)

CASE I.—PERIOSTITIS AND OSTITIS AFFECTING THE
ELBOW.

GENTLEMEN: The first case that we are asked to see to-day is this little child, three years of age, who has a tumefaction about the elbow-joint.

There has, doubtless, an effusion of plastic material—lymph, plasma, or fibrine—taken place into the tissues about this joint, and just here it may be of interest for you to know how you are to determine what the character of the material is that has been poured out.

When the material effused is lymph, plasma, fibrine, the tumefaction has a hardness and density readily recognized; but when the tumefaction fits upon pressure, you may be sure that it is due in a great measure to an effusion of the watery portions of the blood; and in addition the inflammation is generally milder than that which furnishes lymph, or plasma, or fibrine. The swelling in this case, as you see, involves the upper part of the forearm and the lower part of the arm. You will also notice that there is considerable discoloration of the skin over the swelling, and I venture to say that there is in this case an affection of the periosteum, and probably also of the outer portion of the bone. It may be that the deeper portions of the bone are also involved. In other words, there is periostitis and osteitis. Whether there is inflammation of the endosteum is a matter which I cannot determine. This is one of those affections which may result on the one hand from accident, and on the other from taint of the system. It is not certain that this child had a fall or other injury, and I assume that it is not the result of an injury. There is, probably, an impending suppurative action here, and when the abscess has discharged, it is probable that we shall find lesion of the bony tissue. I think we may prognosticate that condition of affairs with safety.

As respects the part itself, I shall recommend to have applied to it a strong solution of acetate of lead with laudanum. The laudanum must be used sparingly, because at this tender age it may be more than properly imbibed.

R. Acetate of lead.	ss.
Laudanum	ij.
Water	℥j.
M.	

Apply this upon flannel, and give the child an anodyne powder three times a day as follows:

R. Dover's powder.	grs. x.
Div. in powders No. viii.	

This material will be first introduced by administering a dose of castor-oil. The diet will be restricted to milk.

CASE II.—REDUCIBLE HERNIA.

This child is aged two years and five months, and, as you see, is a stout, healthy fellow.

The mother has noticed a swelling in the right groin and side of the scrotum ever since the child was a month old, which has been growing since that time. It sometimes disappears entirely. The testicle is at the bottom of the swelling. The tumor extends as high up as the external inguinal ring. It disappears when the

child is asleep, and appears again when he gets up. Upon taxis the tumor disappears very readily, and as it disappears a gurgling noise is heard and sensation felt. The tumor is manifestly a hernia, and reducible.

The testis in scrotal hernia is always situated at the bottom of the tumor; and this is of great value in arriving at a diagnosis between this and other affections. Whether this tumor is a direct or an indirect hernia, I am not able to say. The ordinary affection occurring soon after birth is of oblique descent. It is very rarely that we have direct hernia at this age. All that can properly be done in this case is to apply a well-constructed truss; taking care upon the one hand that the spring shall not be too firm, and upon the other hand, too lax and feeble. It must be just strong enough to keep the parts in their proper place, and prevent the bowel and omentum from descending. The child may become restive if too much pressure is given, while a certain amount of pressure must be maintained, being a little above that which is necessary for the retentive apparatus if any benefit is to be realized. The pressure is for the purpose of inviting the effusion of lymph, which shall connect the edges of the opening and in that way lead to permanent and radical cure. At this tender age, if the truss is well constructed and properly worn, with pressure sufficient, we may reasonably expect a permanent cure in almost every instance; whereas in advanced life, say at forty and above, there is no probability of effecting a permanent cure by means of pressure from a truss.

CASE III.—CONGENITAL HYDROCELE.

This child, three months old, has had a swelling upon the left side of the scrotum ever since he was born. The tumor is not soft and gaseous, as was the tumor upon the child that has just been before us.

The testis is *not* at the inferior extremity of the tumor, as in the other case. Pressure does not reduce the tumor. The tumor never disappears, but is sometimes smaller than at other times. When the integument is tightened over the tumor, a certain amount of translucency becomes apparent. This could be more perfectly demonstrated by placing a light between the tumor and a dark background; but the present examination will suffice.

In this affection, which we may call hydrocele, the testis is at the posterior part of the tumor, not below; although there are exceptional cases to this general rule. As a rule, the testis is situated at the junction of the inferior with the middle third of the scrotal tumor, but nearer to the bottom of the tumor than to the upper extremity. In hydrocele the tumor cannot be diminished in size by pressure, as in the reducible hernia. The tumor may vary somewhat in its bulk, depending upon the state of the system and the condition of the absorbent vessels; hence there is occasionally a diminution in the quantity of water that the tumor may contain; but the tumor may be said to remain in the same condition, and gradually increasing in bulk.

The tumor in this case is not conical, as in the other case, but is quite globular; this, however, is a mere accidental circumstance. In a case like this there is no material change in the overlying structures and integument; but in both the hydrocele and hernia there is usually considerable stretching of the integument. The spermatic cord is usually felt at the upper portion of a hydrocele without difficulty, and it is only when the tumor extends into the inguinal canal that there is any difficulty experienced in its detection; but in hernia the spermatic cord is posterior to the bowel and omentum, and is usually felt in that position. In hernia we

find also that the tumor is more in the groin than is the case with hydrocele. There is more or less of fluctuation in the hydrocele, whereas in the hernia there is never anything of that kind at all. In the hernia the contents of the tumor feel gaseous because the bowel contains more or less of air; and in the reducible variety there is always a gurgling, croaking noise when the reduction is made. Whenever there is any doubt with regard to diagnosis, the exploring-needle at once relieves that doubt. The best exploring-needle that can be used in these cases is the common sewing needle or a cataract needle.

(At this point a fine cambric needle was introduced, and water oozed from the puncture.)

The fluid which is present in these tumors is perfectly clear, is saline in its taste, and coagulable by heat, alcohol, and acids. It is simply the serum of the blood, and has accumulated in this sac because there was a loss of balance in the secreting and absorbing vessels. In the natural state this balance is preserved, and the vaginal tunic is simply lubricated. Nothing more need be done in way of treatment to-day than the simple puncture that has been made. Several punctures of this kind may occasionally, in cases of recent standing, produce a radical cure. The external applications that may be made, and in many cases with benefit, are quite numerous, and among them the following may be regarded as the more serviceable:

R. Tr. iodine.....	One part.
Alcohol.....	Six or eight parts.
M.	

Strong solutions of Goulard's extract, or acetate of lead or of alum, are also not infrequently employed.

When the case is obstinate, the best plan of treatment is to traverse the interior of the sac with one solitary, delicate, well-waxed silk thread, and allowing it to remain for a period of eighteen to twenty-four hours; but not longer than twenty-four hours in any case. For, delicate as the operation is, it is forced enough to excite sufficient inflammatory action and effusion of lymph to glue together the sides of the sac.

When the case is cured by means of external applications, it is not unlikely to occur as the result simply of restoration of balance between the secretory and absorbent powers of the vessels.

CASE IV.—CONGENITAL PHIMOSIS.

This boy is three years of age, and has suffered from his present trouble since birth. You will notice that his foreskin is very much lengthened, and at its anterior extremity there is only a very small opening, smaller than the smallest pin's head, for the evacuation of the urine. When, therefore, the child makes water the foreskin becomes enormously distended, the water passing from the penis; but, instead of escaping from the opening, collects in a pouch which is formed by the foreskin around the head of the penis. This tumor is then emptied by a kind of milking process through the nipple-like opening formed by the anterior extremity of the foreskin. Urinary concretions could be very easily formed in this position if the urine chanced to be loaded with uric acid salts or other salts which enter into the formation of urinary calculi.

It is only a short time since I received a communication from one of my former students, who is now practising in China, in which he stated that he had just removed 104 concretions that had formed in one of these pouches.

If this condition of affairs is permitted to remain, the bladder must necessarily suffer from chronic irritation, in the same manner as when there is obstruction

to the passage of urine dependent upon the presence of stricture of the urethra or enlargement of the prostate gland; and the bladder also becomes hypertrophied from flux of blood to it and through it. Sometimes there is partial paralysis of the inferior extremities as the result of this form of difficulty. The contraction in these cases that prevents the foreskin from passing over the head of the penis is, as a rule, in the mucous membrane, and not in the skin. The skin is sufficiently loose, and there is usually a redundancy which does not seem to be for any purpose whatsoever.

The only rational treatment for a case of this kind is circumcision. There are some surgeons who advocate indiscriminate circumcision, but I do not belong to that number who are in favor of the indiscriminate operation in this country. The operation in tropical countries is a very proper one, because there it is a matter of great importance that there should be great cleanliness of these parts, and that cannot be observed when the prepuce is long and tight.

Circumcision, therefore, I have not the slightest doubt was instituted by Moses as a religious rite in order to induce the people to resort to it on account of the benefit which they would receive from the operation as a hygienic measure. That was doubtless the motive in establishing the ordinance; but there is no reason why the operation should be resorted to under other circumstances, and, in fact, it is an imputation upon Providence that it should be resorted to when there is no necessity for it.

In performing the operation the mucous membrane must be divided.

When the prepuce is long, the skin only may be removed, and the opening in the mucous membrane increased in size by some other means. Sometimes the object can be accomplished by means of a dilator; but in the main that is not a desirable operation. The best manner is to slit the mucous membrane open, and then tack the edges of the skin and mucous membrane together. In many cases, especially in those of long standing, it will be found that the mucous membrane has contracted more or less extensive adhesions to the glans penis. All such adhesions must be carefully broken up at the time the operation is performed, and care taken afterwards that they do not form again.

(At this point chloroform was administered and the operation performed.)

Considerable adhesions are found between the prepuce and the glans penis. The stitches should remain at least one week. Cover the parts with a compress wet in cold water, and over that place a piece of oil-silk. Keep the little fellow quiet in bed. How astonished he will be when he wakes up and sees the head of his penis!

CASE V.—STRICTURE OF THE RECTUM.

This case, gentlemen, is one of interest from the fact that this comparatively young man has had stricture of the rectum for nine years. He is now somewhat over thirty years of age. For about three years he has experienced great difficulty in evacuating the bowels; the desire to evacuate the bowels has been very frequent, and the evacuation has been attended with considerable straining. In consequence of this straining, piles to a moderate extent have been developed. Upon making exploration the obstruction was found about three inches above the margin of the anus. This is the usual situation, the ordinary limits being between two and a half and three and a half inches above.

This stricture usually begins upon one particular portion of the circumference of the bowel, and gradu-

ally extends until, in most cases, it sooner or later involves the entire periphery of the tube; and in proportion as it extends it encroaches on the calibre of the tube.

In this case the discharges are about the size of an ordinary cigar; sometimes cylindrical and sometimes flattened; and from six to twelve discharges occur within twenty-four hours. The great number of discharges is owing to the fact that the bowel above the stricture is not relieved of its contents, and instinctively, if the expression may be allowed in a surgical connection, the bowel takes on contraction to rid itself of its contents, accumulated in consequence of the tightness of the stricture.

When a patient comes and complains to you that he has difficulty in voiding his feces, and also says that it comes away in compressed and cylindrical form; that it is not infrequently tinged with blood, or that it is covered with mucus of a bloody character, or mucus and pus, you may at once suspect the existence of an affection of this kind. Then, in order to satisfy yourselves with regard to the existence or non-existence of the affection, you must make an examination, and the proper instrument to be employed for this purpose is the finger. Oil the finger well, and when introducing it, give it a rotating, boring movement, and you will give your patient no pain; whereas, if you push the finger directly up through the sphincter, the patient will complain of intense pain. This is an item well worth your recollection.

The finger being introduced, you have something by which you are enabled at a single examination to determine the distance of the stricture from the margin of the anus, its consistence, the size of the opening in the stricture, and the extent of the stricture so far as the circumference of the bowel is concerned. Having ascertained these points, knowing the nature of the disease, the question next arises, Is the stricture an ordinary one, such as occurs in other canals, or is it specific in character, the result of epithelioma?

There is an interesting point with reference to this case, and that is with regard to age. I have seen stricture of the rectum at the ages of twenty, twenty-four, twenty-six, and twenty-seven in quite a large number of cases, which is comparatively early in life, when compared with the occurrence of the same affection in other parts of the body; and here, again, as I have already remarked, we have the occurrence of this affection in a comparatively young man.

Another point of interest in the case is the duration of the disease. In very many cases it lasts a great length of time, and perhaps the patient may die of some other affection. In some cases it is chiefly an inconvenience, and that is all.

When this case first came under observation, the stricture was exceedingly tight. The patient was placed under the influence of chloroform, and the dilatation first made with the finger. In a case of this kind the finger is the only proper dilator to be employed. Instruments may be used, but the finger is much more serviceable, because much more safe. It is sufficiently long and delicate, and answers an intelligent purpose.

Afterwards, when some degree of dilatation has been accomplished by means of the finger, it may be carried on by means of gum-elastic dilators, made especially for the purpose. These instruments, however, must be used with the greatest care, lest permanent injury be done.

A spermaceti candle may be used for the same purpose, in case no instruments for dilating are at hand.

While the process of dilatation is going on, the fre-

quency of the discharges may be arrested during the night by giving the patient a suppository at bedtime, consisting of one-third of a grain of morphine rubbed up with cacao butter.

Dilatation in this case has been carried on to such an extent that the frequency of the passages has been very much diminished, and the passages are had with comparative comfort.

Original Communications.

NOTES ON OPHTHALMIC PRACTICE.

EXTRACTS FROM A PAPER READ BEFORE THE KING'S COUNTY MEDICAL SOCIETY, AUGUST 18TH, 1874.

By ARTHUR MATHEWSON, M.D.,

BROOKLYN, N. Y.

THE USE OF THE SALTS OF LEAD IN EYE-WASHES.

1. THE use of the salts of lead as local applications to the eye. It is nothing new that these salts form insoluble precipitates when exposed to the action of the secretions of the eye, and that where there is abrasion of the surface of the cornea from wounds or inflammatory process the use of these agents may lead to the formation of opaque white patches, which disfigure the beauty of the eye, and when they lie before the pupil interfere with vision. Most of the modern writers on the eye refer to these lead deposits on the cornea, and some of them caution against the use of lead applications in case of corneal ulcer; yet nearly all speak of preparations of the acetate of lead among others to be used in a class of cases in which ulcerations are most likely to occur. Thus Soelberg Wells, author of the standard English work on diseases of the eye, speaking of the treatment of phlyctenular ophthalmia, of acute and chronic granular ophthalmia, and of chronic granulation, recommends acetate of lead applications. On page 71 he says: "But if any infiltrations or ulcerations of the cornea exist, the acetate of lead should never be used, as it will be precipitated upon the cornea and give rise to very marked stains." On page 77, after recommending acetate of lead along with sulphate of copper, and nitrate of silver, in the treatment of chronic granulations, he says: "Great care must be taken never to order any preparation of the salts of lead if there is any abrasion of the epithelium of the cornea, or any ulcer of the latter, as it will produce an indelible lead stain." As if in these diseases ulcerations and abrasions of the surface of the cornea, though not at first presenting, were not constantly liable to occur, so that no care likely to be taken will prevent the liability to the formation of these indelible lead stains. Abrasions of the cornea are not only liable to occur in these diseases but are easily overlooked, and may not in every case be readily detected except by the use of a lens and oblique illumination, and in this way the danger of lead stain becomes still greater. That this danger is not merely theoretical, my own frequent experience has taught me. Nothing is more common, especially in hospital practice, than to have patients present themselves with a white patch on the cornea, which is recognized as a lead deposit—perhaps just before the pupil, and abolishing all useful vision—the history of the case being that the patient, having an inflamed eye, got a prescription from a physician, very likely without any caution as to its use, or a wash from the nearest druggist, or somebody's "Eye-water." The

inflammation may have passed away, but the application used to relieve it has left its mark forever. Or the patient may have used the remains of a lotion prescribed for some former trouble, in which there was no abrasion of the cornea, in some subsequent attack in which abrasion did occur, with a lead stain as a result. Or, as often happens, a patient gives to a friend, suffering from what seems to him the same trouble, the wash which has afforded relief to his own symptoms, but does that friend an irreparable injury. Another frequent and provoking experience is, that a patient with some chronic affection of the conjunctiva, though frequently told from the first of the obstinate nature of the disease, gets discouraged and disappears for a time, to return with a disfigured cornea, the result of using a lead-wash obtained on a physician's prescription, or the gift of some officious friend.

I go into these details of my experience of the evil results of the use of a popular prescription, sanctioned by the authority of some of the best-known writers, to show how liable such accidents are to occur, and to justify my opinion that lead applications to the eye should be wholly discarded, and the public be taught to look upon them as dangerous. Certainly there is no necessity for using this remedy when there are so many others equally good, and their use unattended by such dangers. Williams, of Boston, is the only authority I have consulted who takes this common-sense view of the matter.

TATTOOING FOR OPACITIES OF THE CORNEA.

In connection with the subject of opacities of the cornea I will refer to a means of relieving the disfigurement some forms of opacity produce, which may be justly regarded as one of the most valuable recent improvements in ophthalmic practice. Patients sometimes present themselves with a dense white opacity of the cornea, causing an ugly deformity—anxious that a blemish which affects so much their *amour propre*, and it may be their prospects in life, should be removed, and willing to undergo any suffering for that purpose. Formerly there was nothing to do but to send them sorrowing away with no hope of relief except in the somewhat objectionable procedure of enucleation and substitution of an artificial eye, which, however, was sometimes readily submitted to. Now, thanks to the suggestion of coloring the whitened cornea by the process of tattooing, such applicants may be encouraged with the hope of speedy relief. To Wecker, of Paris, is due the credit of suggesting this idea and introducing it successfully into practice. The process is simply to apply a paste of India ink over the whitened portion of the cornea which it is desired to color, and prick it under the surface with a bundle of needles.

As a case illustrating the method of performing this operation and its results I may cite that of Miss E. S., who two years ago, by the slipping of a carpet stretcher, received a severe wound of the left eye, the notched edge of the tool cutting completely across the cornea, and lacerating the iris and lens. Though the wound was so extensive the inflammatory reaction finally subsided, leaving the eye scarcely at all shrunken, but without sight and with the disfigurement of a broad, staring white cicatrix, occupying the entire horizontal diameter of the cornea. What made this blemish all the more noticeable, and the trial harder for the patient, was the fact that her eyes were remarkably large, dark and beautiful. She eagerly accepted the proposal to remove the deformity by tattooing. The tinting was accomplished at two sittings, the first March 31st, 1874, and the second April 17th, it being thought

best, as the eye had been left in a somewhat delicate condition, by the wound extending back toward the ciliary region, to avoid the risk of exciting morbid action by too thorough an application at one sitting. She complained of considerable pain during the operation, but bore it bravely without an anæsthetic, sitting in a high-backed chair, with the head thrown back, the upper lid raised by a broad elevator in the hands of an assistant, the lower depressed, and the eye "choked" by the fingers of the left hand of the operator, who, sitting in front of the patient, pricked in a paste of India ink, applied over the cicatrix with a camel's-hair brush, by twenty or twenty-five gentle strokes with a bundle of a dozen fine sewing-needles bound together with a waxed thread. These were directed obliquely against the cornea with just sufficient force to penetrate the outer surface of the cicatrix. The lids were kept separated for a short time, that the pigment might not be too soon washed or brushed away. The irritation consequent on the operation mostly subsided in two or three days, during which time the patient was kept in a shaded room and a solution of atropine dropped in the eye three times a day, these precautions being taken on account of the delicate condition of the eye. The coloring matter used on the first occasion was the ordinary India ink rubbed with water into a paste of sufficient consistency not to run off the parts where it was applied. At the second sitting the liquid preparation of India ink, by Winsor and Newton was used, as being more soft and smooth and less likely to irritate mechanically. This was dried so as to form a paste. The result at the time of writing (August 17th) is an apparently permanent coloring of the cicatrix, which completely removes the former staring deformity, and produces an effect very satisfactory to the lady and her friends.

Where the whole cornea is opaque and white, the best cosmetic effect may be produced by tattooing a circular spot at its centre to represent the pupil. I have seen a case of Dr. Agnew's in which the resemblance to a normal pupil surrounded by a light gray iris produced in this way was so close as to deceive ordinary observation.

While thinking of this matter of concealing discolorations of the cornea by tattooing, it has occurred to me that the same principle might be applied to the relief of disfigurements of the face and neck, such as those produced by extensive naevi or other permanent discolorations of the skin, some coloring material being used which would produce a natural flesh tint. A subject with a discoloration of some part ordinarily concealed by the clothing would be a proper one for experiments in this direction.

HYPODERMIC INJECTION OF STRYCHNINE IN FAILING VISION.

I close this paper with some remarks on an important contribution ophthalmology has made to hypodermic therapeutics, which, though some articles on the subject have appeared in the medical journals, is not as widely known or so fully appreciated as it should be. I allude to the subcutaneous injection of strychnine in cases of failing vision from atrophy of the optic nerve and some other diseases of the eye. Such cases had hitherto seemed almost hopeless, as long experience had demonstrated them to be under all previously tried methods of treatment. Strychnine, administered by the usual methods, had been often employed, but usually without marked benefit. In 1871 Prof. Nagel, of Tübingen, came out with a series of cases of amaurosis treated by hypodermic injections

of nitrate of strychnine, in which the results stated were so marvellous as to seem incredible. Since that time numerous observations have confirmed the accuracy of his statements, and though there are many cases—the majority perhaps—in which there is no good effect obtained, nearly every one who has given this method of treatment a fair trial has been astonished in some cases in which the sight had been constantly failing under other treatment, and total blindness imminent, to find strychnine injections followed by sudden and most marked improvement. Brown-Séquard has shown by experiment the effect of strychnine in increasing the "reflex power" of nerve-cells when applied directly to the spinal cord, and it seems as if this agent acted more directly and powerfully on the nerve elements when administered hypodermically than when introduced into the system by the stomach. It is only rational to suppose that the influence of the stomach and its varying contents on many medicines must greatly modify their effect on the system, and have much to do with that uncertainty of action which we all have at times so much reason to regret. It is my belief that hypodermic medication is as yet only in its infancy, and that for a large class of drugs, when we wish to get their most rapid, certain, and unmodified influence, we shall administer them by this method, and that the science of medicine will thereby gain much in positiveness and accuracy. However this may be, my own experience has convinced me that in some cases of failing sight from diseases of the optic nerve and retina, strychnine injected hypodermically has a peculiarity and power of action that it never has when administered by the mouth in safe doses. A few cases from my note-book will serve to illustrate.

J. H. R., æt. 32, book-keeper—first seen Dec. 11 in 1873, when he stated that ten weeks before, his vision began to be impaired and had gradually diminished since. At the time of examination, vision was $\frac{1}{16}$ in the right eye, and $\frac{1}{32}$ in the left, the field of vision was considerably narrowed toward the nasal side in each eye. Ophthalmoscopic examination showed a paleness of each nerve on its temporal side. Though the patient had used tobacco and alcoholic stimulants freely, his general health was apparently not much affected. Nitrate of strychnia gr. $\frac{1}{16}$ was injected under skin of right temple. Not much immediate effect was produced. He was ordered to discontinue use of rum and tobacco, and to take a pill of $\frac{1}{16}$ gr. sulphate of strychnia three times a day. On Dec. 13th vision was $\frac{1}{16}$ on the right, $\frac{1}{32}$ on the left. Nitrate of strychnia gr. $\frac{1}{16}$ was injected into left temple, and within fifteen minutes vision rose to $\frac{1}{8}$ on the right and $\frac{1}{16}$ left. Dec. 16th, V = $\frac{1}{8}$ right, $\frac{1}{16}$ left, and after injection of $\frac{1}{16}$ gr. strychn-nitrate rose speedily to $\frac{1}{4}$ right, and $\frac{1}{8}$ left. Dec. 22d, vision remains the same, having thus risen from $\frac{1}{16}$ in the right eye to $\frac{1}{4}$ in less than eleven days.

Another similar case was that of J. H. S., æt. 33, broker, who had been using stimulants and tobacco in excess for a long while, and at the time of his presenting himself, May 22, 1874, was quite tremulous. He had noticed that his sight was failing for two or three months. V = $\frac{1}{8}$ in each eye. Ophthalmoscope showed a hyperemic and hazy condition of each fundus oculi. This case, like the last, presented the general features of what is known as tobacco amaurosis. Injection of $\frac{1}{16}$ gr. nitrate of strychnia was followed by a slight immediate improvement. May 27th, vision was found to have risen from $\frac{1}{8}$ to $\frac{1}{4}$ on the right, and from $\frac{1}{8}$ to $\frac{1}{4}$ on the left. In these two cases it might be claimed that the removal of the exciting causes of the disease,

that is, abstinence from tobacco and stimulants, had much to do with the result. But that could not account for the sudden increase of vision which followed the injections, and experience has shown that it is not alone sufficient. Dr. Edward Curtis reported, at a meeting of the New York Ophthalmological Society last winter, a case in which entire abstinence for a considerable time had no effect in improvement of vision, but this followed at once strychnine injections.

A case illustrating the power of these injections, in a somewhat different condition, is that of D. C., stevedore, æt. 49, who came to the Brooklyn Eye and Ear Hospital, January 3d, 1872, with history of failing sight of both eyes for three months. He had received a blow on the forehead from a falling box, and from this accident dates the failure of sight, which was so great at the time of his admittance that he could barely count fingers at the distance of three feet. The field of vision was very limited. The ophthalmoscope showed marked atrophy of both optic nerves. He was treated by hypodermic injections of *sulphate* of strychnia in the temples, gr. $\frac{1}{16}$ to gr. $\frac{1}{8}$, repeated daily most of the time till February 19th, when the vision of the right eye had risen to $\frac{3}{16}$, or one-half normal vision, and more than ten times the amount he had when treatment was begun. On one occasion vision rose from $\frac{1}{16}$ to $\frac{3}{16}$ within ten minutes after the injection.

In two cases of glaucoma, referred to at a former meeting of this Society, injections of strychnia, following iridectomies, were of marked service in hastening improvement of vision. One of these was a most remarkable case. A young woman, about 20 years of age, was affected with pure primary glaucoma, non-inflammatory, and chronic in its course. One eye was lost, and in the other sight had diminished to the faintest perception of light, at which it remained for many months, in spite of two broad iridectomies, one above and the other below. Finally, an injection of strychnia, employed rather as a placebo than with any hope of its affecting the sight, produced so marked an effect that I was encouraged to repeat it, with the surprising result, within a few weeks, of vision enough to count fingers at the distance of six feet. This patient, Sarah Caddess, is still an inmate of the Brooklyn Eye and Ear Hospital.

I would not be understood as advancing the theory that strychnia can take the place of iridectomies in the treatment of glaucoma, but only claim that it may act, as these cases show, as a useful adjunct.

As to the details of administration, I usually employ a solution of nitrate of strychnia gr. iv, to aq. destillat. fl. $\frac{1}{2}$ i; each minim thus containing $\frac{1}{120}$ gr.; and with an adult patient begin with the injection of three minims or $\frac{1}{40}$ gr., and gradually increase the amount till $\frac{1}{2}$ gr. is injected every day, or every other day, unless some effect is obtained by the smaller doses, or constitutional symptoms, such as stiffening of the limbs or staggering gait, warn that the limit of safety is reached. I have never seen any injurious effect produced, though I have used it daily for weeks at a time, sometimes pushing the amount up to more than $\frac{1}{2}$ gr. at each injection. The injections are made under the skin of the temple or arm—preferably at the former place. I have found that it is not well to trust, without trial, the marking of the ordinary hypodermic syringes, as they vary much, and advise that each one, before use, be carefully compared with some reliable minim measure, so that in employing so powerful a remedy the physician be as certain as possible of the exact amount he is administering.

Reports of Hospitals.

ROOSEVELT HOSPITAL, N. Y.

REPORTS OF PRACTICE AND PECULIARITIES IN TREATMENT.

SURGICAL DIVISION.—DR. BLAUVELT, HOUSE-SURGEON.

FISTULA IN ANO.

A CASE of this affection had been treated by the application of the india-rubber ligature. It remained in position five days. At the end of that time the cutting was nearly completed. The ligature, in consequence of the excruciating pain which its pressure occasioned, was removed, and the operation completed with the knife.

SPONGES.

Sponges had been excluded from the surgical wards. This was done for the purpose of eliminating every possible means of transmission of septic material from one patient to another. Cotton waste is now employed for wiping purposes, and when an open wound or ulcer is cleansed, the *waste* used is immediately destroyed, never being employed upon the second patient.

BURNS.

The following prescription has been employed, and its use has been attended with very gratifying results.

R. Tannic acid.....	ʒi.
Chloroform	gtt. xx.
Simple cerate	ʒi.

M.

Spread upon lint and cover the parts affected.

Glycerine and bismuth have also been somewhat employed of late, but with the result of producing terrible smarting when first applied, usually continuing for an hour or more.

Bismuth and glycerine are united in such proportions as will give a creamy paste which can be conveniently spread upon sheet lint. It is possible that the glycerine was impure, or the bismuth was not an impalpable powder, or both circumstances may have united in producing an inordinate amount of local irritation.

When the burn is deep, such dressings are employed as may be of service in assisting the separation of the slough; when the slough has separated, the excavation is treated as an open ulcer.

ULCERS.

Several ulcers were noticed which presented a remarkably healthy appearance that had been produced by the application of Hay's lotion.

Ulcers are dressed in a particular manner; a piece of sheet lint is cut of the exact size and shape of the ulcerating excavation, it is then wet in the lotion and placed in the ulcer; then a piece of oil-silk is cut of the exact size and shape of the piece of lint, perhaps a trifle larger, and is laid over the lint; the whole is then secured with a woollen bandage. This method has an advantage of being cleanly, which is important.

POPLITEAL ANEURISM.

An interesting case of this kind was seen in which the remedial measures adopted had been attended by an apparent cure. Pressure was the chief means employed. It was at first resorted to for the purpose of guarding against rupture until time could be obtained to perform an operation. The benefit arising from the pressure was so marked that it was steadily main-

tained for four days. At the end of this time all pulsation in the tumor had ceased. Digital pressure was kept up during the day at a point in the upper third of the thigh. During the night pressure was kept up by means of an instrument with a double pad so arranged that pressure could be made with the pads alternately. The pads were alternated every hour, and pressure made at a point near the junction of the lower with the middle third of the thigh. In this manner the most desirable portion of the artery for an operation was reserved with the tissues overlying it in an undisturbed condition, in case the operation became necessary. Some symptoms of suppuration of the sac had been developed, but, under the influence of continued rest, and the constant application of cold by means of bladders of ice, they had almost entirely disappeared. The patient was a man thirty-four years of age. There was no history of syphilis in the case.

AXILLARY ANEURISM.

The tumor had been of good size, and pulsation could be distinctly felt in the axillary space. Suddenly brachial and radial pulsation ceased. The tumor soon began to diminish in size, and its pulsation had also markedly diminished.

It seemed that nature had in some manner performed the distal operation, and the prospect was fair that her operation would prove successful.

PARALYSIS CAUSED BY PRESSURE OF THE INDIA-RUBBER CORD USED IN THE BLOODLESS OPERATION.

A young man had had an operation performed upon one of his arms in which Esmarch's apparatus had been applied.

Paralysis of motion followed, and the visiting surgeons and other competent observers were of the opinion that it had been caused by the pressure made upon the nerves in the application of the rubber cord. Paralysis remained for about one month. Motion was being gradually restored.

EPISCOPAL HOSPITAL—PHILADELPHIA.

MEDICAL DIVISION.—DR. REED, HOUSE-PHYSICIAN.

FACIAL ERYSIPELAS.

ERYSIPELAS had been in the hospital to quite an extent. For local application: saturated solution of *sulphite* of soda. Constitutional treatment: R. of iron gts. xx. every two hours during the day; and gts. xxx. every three hours during the night; quinine, grs. xvi. during twenty-four hours, in doses of two grains. A most terrible-looking case of what was denominated "erratic erysipelas" was seen in a patient far advanced in phthisis. Extensive phlegmonous inflammation of the scalp had been developed. The patient was doing remarkably well under the influence of the soda dressing, iron, quinine and milk punch, of which latter tonic as high as ʒxl. had been administered during twenty-four hours.

ACUTE ARTICULAR RHEUMATISM.

Treatment essentially alkaline, with dry cotton to the joints.

One case, *sub-acute* in character, was noticed in which there was cardiac complication (endocardial). The treatment instituted consisted in the administration of digitaline in granules $\frac{1}{10}$ of a grain each, to quiet the action of the heart. The results obtained were satisfactory. Iodide of potassium also was used in doses of gr. xx. t. i. d.; and the joints were painted with iodine tr.

CHRONIC BRIGHT'S DISEASE.

Basham's tincture is always administered. It is the liq. ferri per acetatis, and the formula for its preparation has been given in connection with the reports from Pennsylvania Hospital. The bowels are kept moderately loose by a senna mixture. Diet nourishing. The hot air or vapor-baths are rarely employed when dropsy is present; hydragogues are very much relied upon.

ACUTE PHTHISIS.

Syr. iodide of iron and cod-liver oil are remedies most commonly used. General hygiene and dietetic treatment is carefully observed.

NIGHT SWEATS OF PHTHISIS.

Sulphuric acid lemonade and hot-sponge baths have been the most successful in controlling this symptom. Atropia, or ox zinc, has not been used.

HEMOPTYSIS.

Gallic or tannic acid is commonly administered.

PNEUMONIA.

Carbonate of ammonia is administered in five-grain doses every two hours from the beginning. It is employed for its stimulating and supporting influence.

A poultice of flaxseed meal is invariably applied to the chest, and covered with oil silk when so ordered for some special purpose, such as increased diaphoretic or soothing effect when considerable pleurisy is present. Turpentine stupes are employed when the pain in the chest is severe. Diet sustaining.

CEREBRAL CONGESTION.

The case was one where the man had received a blow upon the head, and had had epileptiform convulsions. There were present symptoms which were regarded as evidence of *cerebral congestion*. And for the relief of this congestion, fl. ext. ergot was administered as an experiment, having never before been used in the hospital for that purpose. It had just been prescribed in drachm doses, and no effect had been produced when we were present.

CHRONIC CARDIAC DISEASE.

The patient was an old lady who had had valvular disease of the heart for some years, but now was particularly distressed by harassing cough, palpitation, and pains through the chest. The patient was made comparatively comfortable by using tr. digitalis in ten-drop doses three times a day; Hoffman's anodyne to allay cough and distress, and turpentine stupes to relieve local pain.

CAPILLARY BRONCHITIS.

The patient was a girl ten years of age. The poultice employed in the treatment of pneumonia was applied to the chest, and carbonate of ammonia and serpentaria administered internally. Patient was convalescent.

ACUTE PERITONITIS.

The opium plan of treatment is the one regularly adopted.

TYPHOID FEVER.

Treatment mainly expectant. Diet liquid. Do not use stimulants, as a rule, until pulse indicates them. Turpentine stupes, if tympanites is present. Hemor-

rhage from bowels is treated by gallic acid in twenty grain doses every two hours. In cases of actual or suspected perforation opium is relied upon.

SURGICAL DIVISION.

These wards were visited with Dr. Forbes, one of the attending surgeons.

ESMARCH'S APPARATUS.

While adopting this method of controlling hemorrhage during operations, the tourniquet is used instead of the rubber tubing and its attachments, according to the original plan. The tubing had slipped upon one occasion, permitting a fearful hemorrhage, since which time the tourniquet has been substituted.

In the hospitals in New York City a small rubber cord—perhaps $\frac{3}{4}$ of an inch in diameter—is made to encircle the limb from two to five times and then tied. It is thought to be more convenient than either tourniquet or tubing. One case of local paralysis, however, has been produced by the rubber cord. (*Vide* Roosevelt Hospital Report.)

PERMANENT DRESSING OF FRACTURES.

Permanent dressings, such as plaster-of-Paris, etc., are not employed in the treatment of fractures in this hospital.

FRACTURE OF THIGH.

A case of this sort was being treated by simple extension and counter-extension. It is a method very commonly adopted. Place the patient upon a firm bed, apply counter-extension and then extension, by means of weight and pulley, sufficient to retain the proper length of the limb. Long sand-bags are placed along either side of the limb, to give lateral support, and sometimes light lateral splints are applied to the thigh if the muscles are disposed to be convulsive.

Desault's splint is considerably employed in the treatment of this class of fractures.

The "bran-box" is employed very commonly in the treatment of fractures. This is especially true of the compound variety. The fracture-box has sufficient of bran laid upon the bottom to afford a soft bed for the limb; the limb is placed upon it, properly attached to the foot-board; then the sides of the box are closed and the box filled with bran, which can be made to maintain the requisite amount of lateral pressure by packing it pretty firmly at opposite points along the line of the limb.

COMPOUND FRACTURE OF HUMERUS, WITH RUPTURE OF URETHRA.

This patient, a man of middle age, had fallen from a scaffolding and received the injuries indicated. An angular splint was placed upon the anterior surface of the forearm, and extended somewhat above the elbow; upon the outer and posterior surface of the arm a heavy splint of binder's board, with a shoulder-cap, was applied, and the whole secured with a bandage. The wound had been partially closed by sutures, and a large portion of the arm was covered with lint thoroughly wet in laudanum, covered with waxed paper, and then secured with a bandage.

A catheter was placed in the urethra, and retained by means of adhesive plaster. Considerable tympanites had been developed, with considerable abdominal tenderness; wet caps were applied above the ilium with apparent relief from several threatening symptoms.

CHRONIC ULCERS.

Iodoform, strapping with adhesive plaster, grafting,

and various local applications according to circumstances, constitute the treatment usually adopted for this class of cases.

ERYSIPELAS.

Erysipelas had also been present in the surgical wards for some time. Local applications consisted of slippery-elm mucilage, and oxide of zinc ointment. The elm-mucilage is most commonly used, especially in the early stages of the disease. Constitutionally, the treatment is eminently supporting.

CHANCROIDS.

In general, these fellows are cauterized, and then treated as a common open ulcer.

EXSECTION OF THE KNEE-JOINT.

A couple of cases of this kind were seen. The patients were children. The cases were doing well. Several excisions of the knee-joint had been made within a year, and all had done well.

EXSECTION OF HIP-JOINT.

Five cases of exsection of the hip-joint had occurred in the hospital within a year and a half, and all of the operations had been attended with good results.

FRACTURE OF TARSUS.

The injury was produced by a railroad car. All the bones of the tarsus had been crushed except the os calcis. Nearly all the arteries leading to the foot had been ruptured, all the main arteries at least. The patient refused to have amputation performed. Amputation was recommended for two reasons: first, there was scarcely any hope of saving the foot, and permitting it to remain would seriously jeopardize the patient's life; second, if the foot should be saved, it would, in all probability, be a cumbersome and almost useless member, and probably require amputation at some future date. Pirogoff's operation was proposed, being decidedly in favor over Syme's.

The parts were restored in position as well as possible, the foot placed in a bran-box and dressed with lint wet in laudanum for the purpose of restoring vitality. Twelve hours after the receipt of the injury the toes were warm, and the patient again decided, "because the foot was so comfortable," that he would not have it removed.

STONE IN THE BLADDER.

The patient had just been admitted. The symptoms indicated explorations for stone in the bladder. Patient was etherized, and a stone readily detected with the sound. Upon inspecting the perineum, the cicatrix from a former operation was found. The feet of the patient were considerably swollen. He was placed upon a course of preparatory treatment, as follows: first, a bath, then good diet, porter, tincture of iron, grs. x. of iodide of potassium twice daily, and a mild infusion of buchu and uva ursi. Ballardonna was to be applied to the old cicatrix for the purpose of softening it somewhat if possible. After a few days the urine was to be analyzed for the purpose of determining what ground the patient stood upon. The doctor remarked, that generally he performed the operation, using a staff with the groove upon the under side, and a scalpel. Other operations were well adapted to certain cases, but, as a rule, he preferred the operation indicated.

Progress of Medical Science.

BRAIN AFFECTIONS DURING THE EARLY STAGES OF SYPHILIS.—Among the recent facts that have been ascertained regarding the natural history of syphilis none appear to be better established than those showing the possibility that any organ of the body may be affected during the early or later periods of the disease. Lang has collected a number of cases of syphilitic lesions of the brain, and deduces from them the following points of diagnostic value:

1. Headache is an important symptom in cerebral disease of syphilitic origin. Those pains that are localized at certain points and have a nocturnal character are apt to be associated with the later forms of the disease; in the early periods the pain is apt to be diffused.
2. Attacks of dizziness are among the early symptoms, and probably are dependent in most cases on hyperemias of the brain or its membranes.
3. Paralysis are apt to occur suddenly during the early periods of syphilis, with or without loss of consciousness; apoplectic attacks in persons about the twentieth year point rather to syphilis than to other causes. In the latter periods of the disease paralyzes develop gradually, spreading over the muscles; in very advanced cases mental disturbances may also be associated with the disease. Paralysis of certain groups of muscles appear at both periods; the muscles of the eye are more frequently affected in the early periods, and the facial muscles in the later periods. Paraplegias are apt to appear early, and

hemiplegias late. 4. Epilepsies after syphilis are generally connected with old cases of syphilis, and they rarely, if ever, are known before the thirtieth year. 5. Anomalies of the nerves of sensation have seldom been noticed. 6. Weakness of memory, impairment of mental vigor and intelligence, appear both early and late. 7. Mental disturbances have only been observed in the later periods. The few autopsical records of these diseases show that in the early stages inflammation is most apt to attack the more delicate membranes of the brain; encephalitis, with or without arachnitis, is less frequent, while inflammation of the dura mater is quite rare, and only occurs under the form of pachymeningitis interna. There may also be, at first, as stated before, hyperæmias of the brain and its membranes. In the later stages pachymeningitis externa has been most frequently observed; there may also be inflammation of the brain and its membranes, usually excited by the presence of gummy tumors; then there may be gummy tumors alone, and finally it is likely that there is an affection of the cerebral vessels, the nature of which is still obscure.—*Rundschau*, September, 1874.

TRACHEOTOMY WITH THE RED-HOT KNIFE.—Saint Germain, who advised opening the trachea with a button-shaped cautery iron, has tried the following modification of this operation on a three-year old child who was suffering from croup. Locating the crico-thyroid membrane with his finger, he fixed the larynx firmly with one hand, while with the other he took a red-hot, probe-pointed knife, and directing the edge downwards he pressed it into the larynx, just below the edge of the thyroid cartilage; there was no difficulty in doing this, and the loss of resistance showed that the knife had entered the cavity. The knife was thus made to cut downwards through the cricoid cartilage and the first ring of the trachea. The operation was entirely bloodless. Using a dilator, he found no difficulty in introducing the canula. The case progressed favorably from this date.—*Gaz. Med. de Paris*.—*Wien. Med. Woch.*, 26, 1874.

BELLADONNA IN THE TREATMENT OF EXOPHTHALMIC GOITRE.—Dr. Smith, of London, strongly advocates the use of belladonna in this disease, and bases his reasons for so doing on two cases which came under his treatment. One was a young woman, twenty-four years of age, who began to complain of weakness and a tired feeling in her eyes, palpitation of her heart, and a remarkable fulness in her neck. Her sufferings were so great that she was obliged to give up her work. For six months or more she took preparations of iron, but obtained no relief. Her eyesight was now much affected, and she felt a constriction about her throat and difficulty in swallowing. The right lobe of the thyroid gland was considerably enlarged, the carotid could be seen to beat from a distance, and a distinct murmur could be heard over it. The heart beats were violent and the tones loud, but no murmurs were heard. The patient could get no sleep at night, and was harassed with violent palpitation and copious sweats. She was then treated with digitalis and nux vomica and the constant current, but in vain. Iron with ergot and veratria were then given. The symptoms continued to grow worse. Belladonna was resorted to for the reason that most authors connect the disease with a paralysis of the cervical sympathetic, and John Harley and others regard belladonna as a stimulant for the sympathetic. Five drops of the tincture were given hourly and produced an excellent result. The pulse fell to ninety, and then

after four days to eighty. The patient was now, for the first time, able to take a walk. Ten days later a drachm was given daily in divided doses. At the end of two months there was entire disappearance of all bad symptoms, such as enlargement of the thyroid, exophthalmos and palpitation, and the patient was regarded as cured. The second case was a lady, twenty-two years of age, who had all the symptoms of the foregoing case, except exophthalmos, and, in addition, had a peculiar red rash upon her face after any excitement. The eyelids in this case were swollen, and the patient suffered much pain in her eyes, though there was no conjunctivitis. The pulse was 130, and the right lobe of the thyroid was enlarged. She also suffered from constipation, and in the night had rushing of blood to her head and a sense of fulness there, with palpitation. These attacks ended with copious sweating, after which the patient was much exhausted. Such remedies as iron, digitalis, valerian, zinc, ice to the head, aconite, iodine, and the constant current gave her no relief. Belladonna seemed to be equally successful in this case, except that violent headaches supervened, and epistaxis and angina pectoris, which last was overcome by chloroform. After a month's use of belladonna the patient seemed to be restored to her former health. The thyroid did not diminish in size, but became firmer and harder. Interesting points in these cases were, that the patients gained in flesh under the treatment, and that when it was suspended the old symptoms returned, but when renewed they soon abated.—*The Lancet*, 26, 1874.—*Allg. Med. Central Zeitung*, 72, 1874.

TREATMENT OF SYPHILIS ACCORDING TO THE VIENNA SCHOOL.—Zeissl states that in his experience he has found that iodine in the proper form will arrest or modify the first manifestations of syphilis, so that only a short course of mercurial inunction will be necessary to effect a cure of the disease. Iodine when used in this way will not cause the induration to disappear as rapidly as the mercurials, but it has much more effect upon the skin and mucous lesions. Desirous of avoiding the iodide of potash, he has given iodine in the form of the tincture in the following formula: Tinct. iodinii, 3 ss.; aque destill., 3 vi. M. A teaspoonful morning and evening. Under this method of treatment the lesions of the skin and mucous membranes disappeared in from fourteen to forty-eight days. Iritis and the pustular syphilides were the most obstinate forms of the disease to be met with, and for them mercurial inunction was required. He had never observed any acne follow the treatment with iodine. He found iodoform of great use as a local application to indolent ulcers, and also as an internal remedy in the form of pills. The dose should be from two to three grs. daily.

Sigmund does not think that the internal use of corrosive sublimate has any advantage over the mercurial unguents; it is necessary at the same time to be on the watch for digestive disturbances; the patients must also avoid exposing themselves to taking cold, just as during the treatment by inunction. The sublimate should not be given to old people or young children. He does not believe that there is any advantage in combining the iodide of potash with the mercurials. Psoriasis and certain forms of skin infiltrations are successfully treated by local applications of the sublimate, but there is no special advantage in using it hypodermically; if, however, it is advisable to use some form of mercury in this way, calomel is to be preferred.—*Wien. Med. Woch.*, 13, 19, 31, 35, 46, 1873.

THE RELATIONS OF GENERAL MEDICINE TO SPECIALISM.

It is within the recollection of the majority of the medical men who have been engaged in the practice of their profession for the past fifteen years, how bitter was the opposition against the cultivation of specialties. The discussion of the merits of the question was a feature of the annual meetings of the American Medical Association and of all the other large bodies, and almost invariably led to bad feeling among the disputants without a promise of a solution of the difficulty, or an attempt at a compromise. Finally, in view of the inevitable quarrel which terminated the family talks upon the question "to be or not to be," all discussion was by common consent waived, and the conservative majority signified their willingness to have the truth proven by the survival of the fittest. Since that time many changes have occurred, and it is not saying too much to affirm that specialism has not only worked its triumphant way to the front rank of usefulness, but has proved itself indispensable to progress in medicine. If any one doubts the latter assertion, let him contemplate the astonishing advances which have been made by the careful cultivation of the different special branches of study by the first minds of the civilized world, and the opening up of new fields of investigation in every department of general medicine.

We all admit that it is worse than folly to attempt to be well enough informed on the different specialties to enable us to be independent of the aid of specialists in our general practice. The more we appreciate the thoroughness with which the different specialties are studied, the more willing are we to admit that any one of them requires the devotion of a lifetime. The circle of each special study is widening to such an extent from year to year, that we may well doubt

whether a lifetime may after all be sufficient to master all the details which thousands of earnest workers are constantly accumulating. What may be said of the specialists can with equal truth be made to apply to general medicine and surgery; and the general physician or surgeon, far from being jealous, as formerly, of the apparent encroachments of specialism, must congratulate himself that he has now a better opportunity for keeping pace with the advancements in his own lines of practice.

The very impossibility of keeping up with each specialty, and becoming equally well informed in all branches, brings us to the question how we can best draw that distinction between general and special practice as shall best serve the interests of medicine and secure the greatest good to our patients. In the treatment of certain affections under the domain of specialism there is a point beyond which the general practitioner is not expected to go, and from which point the case should be resigned to more skilful hands. It is not expected because a particular organ becomes diseased that the case should be given at once into the hands of a gentleman to whose specialty the diseases of such an organ may belong. A general practitioner is expected to treat a simple conjunctivitis, an ordinary case of otitis, a trivial affection of the throat and the like, but at the same time he presumes to be competent to judge between a mild and a grave affection of any of the special organs. In old times the treatment of almost all affections was monopolized by the general practitioner, and the knowledge of these affections was so limited that such a thing was possible; now, however, the specialist comes in to commence treatment where the general practitioner leaves off, and from that point is capable of carrying it to a successful issue and to bring about recoveries the possibility of which were hardly dreamt of before. It is in consequence of the possession of this special skill that the specialist has a claim upon the practitioner and upon the patient.

The precise time when a practitioner should resign his case to the specialist must vary with the intelligence of said practitioner, the appreciation of his responsibilities, and on the result of a culpable neglect. For practical purposes, however, we are warranted in assuming that so soon as special skill is required in the treatment, or so soon as there appears to be a liability that such skill may be needed, the case should be gracefully resigned.

We are not prepared to deny that this is not the general custom, but the exceptions are sufficiently numerous to prompt us in calling attention to them. The younger medical men are particularly liable to create these exceptions, and perhaps they are not so much to blame for so doing as are their teachers. The primary cause would appear to be in the manner in which they are taught at the different medical schools. In the anxiety to give the best of medical instruction, the

teachers attempt altogether too much, and sacrifice the time which should be devoted to the gaining of useful knowledge to what may be termed a devotion to high art in medicine. The student is made to believe that he is as capable of performing an operation for cataract as he is of treating an ordinary case of pneumonia, or that there is as much of a chance for him to ligate the arteria innominata as there will be to perform version. Is it to be wondered at that when such cases may, by some curious accident, fall in his way, there will be any hesitation on his part in assuming the responsibilities. It is truly an amusing and at the same time a melancholy suggestive circumstance, to see the operating theatre almost invariably crowded, while the fever wards and the lying-in chambers are so shamefully neglected. The rarer the operation, the greater the number present, each student expecting, of course, that he must have an opportunity of making his reputation upon just such a case. He may have such a case, but if he does, all we can do is to pity the poor patient who may trust to the unwarrantable conceit of such an adviser.

We believe it necessary to do everything which may tend to improve our systems of medical education, to establish extra and special chairs in the general courses of lectures; but the instruction in all these special departments should be given with the sole idea of their utility to the ordinary practitioner. As at present carried on, the system is apparently calculated to induce the student to believe that when he graduates he can dare to attempt anything ever done before by anybody and everybody. The difficulty, we imagine, is, that there is not enough care taken to point out those cases which, as a general practitioner, he may be called upon to treat, and those cases which he must not treat unless he has a more thorough preparation than the college course allows. In fact, the graduate should be taught what is general practice, and what belongs to the practice of a specialty. To be well prepared to engage in general practice, he must have the general foundation of knowledge well laid, and such comprises all the ordinary diseases of every organ. The teachers of specialties can certainly occupy their time to no better advantage than by teaching the principles of treatment, the methods of diagnosis, the necessary measures to be adopted to prevent accidents, and the symptoms which should always demand the resignation of the case to an expert. This very kind of teaching gives the student the best possible chance to succeed in general practice, and the best possible preparation for the commencement of the study of a specialty.

In the matter of simple justice to the specialist who devotes his whole time to the study of his branch, the general practitioner should always be ready and willing to give him every opportunity for the exercise of his special skill. Nothing but good can come of this to all parties concerned. In regard to securing skilful services, this remark applies with equal appropriateness to such gentlemen who may not, in the strict accepta-

tion of the term, be called specialists. These gentlemen may be said to occupy medium positions between the specialist and the general practitioner; their special skill in the treatment of one or more diseases may be viewed in the light of a cultivated accomplishment. We have instances of this in the particular attention which a physician pays to the diseases of a particular apparatus, in the experience which a surgeon accumulates in the performance of a particular operation. Such gentlemen deserve encouragement; and no conscientious physician or surgeon who has the best interests of his patient at heart can ignore the claims of such experts; in fact, by so doing he would sacrifice the dearest of all professional obligations, to the paltry and mean consideration of a few extra dollars in his own purse.

Reviews and Notices of Books.

RÜDINGER ATLAS OF THE OSSEOUS ANATOMY OF THE HUMAN EAR. Translated and edited, with Notes and an additional Plate, by CLARENCE J. BLAKE, M.D. Published by A. Williams & Co., Boston. 1874.

EVERY earnest student can probably remember how desperate were his efforts, while "studying the bones," to obtain even a moderately clear idea of the concealed portions of the temporal bone. Even with the aid of good dry preparations and the illustrations of the best text-books, he must have failed in his efforts to gain a clear insight into this most fascinating portion of the human frame. In the present work the beauties of the temporal bone are unfolded, one by one, with marvelous clearness. The photographic representations give a naturalness to the parts which no degree of skill in engraving could ever attain. Delicate dotted lines, with numbers attached, which correspond with those given in the text, render it an easy matter to verify each point in the anatomy with absolute accuracy.

To the original series of Rüdinger's plates Dr. Blake has added one which, in importance, at least equals any other in the series. In the preparation from which the photograph is taken, the anterior portions of the external auditory canal and tympanic cavity have been cut away in such a manner as to show not only the relations of the meatus, tympanum, Eustachian tube, and antrum mastoideum to each other, but also many of their anatomical details. An instructor, well provided with specimens, and with needle in hand as a pointer, could hardly demonstrate these parts more satisfactorily to the pupil than do these carefully prepared photographic plates.

We can join most heartily with the editor in expressing the hope that a sufficient interest will be shown in the present series to justify the publishers in issuing further works of a similar character.

BELLEVUE HOSPITAL.—The following gentlemen have been appointed in accordance with the new regulations: College of Physicians and Surgeons, Dr. T. M. Markoe and F. Delafield; Bellevue Hospital Medical College, Drs. F. H. Hamilton and E. J. Janeway; University Medical College, Drs. E. Mason and W. H. Thomson; and from the profession at large, Drs. J. W. S. Gouley and Gouverneur M. Smith.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 8, 1874.

DR. AUSTIN FLINT, PRESIDENT, in the Chair.

The first paper for the evening was read by Prof. J. C. Dalton, M.D.,

"ON A NEW METHOD OF OBSERVING THE LOCATION OF ABSORPTION BANDS IN ORGANIC FLUIDS."

of which the following is an extract:

The difficulty in observing absorption bands is precision of measurement by the ordinary means used in the measurement of the lines in sunlight.

The cross lines in common use at the eye-piece of the observing telescope are not necessary at all, and are not convenient in the observation of absorption bands of organic fluids.

A better plan is to place in the eye-piece of the observing telescope a simple *vertical* wire. This works well for the observation of the bright portion of the spectrum; but for the dark portion of the spectrum it does *not* work well. To overcome this, make a lateral opening in the eye-piece, and attach a mirror in such manner as to throw light upon vertical wire, and make it appear like a bright line when the darker portion of the spectrum is to be observed. The plan for observation to which more special reference was made, was one by which the position and dimensions of absorption bands, with reference to the sun-lines, which are always used as a standard of comparison, may be seen at a glance without graduating scale or vernier. By this means, when one glance has been made, it is possible to tell another person exactly where the bands are. The ordinary arithmetical calculation of the old method, which, for a great many persons is exceedingly laborious, is entirely done away with. For this purpose a third telescope is used, bearing a scale. This telescope is so adjusted that the scale and spectrum can be seen at the same glance. The peculiarity of the plan consists in the peculiarity of the scale.

First, an arbitrary scale is made upon card-board (twenty inches long by seven or eight wide is a convenient size), which runs up to about 200. A horizontal band is left vacant between the upper and lower portion of these scale lines, just wide enough to take in the spectrum. This arbitrary scale is then photographed down to a size to fit the third telescope. It is then verified by the sunlight. When verified, a negative is made for producing permanent scales.

Great difficulty was experienced at first in obtaining a suitable negative, one which would leave sufficiently clear and well-defined lines and sufficiently black interspaces. Such a negative was finally produced by Mr. Mason, photographer at Bellevue Hospital.

Another precaution is, the telescopes must bear a proper angular relation to each other, in order to bring the scale and spectrum into perfect view at the same time, and when this has been obtained, the instruments must be fastened permanently by means of screws or other apparatus specially designed for that purpose.

The second paper for the evening was read by Dr. Thomas R. Pooley,

"ON SOME OF THE CAUSES OF SUDDEN BLINDNESS."

Among the causes enumerated were hemorrhage into the vitreous, glaucoma fulminans, large and sud-

den detachments of the retina from the choroid, embolism of the central retinal artery, ischæmia retinae, transient and complete anæmia of the retina preceding epileptic attacks, and certain cases occurring in the course of Bright's disease, denominated "uræmic amaurosis." The latter is a condition differing from the retinitis of Bright's disease.

The Academy then went into executive session.

Stated Meeting, October 15, 1874.

DR. AUSTIN FLINT, PRESIDENT, in the Chair.

ANCHYLOSIS AND ITS TREATMENT.

After the reading of the minutes of the previous meeting, the President introduced to the Academy their distinguished guest, Mr. John Eric Erichsen, of London. Prof. James P. White, of Buffalo, was also introduced as a newly elected Corresponding Fellow of the Academy. Prof. White responded with appropriate remarks. The paper for the evening was then read by Dr. Sayre upon "Anchylolysis and its Treatment."

Two forms of this condition were recognized.

First, True, osseous, complete, in which there is no motion; *second*, false, fibrous, incomplete, in which there is limited motion, although in some cases it may be exceedingly slight. Anchylolysis is not a disease of itself, but is a result. In fibrous anchylolysis it is possible that motion cannot be detected at the time of the examination; but if the examination is followed by pain in the part within the next twenty-four hours, it may be regarded as being diagnostic of mobility.

The manner in which the breaking-up process was to be performed and the after-treatment to be adopted were fully discussed.

It was believed to be better to restore the joint to its normal position by means of manual force, assisted by tenotomy, myotomy, etc, rather than to resort to the slow process of gradual extension.

If sections of tendons or muscles are made, the operation should be performed, and the external wounds be permitted to heal before *brisement* force is resorted to. When resorted to, it should be *thoroughly* applied, for one of the most common causes of failure in effecting a cure arises from the incompleteness with which the breaking-up process is performed.

The limb should *immediately* after the operation be *firmly* bandaged from the tips of the extremities to a point well above the joint affected, care being taken to thoroughly strap in the joint affected before passing the roller over it, and also to cut off a portion of the blood supply to the limb, by placing a piece of sponge over the main artery, and securing it by the bandage in such a manner as to partially compress the vessel. The limb is then to be placed in some form of apparatus, no matter what, that will secure complete and perfect immobility until all danger from the supervention of inflammation has passed away. Bags of ice are to be kept around the joint, and such internal remedies administered as may be necessary to meet the rising emergencies. Several cases were then presented to the Academy in which the results obtained were eminently satisfactory.

Dr. Post was of the opinion that the *presence* of pain at the time of the examination, if carefully discriminated from the pain of pressure necessary to be made in making the examination, is diagnostic of fibrous anchylolysis; and its *absence*, under the same circumstances, is equally diagnostic of bony anchylolysis.

Dr. Sayre regarded the absence of pain at the time of the operation as unreliable; for in several cases he had known pain to be absent at the time of the examination, and the subsequent history of those cases demonstrated that the ankylosis was fibrous in character. Those patients, however, were examined under the influence of anesthetics; but the pain which followed the examination was not complained of until several hours afterwards.

Mr. ERICHSEN, of London, was invited to speak upon the question under discussion, and remarked substantially as follows:

There are two or three points in connection with Dr. Sayre's paper which are entirely new to me. One, especially, is with regard to establishing a diagnosis between the true and false ankylosis by the production of pain at the time of the examination, or its development within a short time after the examination. In my own practice I have not observed this fact; in point of fact I have overlooked it, but shall look for it in the future. The plan which I have usually adopted in examining the joint is to first place the patient under the influence of an anæsthetic, and then make a careful examination for the purpose of determining whether motion is present or not; and I cannot recall to my mind any case in which I was not able to detect motion in false ankylosis by giving attention to one or two simple points.

Flexing the portion of the limb nearest to the trunk, and then placing the two thumbs, one just *above* and the other just below the edges of the articular surfaces; for instance in the knee-joint one thumb is to be placed *below*, over the head of the tibia, close to the articulating surface, and the other *above*, over the condyle of the femur, at a corresponding position, and then, having an assistant, make efforts at producing motion. In this way I have always been able to determine whether motion was present or not. I can readily conceive, however, that there are cases in which there might be extreme difficulty in determining whether motion is present or not.

With regard to *brisement force*, I have had some experience in its practical application. In the *brisement force* a good deal depends, so far as result is concerned, upon the kind of false ankylosis we have to deal with; for I have to go one step farther than did Dr. Sayre, and subdivide false ankylosis into several different kinds.

In the first place, we have that form of false ankylosis which is common enough as the result of rheumatic inflammation or blood-poisoning, which is closely allied to rheumatism or pyæmia; or to a condition between the two perhaps, in which there is a tendency, not as in pyæmia, to the deposit of pus nor the development of the ordinary symptoms of rheumatic poisoning, but of that kind of poison of which gonorrhœal rheumatism is an illustration. In this kind of poisoning ankylosis is very common, and in some cases is extreme and almost perfect. In these cases, however, the joint structures themselves, the synovial membrane, etc., are perfectly sound, and when you break down such a joint as that, you can obtain perfect mobility afterwards. But there is another class of cases of fibrous ankylosis, of which I have seen a good many, and in which I am not so well satisfied with the *brisement force*. These cases are those in which destruction of the synovial membrane has taken place, bands of adhesion have perhaps stretched across the articular surfaces, and the ligaments have become softened, etc.

Such a case presented itself to me not long ago. In that case the joint was broken down after death.

Upon dissection something like the following condition of things was found: The synovial membrane had disappeared, as the result of the old disease, there being merely a quantity of fibroid tissue binding the joint together. The posterior crucial ligament was torn off from the tibia, and had torn away with it a scale of the tibia. The ligamentum posticum was thrown into folds, and could not be forcibly torn off. In these cases I do not believe you can ever restore mobility. We can get the limb into a good position, which may give the patient very much benefit, but never get mobility of the joint. In the knee-joint there is a peculiar deformity, which will enable you to diagnose the presence of this condition of affairs; it is a displacement of the tibia backwards, with a projecting of the popliteal space, so that when the limb is restored to its normal position as near as possible, the articulations are not, and cannot be fully restored to their normal position. It is the puckered condition of the ligamentum posticum that prevents the articular surfaces from being restored to their normal position.

Another cause of partial ankylosis is *slight displacements* of the articular surfaces of joints. This is not very infrequently seen at the shoulder-joint, and in that case is probably due to some peculiar condition of the circumflex nerve. In such cases, when the patient is placed under the influence of an anæsthetic, motion can be freely made in all normal directions, but the ankylosis will return again after a short time. I would therefore make a distinction between those cases in which the synovial membrane is intact and those in which it is destroyed. In the first class of cases the *brisement force* is of great value. When it is resorted to, I fully concur with Dr. Sayre that the limb should be placed in an innovable dressing at once.

There is another point referred to in the paper of Dr. Sayre which I feel I should not neglect to call attention to, and that is, in the treatment of osseous ankylosis. The surgeon should not content himself with simply cutting across the bone, but a portion of the bone should be removed; and if for the relief of the hip-joint, it should be removed above the insertion of the psoas and iliacus muscles. If the bone is simply cut across, it may permit of restoring the limb to a straight position, but ankylosis will follow the operation.

I have never seen a case in which simple section of the bone had been made, in which the result has been anything except ankylosis.

The principle for which the Doctor contends is this, you must saw out a piece of bone, and unless you do that you will get osseous union again, your operation placing the bone in the same position as that which obtains in a compound fracture, consolidation taking place at the end of a few months at longest; whereas if you cut out a portion of bone you will get mobility established the same as you may when the bone is excised for the cure of hip-joint disease. I think that this point is an important one, as to the comparative advantages of a simple section or excision of a portion of the bone. I think there is special advantage in the latter method of operation in restoring mobility to the limb, rather than simply sawing the bone across, leaving it something in the same condition as it would be with a compound fracture in the same position.

Upon motion of Dr. FINKEL, a vote of thanks was given by the Academy to Mr. Erichsen for his highly interesting remarks.

The paper was further discussed by Drs. Buck, Gouley, and Crosby.

NEW YORK MEDICAL LIBRARY AND
JOURNAL ASSOCIATION.*Stated Meeting, October 9, 1874.*

DR. J. C. PETERS, PRESIDENT, in the Chair.

SEPTIC ENTERITIS.

THE paper for the evening was read by Dr. A. Jacobi, entitled, "Septic Enteritis."

This title was given to the disease for the reason that in the larger number of cases it localized its effects upon the mucous membrane of the intestines, and especially because in all those cases which had of late come under the author's observation the intestinal symptoms were most prominent and most dangerous.

After giving a review of the anatomy and physiology of the intestines, it was noticed that the first stage of an enteritis depended upon the condition of the tissue in which the disease takes place. There is the very thin epithelium which does not prevent external irritations from coming in contact with the deeper portions of the intestine. Farther, it is noticeable that enteritis, or hyperemia of the intestinal mucous membrane, is facilitated by a peculiarity shown in the anatomical condition of the arteries and veins. They both perforate the intestine in an oblique direction, and the veins have much thinner coats than the arteries. In the mucous membrane of the intestine whatever irritations take place they exert very great influence, for two reasons: they produce a direct local irritation and cause increased peristaltic motion, which produces increased facilities for absorption, especially through the veins.

The causes of Catarrhal Enteritis were: Obstructions of circulation in the liver; a number of diseases of the organs of circulation and respiration, such as some form of chronic valvular disease of the heart, etc.; disturbances of the circulation of the periphery of the external integument; collateral edema of peritonitis, especially puerperal; a large number of nervous disturbances—some have supposed that the diarrhoea of cholera is the result of depressing influence of the poison upon the nervous centres; local irritation, such as obtained by the administration of drastics, etc.; presence of a large quantity of bile in the intestines; sometimes presence of parasites; sometimes presence of a large number of fungi; sometimes the result of irritation from faecal matter; sometimes the result of influences, the nature of which we have no definite knowledge; sometimes the result of the presence of putrid material, either in the intestine or in the blood of the entire system of the patient, such as the diarrhoea of typhoid fever, etc. What is putrefaction? What is sepsis? The presence of something foreign has always been presumed to exist in the blood of all those patients who suffer from diseases that Virchow has called infectious, and other observers zymotic. For some time it was assumed that something alive was the cause of this class of diseases.

At this point commenced quite an extended discussion of the various organisms which have been found in the human body in connection with certain diseases, such as vibrios (*Vibrio albens*), bacterie, micrococci, etc. The conclusions of Billroth were finally presented, which were that certain organisms are found in connection with a certain class of diseases, but that they are not necessarily present.

Are the organisms which produce sepsis identical? We have no power of the microscope to determine this point. It may be that these microscopic organisms

secrete a poison independent of the organism itself, the same as we now know that microscopic fungi will produce poisonous effects, independent of the fungi itself.

When the putrid materials are introduced into the stomach the effects are various; the intensity of the symptoms depending upon the quantity of the poison taken in. Sometimes the effects are nothing; sometimes increased temperature, general debility, death; sometimes death from inanition. The same results can be obtained by injecting the material into the cellular tissue; and here again the quantity injected influences the subsequent phenomena.

When injected into the veins, the intestines are *always* affected. The quantity again has its influence. When the liquid has been dried, and subsequently moistened, it has the same effect. When the liquid has been exposed to the effect of heat up to the boiling-point, and then introduced into the animal economy, the effect will be the same.

With the introduction of putrid gas the results vary a great deal. There is less effect when the material is brought into contact with the mucous membrane than when brought into immediate contact with the blood.

When large quantities are injected into the system, death may take place within a few hours, without producing but little change in the internal organs. When smaller quantities are taken, intestinal symptoms are developed in preference to all others—hyperemia of the small intestines, sometimes of the liver, the spleen, but nothing of the kind in the brain. Is the poison chemical? This is a mooted question.

The chief effects of the disease are manifest in the stomach and intestines. A large majority of changes take place just above and just below the valves, where the glands are more numerous and of greater size. In all those places where the faeces are accumulated and undergo disintegration the changes are very much more perceptible.

No organisms were found in the case which fell under the doctor's observation. The general history of the case was as follows: Patient was sick seven or eight weeks. As far as stomach and intestines were concerned, was perfectly well before the attack of diarrhoea, which was persistent throughout. Early the patient stated that she felt very bad, indescribable; and that she certainly should die from the sickness. Vomiting attended the diarrhoea at first, but soon disappeared. Pain was soon developed along the region of the colon, especially the ascending and transverse branches, and persisted throughout.

Temperature ran up to 104°, 105°, 106°.

Passages frequent, serous, and at one time slightly bloody. Emaciation gradually developed. Nervous symptoms gradually developed; occasional delirium, etc. Pulse 120 to 126. Transfusion was resorted to towards the close, but with only temporary results. Medicines had but little influence throughout the entire course of the case. Perspiration was free, especially over the trunk, but not excessive.

Stated Meeting, October 16, 1874.

The paper for the evening was read by Dr. A. D. Rockwell, upon "The Tonic and Antispasmodic Relation of Electricity to the Diseases of Childhood."

It contained a brief outline of the physiological and chemical action of electricity, and also the power which the agent possesses for sustaining nutrition.

Its application in the treatment of certain spasmodic diseases of childhood was alluded to and cases cited. The doctor was certain that he had seen some benefit

from its use in the treatment of chorea, but especially those cases of long standing which had resisted a variety of other treatment.

A single case of spasm of the glottis had been treated with electricity, and apparently with great benefit.

Whooping-cough had been treated in several cases by both central galvanization and local application of the agent, and with some satisfactory results.

Marasmus.—Some cases of this affection had been treated by the use of electricity, with some encouragement for further efforts in that direction. In the case more particularly referred to, the electrical treatment was associated with other forms of treatment, medicinal, etc.

DR. PIFFARD presented a few novelties in the way of apparatus, after which the Association adjourned.

NEW YORK MEDICO-LEGAL SOCIETY.

Annual Meeting.

CLARK BELL, ESQ., PRESIDENT, in the Chair.

THE MEDICAL JURISPRUDENCE OF POISONING.

THE paper for the evening was read by Prof. R. Ogden Doremus. "Upon the Duties of Members of the Medical and Legal Professions, Toxicologists, Pharmacologists, and County Officers in Cases of Poisoning, and the Necessity of Proper Legislation upon the Subject." The following is a brief outline of the paper:—

"The crime of taking human life by poison is the worst of crimes."

First. With regard to the duties of the physician when called upon to act in a case of suspected poisoning.

It is a common opinion that the *stomach* is the chosen organ for the reception of the poison, and therefore the only part of the body necessary to be carried to the analyst for examination. This is a mistaken notion, and great attention should be paid to the preservation of articles of diet, dishes, and papers which had contained medicines, etc. For example, *arsenic* had been found in a paper which had held a seditil powder that had been taken by a patient who had died unexpectedly.

The physician should be careful and preserve vomited matters, whether upon the clothing, carpet, or upon the ground. Urine and feces should be preserved.

Hypodermic injections are, in these days, constantly used by the medical profession, and frequently such injections are entrusted to the patient or some of the friends. Too great care, therefore, cannot be exercised in examining *every portion* of the body; under the nails; between the toes; in the hair, etc., etc., for evidence concerning the use of this instrument. This is rather a novel part of observation for the medical profession, but the omission of such search is not infrequently profoundly regretted by the physician when placed upon the witness stand.

When the stomach is removed, it should first be ligated at both cardiac and pyloric extremities, and this should be done *invariably*. The necessity of this precaution is at once apparent if a volatile poison has been used, but should not be neglected under any circumstances.

The intestines are rarely sent to the chemist; but these are preferable to the stomach in case but one can be obtained, and a choice must be made. The same precautions should be used in removing the intestines as in removing the stomach. It is well, also, to preserve pieces of the liver, kidneys, and organs of

generation. Self-sealing fruit-jars are very good receptacles for the specimens to be preserved. Days, dates, and details should be strictly kept. When placed in such jars they should be kept under *lock and seal* until given into the hands of the chemist.

Second. With regard to the duties of the toxicologist. A word of caution for those who would attempt such an investigation. These investigations should be intrusted only to the hands of the chemist.

When the toxicologist leaves the room in which the examination is going on, he should fasten and seal every door and window. He should only employ new vessels, clean, and cleansed by himself. His chemicals should be of known and not of merely reputed purity. Even the ordinary copper water-bath should always be avoided. The chemist should be exceedingly cautious about starting with any theory when he commences his examination. But suppose the prisoner asserts the commission of the crime, and announces the poison used. No dependence whatever is to be placed upon the sayings of those who have committed the crime.

It is not sufficient that the chemist satisfies *himself* of the presence of poison. In the Wharton trial three chemists made examinations, and were only able to testify that they found antimony sufficient to satisfy themselves. The microscope and spectroscope must be brought to the aid of the chemist in making his examinations.

Another important item stated was, that the extent of the chemical research should be left to the judgment of the chemist and of the district attorney. The doctor was of the opinion that the law governing the druggist and regulating his sale of poisons should be amended. Certain articles can be obtained only upon the prescription of a physician; while others, far more potent as poisons, may be obtained without question. How shall it be regulated? Coroners should have the power to ask the services of the toxicologist. The expert toxicologist may be able perhaps to detect certain important items which even the careful post-mortem physician will not be able to obtain. The parts then removed may be immediately placed in his hands, which saves one link in the chain of evidence.

The coroner should have authority to order an examination apart from the district attorney.

The public should be excluded by law from the court-room during the hearing of testimony unfit for public ears. If this could be legally obtained it would be most desirable. There are certain methods of poisoning, and certain articles used, that are not generally known, and a public exposition of the same is only enlarging the field for criminal action.

At the close of the paper, Prof. Doremus offered the following resolution, which was adopted:

Resolved, That a committee of five, consisting of two physicians, two lawyers, and one chemist, be appointed from the members of this Society, to take into consideration what additional enactments relative to poisoning cases are called for; and that said committee report at some future meeting of the Society. A bill, embracing such necessary changes, to be presented to the next legislature.

WHAT A BABY IS WORTH.—The *Chicago Post and Mail* gives the following as the immediate cost of a first-class baby: Physician, \$50; midwife, \$25; wet nurse, \$50; dry nurse (one year), \$150; clothing, \$200; baby carriage, \$25; total, \$500.

Correspondence.

CASES FROM PROF. GUSTAV SIMON'S
CLINIQUE AT HEIDELBERG.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR:—A visit to Heidelberg, on the 26th of September, afforded me an opportunity of becoming acquainted with Professor Gustav Simon, and of seeing some of his operations, which, during the last few years, have attracted so much attention in the surgical world. Only a few days after my arrival, by a somewhat extraordinary coincidence, Mr. Spencer Wells, of London, who was returning with his family from Switzerland, came to Heidelberg on the same mission as myself. I had previously notified Professor Simon of my intended visit, and Mr. Wells had also done the same for himself; the consequence was, that the Professor had secured a large collection of interesting cases in the hospital where he daily holds his surgical clinics. Thinking that a short account of some of these cases might prove of interest to many of your readers in the United States, where Professor Simon is so well and favorably known, I ask for the same a place in the Record.

NEPHROTOMY.

The first case to which I shall refer is that of the woman upon whom Professor Simon performed nephrotomy four or five years ago, for the relief, as it will be remembered, of an uretero-abdominal fistule,—an accident resulting from the operation of ovariectomy. The patient is about forty-five years of age and her general health appears to be good. A secondary result of the same operation is a large abdominal hernia, for which Professor Simon will also operate, as he had done in a similar case only a few weeks earlier, which was exhibited for examination. His operation consists in removing the integuments to form two broad and somewhat semicircular, raw surfaces, at equal distances from the linea alba, and then uniting the same with deep and superficial sutures. In order to give greater strength to the cicatrix at its lower extremity, where the strain is greatest, a long tegumentary flap with pedicle, two or three inches above the pubes, is taken from either side and secured by suture between the raw surfaces described.

RENAL CYST.

The next case presented was that of a man, about thirty years of age, who had what appeared to be a deep wound in the right flank, from which issued a thin, watery fluid. Professor Simon said that there had been a renal cyst which he had opened, and that the discharge had continued, though it was now comparatively slight. He introduced a probe, to the depth of five or six inches, and then demonstrated the case with which the point of the index-finger could be carried into the cyst. Professor Simon proposes in this case, after waiting a little while longer, to refresh the sides of the wound and close the same with a small canula, having a clamp adjusted upon each end and secured by a top-screw. This canula has a broad and deep curve and a slit at its middle to allow the secretions in the cyst to enter and pass off. It is to be introduced through the two edges of the wound upon a trocar needle which is afterwards to be withdrawn.

ARTIFICIAL ANUS.

Another man, aged about forty, was brought before us with an artificial anus in the right iliac region, the re-

sult of strangulations of a scrotal hernia. The opening in the bowel was situated at the caput coli, and, owing to its great size, prolapsus of a large part of the ascending colon readily took place upon the removal of a pad which had constantly to be worn. The case was interesting, as affording the opportunity to see, outside of the abdomen, the ileo-caecal valve and appendix vermiformis; also, as illustrating the time it took, by hydrostatic pressure, for a stream of water to travel through the rectum and colon, which did not exceed one minute. From repeated experiments in our presence it seemed to make very little difference whether the patient was in the recumbent or erect position. This poor creature appeared to be very well contented with his condition, as shown by his indifference to be operated upon. He is a tailor, following his vocation, and is always glad of the opportunity to make a few krentzers by exhibiting himself at the clinique.

PROLAPSUS OF RECTUM.

In connection with the preceding case, I will refer to two others which were presented to our notice, both women. One had extensive prolapsus of the rectum, the result of a complete division of the sphincter ani backwards, which she said had been made by a surgeon in New York, for the relief of a fistule. The other woman, from St. Louis, had a recto-vulval fistule, quite simple in its character. Upon the first-named Professor Simon had performed a plastic operation with some benefit, though the condition of the poor woman is still deplorable. These cases, with their histories, were interesting to me from the fact of their coming to Heidelberg, to be treated by Professor Simon, from these two American cities where so much attention is given to this subject.

RETROFLEXION AND PROLAPSUS OF THE UTERUS.—THE
PASSAGE OF THE HAND INTO THE RECTUM.

The case to which I will now refer—that of a woman with retroflexion and prolapsus of the uterus—is one of unusual interest. Professor Simon had performed several weeks before the operation of *episiotomyorrhaphy*, and the result, as to the prolapsus, was satisfactory, although, with regard to the retroflexion, little was accomplished. The patient insists that she is no better than she was before the operation, and that, owing to her extreme suffering, at her menstrual periods especially, she is willing to submit to any other operation that promises relief. Professor Simon had thought that the removal of the body of the uterus, under these circumstances, might be justifiable, and, having already demonstrated upon the cadaver the case with which the fundus could be seized and drawn through an opening in Douglas' *cul-de-sac*, he was ready to put the novel procedure in execution. His colleagues, however, did not sanction the proposal, and it was given up. Mr. Wells and myself were asked for an opinion in the case, which we gave adversely also. But the interest in this case did not stop here, as will readily be seen. The subject of rectal and vesical explorations, which has attracted so much attention in England and America during the last two or three years, was illustrated by Professor Simon upon this patient in the most practical manner. The passage of the hand into the rectum as a means of diagnosis, I believe, originated with him, and, bold and reckless as the procedure may appear to many, it is destined, when better understood, to prove a most valuable means of diagnosis. To be able to pass the hand and arm, per anum, to a point in the abdomen that the left kidney and false ribs can be felt, and the

abdominal wall, of the same side, to the median line, he lifted up, at every point, upon the ends of the fingers, seems almost incredible; and yet I saw this practised by Professor Simon upon his patient. Both Mr. Wells and myself, at the request of the Professor, made the same exploration, with a satisfactory result.

From what I have seen and heard of this procedure, at the clinique of Professor Simon, I am convinced that the dangers and accidents supposed to attend it have been greatly exaggerated. He says he has met with no difficulty, except, now and then a little incontinence of the feces, which, however, continues only two or three days. The preparation for the operation consists in complete anesthesia and in thoroughly washing out the large bowels. The latter Professor Simon prefers to do by hydrostatic pressure, using for this purpose a graduated glass cylinder with a faucet near its bottom, and a long rubber tube terminating in the ordinary clyster nozzle. From two to three quarts of water usually suffice. The apparatus is held by an assistant three or four feet above the patient. Professor Simon has now operated eight times through the anus for recto-vaginal fistule, and he thinks the procedure is preferable to the ordinary method where the fistule is situated high up. Why not approach the male bladder in the same manner, in cases of chronic catarrh and ulceration, and of great enlargement of the prostate gland where micturition is attended with difficulty? Cystotomy, under such circumstances, I have long thought to be not only a justifiable procedure, but one likely to be attended with good and encouraging results.

EXPLORATION OF FEMALE BLADDER BY THE FINGER THROUGH THE URETHRA.

As to the exploration of the female bladder, with the finger passed through the urethra, Professor Simon has had a large experience. He illustrated the procedure upon the last-mentioned patient and also upon several others. He said that he had not found incontinence of urine to follow it. In the particular cases examined before us the bladder was filled with water and the power of retention fully shown. The distention of the urethra is effected by means of a set of dilators made of hard rubber, and ranging in size from that of the largest male catheter to that of the thumb. The dilatation is begun and carried on to the point of distention of the urethral orifice, where the latter is notched on the two sides and in front, the main seat of resistance. After this, the requisite dilatation for the index-finger to pass is easily reached.

In this little procedure there was nothing very novel. Professor Simon, however, had turned it to good account in a case of fungous growth from the vesical mucous membrane, which he diagnosed with his finger and detached with a gouge-shaped scraper. He had also employed the method with great satisfaction in differentiating the size of a fistule, shut in by a col-pocleidic operation, performed by another surgeon. The patient who had been subjected to this expedient became dissatisfied with what she had been told was a cure, and came to Professor Simon to be "*uncured and cured over*." Upon examination he found the closure firm and complete, and no way, except through the urethra, to determine whether the fistule was small or large—this point being considered of the greatest importance, as upon it depended, he said, the justifiability or unjustifiability of re-establishing the vaginal tract. The ready method of vesical exploration with the finger, fortunately for the patient, showed the fistule to be small and curable by the coaptation

of its edges. Thereupon the occluded portion of the vagina was opened and the fistule brought into view; this proved to be of the urethro-vesico-vaginal type, scarcely large enough to admit the point of the index-finger. The patient was presented to our notice in this condition. Professor Simon proposes now to refresh and unite the edges of the fistule in the ordinary way.

KALPOKLEISIS.

A case of much interest and importance in its bearings upon the operation of kalpokleisis was next presented—a woman from Russia, aged 32, who was about five months advanced in pregnancy—as indicated by the ordinary signs, and by rectal exploration which proved, under the circumstances, to be of essential service in settling this point. Professor Simon said that ten years ago this patient first came under his care with a large vesico-vaginal fistule, and, believing at that time the coaptation of its edges to be impossible, he determined to shut up the vagina by uniting its two walls in the urethral portion. This he readily effected, and, in a kalpokleidic condition, the woman returned to her family, little supposing that she would ever again have to endure the perils of child-bed. Now she comes back in great distress of mind for further advice, believing her life to be in imminent peril. Professor Simon at first thought that the enlargement of the uterus might be due to fibroma or hematometra, but the investigations in question dispelled all doubts upon these points. Upon examination, the seat of the original vaginal closure was found to be about three-quarters of an inch from the urethral orifice. The transversely running cicatrix was plainly seen, but near its middle there was a break, indicating the entrance to a sinus, through which a small probe readily passed and from which urine issued. The discovery of this sinus at once settled the question as to how the spermatozoa had reached the cavity of the uterus and caused impregnation; though it is by no means improbable that they journeyed through the more circuitous route of the urethra, which was seen to be quite patulous, and then, through the vesico-vaginal fistule, reached their ultimate destination. Normal urine does not kill them. Therefore, complete closure of a vagina by kalpokleisis, with a coexisting urinary fistule, does not always presuppose impossibility of impregnation.

The object in this case being to save the child if possible, Professor Simon was in some doubt as to the best course to be pursued. Mr. Wells thought it better to wait until labor set in, and then to open the vagina before the advancing head of the child. He said that he had advised this course in a similar case upon which he had operated a few years ago with a good result. I believe myself that this practice is the best in those cases where there is no doubt that the vagina, above the seat of the closure, is open and free of resisting bands; but if the previous history of the case is not known, and an unfavorable condition of the vagina at the beginning of labor be found to exist, such a course would not only jeopardize the life of the child but that of the mother. Even if the latter should escape with her life, increased injury to the vaginal walls from pressure of the child's head would necessarily result. Not being acquainted with the actual condition of the vagina in the case in question, I therefore favored, as preparatory measures, the immediate division of the kalpokleidic obstruction and any adhesions or bands which might be found, to be afterwards followed by dilatation of the vagina to the fullest extent.

URETHRO-VESICO-VAGINAL FISTULE.

Professor Simon now concluded his presentation of cases by an operation for urethro-vesico-vaginal fistule of a large size. A detailed account of his procedure would doubtless prove of great interest, but, finding my letter already exceeds the limits intended at the outset, this must be deferred to another time. Suffice it at present to say that the method employed is peculiarly Professor Simon's—the best in Europe—and he is a most painstaking operator, ranking with the first in this or any other country. After finishing this operation the Professor politely invited me to demonstrate my method of operating if I wished to do so—an act of liberality that at once shows him to have an exalted appreciation of the claims of other countries and of the best interests of humanity. His example, in this regard, might well be imitated to a greater extent than it is by the public institutions of our own country with great advantage to science. I accept this kind invitation, and shall return to Heidelberg for the purpose of operating towards the close of this month, at which time Professor Simon enters upon his regular course at the hospital.

Respectfully yours,

NATHAN BOZEMAN.

COBURG, GERMANY, Oct. 7, 1874.

SPECTRAL ANALYSIS.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—It is with regret that I feel compelled to call attention to the numerous errors contained in the article upon spectrum analysis contained in your issue of Oct. 15. In brief, the article has two prominent faults. Firstly, questions of fact in spectral science are incorrectly stated; secondly, much more is claimed for it as a medico-legal reliance than the true facts warrant. These two propositions I shall endeavor to substantiate by quotations from the author's paper, followed by comments.

Page 529, speaking of the Fraunhofer lines, our author says: "Kirchoff left us a map of these, a masterpiece of correctness and skill, containing many hundreds of sun lines, and our distinguished Rutherford has photographed them right from the sun itself. The exactness of these two mappings is truly wonderful." The facts are, that only a comparatively small number of lines in Kirchoff's maps are coincident with those in Rutherford's photograph, due to the fact that the whole mass of lines from A to about F, on Kirchoff's map, could not be obtained photographically by Rutherford's processes, and the additional fact that the immense number of lines, more refrangible than the line H, which are found in Rutherford's, belong to the ordinarily non-visible portions of the spectrum, and were not seen by Kirchoff. A similar error is committed in reference to Prof. Henry Draper, who "has given us a map containing a great number of sun lines, invisible under ordinary circumstances; these additional lines are made evident at both the red and violet part of the spectrum." The fact is, Draper's photograph shows no lines in red, orange, yellow, or green, for reasons known to every photographer and physicist.

Further on, our author speaks of the waves of sound, heat, and light as being produced in the all-pervading ether, and differing from each other simply in velocity: "The vibrations least in velocity produce sound, those coming next produce heat, and those having the highest degree of velocity produce light"!!!

Surely any schoolboy would have told him that the

waves of sound are produced in the atmospheric air, and that its particles have their motion in the same direction in which the waves progress; while the vibrations of heat and light take place in the luminiferous ether, and that the particles of this ether move in a direction at right angles to that in which the waves are progressing. The eloquent description by Dove, of the iron bar swinging at the rate of "billions of oscillations per second," is a little too imaginative.

Page 531, speaking of the extreme sensitiveness of spectral analysis, he says: "This sensitiveness led to the discovery of *five* new metals." Bunsen discovered in this way cesium and rubidium, Crookes discovered thallium, and I forget who discovered indium; but what is the fifth new metal, and who discovered it?

Speaking of the crystals of hæmato-crystalline he says: "No putrefactive process can annihilate their integrity. Their stability, and indestructibility admirably fit them," etc. The fact is, that like all bodies possessing a complex chemical composition, they are very liable to undergo decomposition. I need hardly say that it is almost impossible to keep this substance, whether in crystals or in solution, unaltered for any length of time. Exposure to ordinary atmospheric influences, to say nothing of acids, alkalis, etc., invariably affects it.

In the next paragraph our author says: "We will find that these qualities of hæmato-crystalline are of the greatest importance in medico-legal cases. When the outer form and integrity of the blood-corpuscles have been destroyed by the various means which the criminal may find within his reach, and when the microscope sends our questions back unanswered, it is yet perfectly practicable to produce the crystals."

The fact is, that crystals of hæmato-crystalline can only be obtained from fresh, and not from dried or chemically altered blood.

Page 534, he says that the criminal who burns the body of his victim will not thereby escape the searching scrutiny of the spectroscope, for spectral examination of the ash will reveal the presence of "sodium potassium, lithium, *caesium*, *rubidium*, and calcium."

Let me ask, Will not the ash of a dog's remains yield the same spectrum, especially if he has been drinking of the waters of *Durkheim*?

Farther on he says: "When called upon to analyze a metal or mineral poison, we must bring it to a high state of incandescence." The fact is, that all incandescent metals give the same, that is, a continuous spectrum. It is necessary, first, to vaporize them, or some of their salts, especially the chlorides, and then to render their vapor incandescent before we can obtain *distinctive* spectra.

Page 535, speaking of the Wharton trial, he regrets that the "analytical powers of the spectroscope were not brought into requisition. There could not have been an assailable point to the answer which the spectroscope would have given to the question, whether the substance found was arsenicum, antimony, or gelsemium." Will our author inform us what the spectrum of gelsemium is, and whether we are to obtain it from its ash or its solution?

Page 536, he says: "It is evident, and held so by physicists abroad, that no blood examination is perfect and unassailable that is not verified by spectral analysis, and that no conscientious verdict should be given, and no judgment of death pronounced in cases of poisoning, without the positive proofs attainable from the same source."

In the first place, the extreme delicacy of the spectral test would render it unsafe as a medico-legal resource

in the case of the metallic and mineral poisons; and it remains yet to be shown that any of the vegetable poisons can be taken into the system, and after death extracted from the tissues in a condition to be demonstrated spectroscopically.

HENRY G. PIFFARD.

New Instruments.

A NEW UTERINE SPECULUM.

By ALEXANDER S. HUNTER, M.D.,

NEW YORK.

THAT a speculum is chiefly needed for the purpose of facilitating intra-uterine applications and investigations, it is believed will be acknowledged.

It will then follow that such an one is needed as will, without pain, remove that "troublesome angle" formed by the diverging axes of the uterus and vagina, and as will fix and retain the uterus and vagina in the relative position thus required without the aid of an assistant.

Although we have scores of varieties, that we have not yet an instrument offering these advantages is my apology for adding to the number one having them in view.

It is an instrument made to operate on the principle of the fulcrum and lever, with the patient in the supine position, and utilizes to accomplish its object certain points of support and bearing afforded by the female genitals.

Reference is here made to the posterior aspect of the cervix, the posterior portion of the sphincter, to the perineum, and to the vagina at its anterior uterine attachment.

The instrument consists of two blades, viz., a superior and an inferior, which are of equal length, but so united that the open extremity of the upper blade projects beyond its fellow one-fourth of an inch. In this respect it differs from all other instruments of its kind, and necessarily, for the reasons which follow: 1st. If the extremities of the blades are of equal length, then, with the instrument inserted, its blades separated, and the perineal extremities depressed, while the open extremities are elevated,

they will carry upwards also the vagina and cervix. Now the under blade will occupy the horizontal, and consequently the shortest distance from vulva to cervix, ought it not, therefore, to be the shorter? Again, since the upper blade has to take the oblique, consequently the longer distance from vulva to cervix, and since it is essential that its extremity should support the cervix, does it not follow, therefore, that it ought to be the longer? 2d. With a longer under blade, is not the uterus not only left in its normal position, but absolutely held there by the pressure downwards of the blade in the cul-de-sac? and does not this add to the angle and additional embarrassment in intra-uterine therapeutics? If it were the office of the speculum instead of the index-finger to diagnose positions of the uterus, or if it were simply required of it to expose the anterior aspect of the cervix, then there might be a reason for such construction.

The upper blade is also wider at its middle third, that it may the more thoroughly lift the convex wall out of the line of vision.

Its width is reduced at its open extremity, and curved downwards, that when separated from its fellow it may not unduly strain the vagina. The under blade corresponds in width with the upper, except at its middle third, where it is one-fourth of an inch narrower.

This reduction compensates for the increase of the upper blade at this point, and secures a uniform distention of the vagina.

It also prevents the pinching of the folds of vagina on withdrawing the instrument; and since this blade has simply to oppose the posterior or concave wall, which wall at its middle third would almost of itself remain without the field, there is no disadvantage in the reduction.

The under blade at its joined extremity is curved downwards seven eighths of an inch, and so spread as to make the most of the sphincter and perineum for a fulcrum; from this projection there extends a lever one and a half inches in length, the free end of which is terminated by teeth.

The under-garment of the patient being secured by her weight, affords the power for the successful working of this lever.

With the fulcrum, lever, and power we are able to so retract the perineum, and to so elevate the upper portion of the vagina and the cervix as to remove entirely the angle formed by the diverging axes. If the patient be fleshy, more power will be required to elevate the vagina and cervix; happily for us, we then have the power applied at a more advantageous angle.

The open extremity of the under blade is curved upwards for three reasons: First, That it may the more readily traverse the posterior or concave wall of the vagina, when separated from its fellow and depressed at its other extremity by the lever. Secondly, That it may not unduly distend the vagina at its uterine attachment when the blades are separated. Lastly, and chiefly, That it may impinge against the posterior aspect of the cervix and carry it upwards. It is thickened at this extremity, and so rounded as to distribute the pressure, rendering its use as painless as possible. The blades are shorter than those of other instruments, that the uterus may be brought as near as possible to the vulva. They are, however, long enough for any and every case, since they are so thoroughly maintained in the vagina by the lever; or if it be desired to leave the uterus in its normal position (not using the lever), then by the projection on the under surface of the under blade, which passes just within the sphincter.

That the instrument may answer for all capacities of vagina, the blades are narrow at their joined extremity, and are so united as to form, when separated even to a slight extent, an ovoid opening through the sphincter; the largest operating capacity with the least possible distention of the sphincter is thereby secured. Professor Dunster has also called attention to the advantage which this form affords.

A word with reference to the use of the instrument, as above described, may be of service. Having placed the patient in the supine position, with the shoulders slightly elevated, and ascertained by the touch the position of the os, carefully insert the instrument on its side, through the sphincter, carry its extremity up to within an inch of the cervix, rotate it to its proper position, and separate its blades about one and a half inches. The instrument may now be pressed inward, in the direction of the cervix, or partially withdrawn, and returned again and again, if need be, until the cervix is found to have taken its place between the blades.

This can be done without producing pain, since the extremities of the blades are terminated by approaching curves.

If the uterus be anteverted, then its cervix may be lifted into the field of the speculum by the aid of a sound slightly inserted in the os externum. If a fold of vagina should surmount the extremity of the under blade, so as to prevent the cervix from occupying the field, then carry the handle of the sound or other broad instrument along the upper surface of the under blade until it reaches the cul-de-sac, which will cause the fold to recede beneath the blade. Now flex the pelvis on the vertebral column. This position, even on a couch ill-adapted, can be secured either by placing a book or other support under the pelvis, or by flexing the thighs so as to form with the trunk a right angle, which position the patient can for a short time herself maintain by grasping with either hand the upper third of each tibia. The cervix and upper portion of the vagina may now be so elevated, and the perineum so retracted as to make the common axis of the uterus and vagina form one and the same straight line, and may be so maintained without producing pain, and without the aid of an assistant, by simply attaching the teeth of the lever to the garment of the patient.*

Not having the angle with which to contend, we need not widely separate the blades, and may therefore spare ourselves the annoyance of the protruding vaginal walls, and our patients the pain to which they have been so often subjected by indiscriminate and rapid dilatation. We should not forget to give the muscular fibres time to relax. Are we not in a measure ourselves responsible for the horror which so many females have for the use of instruments, and if so, might not their more cautious use add to the number of cures, and consequently reduce the number of those who now continue to suffer their maladies, rather than, like the woman with the issue, "suffer many things of many physicians?"

363 BROOME ST., Sept. 19th, 1874.

DR. CHARLES FAYETTE TAYLOR, of this city, has been elected Corresponding Member of the Medical Society of Vienna.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from October 19, 1874, to November 4, 1874.

HEAD, J. F., Surgeon.—S. O. 229, c. s., A. G. O., relieving Surgeon Head from duty in Department of Dakota, is revoked. S. O. 237, A. G. O., October 31, 1874.

STIMMERS, J. E., Surgeon.—Assigned to duty as Medical Director of this Department. G. O. 19, Department of the Platte, October 24, 1874.

THE following named officers will report in person to the President of the Army Medical Board, now in session in New York city, for examination for promotion, and, upon its completion, rejoin their respective stations:—Assistant Surgeons A. Hartuff, J. H. Janeway, J. R. Gibson, J. M. Brown, H. E. Brown, and Elliott Cones. S. O. 233, A. G. O., October 27, 1874.

KNICKERBOCKER, B., Assistant Surgeon.—To report in person to the President of the Army Medical Board, now in session in San Francisco, California, for examination for promotion, and, upon its completion, rejoin his proper station. S. O. 233, c. s., A. G. O.—Assigned to duty as Post Surgeon at Fort Colville, W. T., when relieved by Assistant Surgeon Bartholf. S. O. 149, c. s., Department of the Columbia.

NOTSON, W. M., Assistant Surgeon.—Assigned to duty as Post Surgeon at Fort Cameron, U. T. S. O. 162, Department of the Platte, Oct. 30, 1874.

KINSMAN, J. H., Assistant Surgeon.—Leave of absence further extended fifteen days. S. O. 237, c. s., A. G. O.

BARTHOLF, J. H., Assistant Surgeon.—Assigned to duty as Post Surgeon at Camp Harney, Oregon. S. O. 149, Department of the Columbia, Oct. 23, 1874.

CRONKHITE, H. M., Assistant Surgeon.—Relieved from duty in Department of the South, to report in person to the President of the Army Medical Board, New York City, for examination for promotion, and upon its completion, to the Commanding General Department of Arizona for assignment to duty. S. O. 233, c. s., A. G. O.

HEIZMANN, CHARLES, Assistant Surgeon.—Granted leave of absence for 15 days. S. O. 162, c. s., Department of the Platte.

WHITE, R. H., Assistant Surgeon.—To report to Lieut.-Col. Brooke, 3d Infantry, commanding troops in New Orleans, La., for assignment to duty. S. O. 162, Department of the Gulf, October 13, 1874.

DE HANNE, J. V., Assistant Surgeon.—To report in person to the President of the Army Medical Board, now in session in New York City, for examination for promotion, and, upon its completion, to the Commanding General Military Division of the Atlantic for assignment to duty. S. O. 229, A. G. O., Oct. 23, 1874.

ROSE, GEO. S., Assistant Surgeon.—Relieved from duty in Department of Arizona, to report in person to the President of the Army Medical Board, New York City, for examination for promotion, and upon its completion, by letter to the Surgeon-General. S. O., 233, c. s., A. G. O.

CARVALLO, C., Assistant Surgeon.—Assigned to duty at Fort Stanton, N. M. S. O. 166, Department of the Missouri, Oct. 14, 1874.

* Sims' speculum diminishes the divergence of the axes by retracting the perineum, to do which it generally, however, requires the aid of an assistant with a tenaculum, and always the gravity of the viscera in the position employed adds to the divergence which is to be overcome.

ELMBREY, F. W., Assistant Surgeon.—Granted leave of absence for six months, with permission to go beyond sea. S. O. 224, A. G. O., Oct. 28, 1874.

MATTHEWS, W., Assistant Surgeon.—Assigned to temporary duty at Fort Hamilton, N. Y. H. S. O. 213, Mil. Div. of the Atlantic, Oct. 28, 1874.

WOODRUFFE, E., Assistant Surgeon.—To report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, to the Commanding General Mil. Div. of the Atlantic for assignment to duty. S. O. 224, A. G. O., Oct. 16, 1874.

DICKSON, J. M., Assistant Surgeon.—To report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, to the Commanding General Department of the South for assignment to duty. S. O., 233, c.s., A. G. O.

Medical Items and News.

DR. RICHARD W. BULL.—At a regular meeting of the Roman Medical Society, held October 19, 1874, the following resolutions were adopted:

Whereas, Since the last session of our Society, death has for the first time invaded our circle and has stricken from our roll of members the name of our very dear associate, Richard W. Bull, be it

Resolved, That we unite in offering to the family of our late member the assurance of our deep sympathy, not in the hope that we can lighten the burden of their grief, but as an expression of our claim to share their sorrow, as sincerely as we mourn the loss of him who was dear to us as a devoted friend, and known to all as a true man in the fullest meaning of the name.

Resolved, That these resolutions be entered on the minutes of the Society, that they be published in THE MEDICAL RECORD, and that a copy be sent to Mrs. R. W. Bull.

Committee.—Walter de F. Day, President; Woolsey Johnson, Henry C. Eno, Thomas T. Sabine.

MEDICAL BOARD OF BELLEVUE HOSPITAL.—The Commissioners of Public Charities and Correction have increased the Medical Board of Bellevue Hospital from sixteen to twenty members by the appointment of Drs. William T. Lusk, William M. Polk, C. A. Budd, and Abraham Jacobi.

NEW YORK HOSPITAL.—The library of this institution having been removed to No. 8 West Sixteenth street, and conveniently arranged in elegant and spacious apartments, is now open to the profession. Through the liberality of the governors its free use for consultation and reference is granted to all visitants of this city and from abroad who may be known to or are properly introduced to the librarian. One of the rooms is devoted exclusively to periodicals, embracing those of Great Britain, Germany, France, and the United States; these will be added to from time to time so as to make this department as complete as possible.

To render these and the numerous other works which belong to the library fully available to the profession, the governors have made the most liberal provision, and hereafter the rooms will be open at the following hours, viz., 10 to 12 M.; 1½ to 5 P.M. and 7½ to 10 P.M., daily.

THE VANDERBILT UNIVERSITY AT NASHVILLE, TENN., has a Department of Medicine and Surgery. The first course of lectures commenced this fall.

MEDICAL CHARITIES IN ST. LOUIS.—There are thousands and tens of thousands of people in our large cities who, if they can get medical attendance and medicines gratuitously when sick, and quarters in hospital if disabled by accident or disease, will never provide for a day ahead, but spend half their earnings at dram-shops (for the number of which St. Louis has an unenviable reputation). The more charity, the more left for whiskey; and the more whiskey, the more charity needed; until the city is given over to saloons and charity institutions; one-half of the population engaged in making drunkards, and the other half working hard to take care of them.—*St. Louis Medical Journal*.

VIVISECTION.—The following preamble and resolutions were adopted by the Medical Society of the County of Westchester, at the meeting held at White Plains, October 20, 1874:

Whereas, The Medical Society of the County of Westchester, in common with the profession of the State, recognizing the benefits which have accrued from the judicious experimentation upon the lower animals in the interests of society and humanity, and

Whereas, It is believed an effort is to be made before the next Legislature to repeal or alter that portion of the existing laws of this State which permits "any properly conducted scientific experiments or investigations;" therefore

Resolved, That this Society believes that the repealing or alteration of said laws so as to interrupt in any way the present existing facilities for scientific investigation will result in arresting the progress of discovery of the varied phenomena of life, and the causes and prevention of disease.

Resolved, That in no department of physical science has greater progress been made than in Physiology and Pathology, and that no discoveries have conferred greater blessings on mankind than those embraced within their domain, exemplified in the brilliant discoveries of HARVEY, AMBROSE PARE, and JENNER, the many illustrious savans of the continent and our own country, all of which have been made and established through the important and indispensable aid of vivisection of the lower animals. That such investigations are conducted without unnecessary pain or wanton cruelty, and usually with the aid of anesthetics.

Resolved, That the members of this Society, duly appreciating and honoring the wisdom of the framers of our existing laws relating to this important subject, earnestly desire that they may continue unchanged, that the progress of research and discovery which has hitherto distinguished our State may not be interrupted. Unanimously adopted.

WM. H. HELM, M.D., *President*.

J. FRANCIS CHAPMAN, M.D., *Secretary*.

OFFICE THIEF.—There is a man who makes it his business to call upon physicians at odd hours, and, of course, appearing disappointed in not finding the "doctor in," writes a note in the office. One such individual is known to be a sneak thief, and answers the following description: Age 28, 5½ feet high, dark complexion, red cheeks, black eyes, small black moustache, and short black side-whiskers, wearing round black hat, calico shirt and red stripe, large dark brown overcoat.

While waiting or writing, unwatched, this person has stolen many valuable articles from physicians. We advise our readers to be on the look-out for this person and allow him to wait in their office until a policeman is sent for.

Medical Department of Life Insurance.

THE INFLUENCE OF CERTAIN EMPLOYMENTS UPON THE HEALTH OF THOSE ENGAGED THEREIN.

By DR. LUDWIG HIRT,

OF BRESLAU, GERMANY.

(Translated by R. PERCY ALDEN, of New York.)

THE EFFECTS OF ZINC VAPORS ON WORKMEN ("BRASS-FOUNDERS' AGUE.")

Greenhow, Med. Times and Gaz., Vol. i. p. 227. 1812. — *Schützer*, Fieber bei Messinggiessern, Preuss. Vereins-Zeitung, N. F. V. 25. 1862. — *Husenmann*, a. a. O. S. 929. 1862. — *Greenhow*, Med. Chir. Transact. xxv. p. 177. 1864. — *Lévy*, Traité d'Hygiène publique et privée, vol. ii. p. 929, ff. 1869.

THE cause of the affection in question was for a long time an object of dispute: while Plaseller, who distinguished it by the name of "brass-workers' dust fever," believed that it existed in consequence of the inhalation of zinc-dust, Blandet, Bequerel, Greenhow and others supposed that it might be brought into connection with the vapors of zinc. The probability of this view will become almost a certainty by observing that workmen who are exposed to the influence of zinc-dust, without inhaling vapors, are never subject to the "brass-founders' ague."

It remains now only to ask, Whether the vapors of zinc alone, or together with those of other metals, cause a tendency to the disease? We have often noticed in various places that the workmen in zinc-furnaces, in other words, people who breathe scarcely anything but vapors of zinc, remain almost entirely exempt from the disease, while those workmen who are engaged in casting—brass-workers, brass-founders, girdlers, etc.—acquire it very frequently.

Now, whether it is the copper fumes which are formed simultaneously with the fumes of brass, which work together to cause the origin of the trouble, or whether the ultimate cause of "brass-founders' ague" is to be sought in the arsenic which is contained in small quantities in the zinc, is not yet easy to determine, while we for our part do not hesitate to pronounce the "brass-founders' ague" to be an acute case of metal poisoning caused by the fumes of zinc and copper.

The author has twice in his own person, and repeatedly in brass-founders, observed the symptoms and course of the disease somewhat as follows:—

Some hours after a person has attended the casting a peculiarly uncomfortable feeling all over the body is noticed, pains in the back (more or less severe), and a general lassitude necessitating retirement from one's customary occupation; while the pains shift, now to this side, now to that, and annoy in the highest degree, there is nothing remarkable to be observed either in the pulse or in the respiration. However, in a short time—usually soon after the sufferer has gone to bed—chills set in, which soon increase to a violent ague lasting a quarter of an hour or longer; in such cases the pulse within half an hour or an hour reaches 100 to 120 beats per minute. A tormenting cough, with a sore sensation in the breast, appears, and a pain in the forehead, increasing more and more with the violent spasms of the cough, makes the situation unpleasant in the highest extreme. Soon, however—at most after a few hours—the turning-point of the disease is

reached; profuse perspiration marks the beginning of the stage of deservence, and during a gradual disappearance of the symptoms the sufferer falls into a deep sleep, from which he awakes either cured or at least convalescent—only a general lassitude and slight headache reminding him of what he has undergone.

Running its course in this way, the "brass-founders' ague" appears very frequently, and at least 75 per cent. of founders, etc., have to undergo it once or oftener.

Whoever has once had it, enjoys the pleasing prospect of getting it again at every casting. It probably never happens that one gets accustomed to the danger; only very few individuals, as a rule, enjoy immunity from it.

The *diagnosis* is at times difficult, if the moment of seizure be not known, and the mistake is commonly made of confounding it at its commencement with a violent attack of intermittent fever; its further progress will soon show the error. Further mistakes are owing to the rapidity with which the complaint disappears;—at the second visit of the physician, the patient is found restored to health,—scarcely conceivable!

The *prognosis* is absolutely favorable when no complications are present, and entire restoration of health follows, at the latest, in forty-eight hours.

The "brass-founders' ague" does not require any special treatment. Hot milk is given for the troublesome cough, and experienced founders partake of it in large quantities on the day of casting, under all circumstances.

No means of preventing the breaking out of the disease are of any avail.

THE EFFECTS OF VAPORS OF SALT ON WORKMEN.

Hazel, Fr., De Valetudine salis coctorum. Altorf, 1731.—*Hulfort*, a. a. O. S., 606. Berlin, 1845.—*Trautwein*, Der Salinenprocess, die Arbeiter in den Salinen u. deren Krankheiten. Casper's Vierteljahrscr. Bd. VIII. S. 17. 1855.—*Hirt*, L., Ueber die Gesundheitsverhältnisse der Salinenarbeiter. Wien. med. Wochenschr. 7. Jahrg., No. 88, 89. 1867.

By the term "vapors of salt" we mean the air prevailing in rock-salt mines, and in the boiling-houses of salt-works, and which may be recognized by a person unused to it by its salty taste. There is also to be mentioned here the air prevailing in the neighborhood of "drying-houses," chemically changed by the evaporation of salt-water—the "drying-house air"—which through a relatively considerable amount of salt particles is characterized by free muriatic acid, arising from the decomposition of the chloride of potash of the salt-water. The influence which this salt vapor has upon the workmen has been frequently misunderstood and over-estimated. When we learn from Italian physicians, such as Ramazzini, Lanzouini of Ferrara, and others, that workmen become cachectical and dropical from the inhalation of vapors of salt; when Daniel Drake ("A Systematic Treatise, etc., on the Principal Diseases of the Interior Valley of North America," etc., Cincinnati, 1850) informs us that the refiners in the American salt refineries suffer from diarrhoea and defective composition of the blood, these statements must easily excite our wonder, and cause us to reflect that in these diseases, if otherwise the observations of this widely extended professional research are correct, atmospheric influences are perhaps to be taken into consideration.

The condition of health of workmen breathing vapors of salt bears witness, as we have frequently had

opportunities of verifying, to the fact that the kind of air in question has absolutely no unfavorable effect on the organism, and that there are no diseases which are alone referable to this cause. Our researches, undertaken in this direction, refer to the rock-salt workers in Stassfurt (1872), and to the salt-mine workmen (driers and refiners) of Reichenhall (1867) and Schönebeck (1872).

Among the Stassfurt workmen the state of health is generally very good, and hugh diseases especially are very rare; there is likewise nothing unusual to be observed in the way of diseases of the digestive organs; and only when a thick mass of powder-smoke is collected in the galleries, in consequence of heavy blasts, do the workmen complain of nausea, headache, etc.—slight inconveniences, which certainly have no connection with vapors of salt. For actually harmful influences in this branch of industry, see Hirt, "Krankheiten der Arbeiter," vol. ii, p. 162.

The examination of the salt-miners furnished similar favorable results, especially that of the driers, who are not obliged, like the refiners, to work in a high, steady temperature, 82° to 89° Fahr., with considerable bodily exertion. While in consequence of this we noticed in the latter, occasionally, general lassitude, languor, indolence, a paleness of the face, etc., the state of health of the former, who live under the influence of vapors of salt, was certainly remarkably good. Neither diseases of the respiratory nor digestive organs were to be observed among them. On the contrary, their health is better and more lasting than that of any other class of workmen.

THE EFFECTS OF OIL-FUMES ON WORKMEN.

Ramazzini's Abhandlung, bearbeitet von Ackerman, Bd. I. S. 28 ff. u. Bd. II. S. 214 ff. 1780.—Hilfart, a. a. O. S. 605. 1846.

In order to study the effects of fumes of oil upon workmen, and especially to determine whether, as a consequence, particular forms of disease are developed, it is necessary to distinguish between the fumes which the *fat oils* and those which *volatile oils* produce in the course of their extraction and manufacture.

Let us dwell for a moment on the former class, and if we take rape-seed oil as a specimen of the kinds of oil most frequently used, we shall find that in the reduction of this oil a peculiar smell is diffused all over the working-rooms, which is by no means agreeable to these unaccustomed to it. It moreover frequently happens that during the first hour of their stay, sensitive persons suffer from headache and nausea, and often vomit. From this fact we must not, however, conclude that any pernicious effect of the fumes is noticeable among workmen used to the oily atmosphere.

Ramazzini was the first (and is, doubtless, the only one) who has complained of the dangerous consequences of the fumes of oil, and astonished us with the information that the workmen suffer from coughs, choking-rheum, vertigo, and cachexy.

Our own investigations, which were made in very extensive oil-works, have in this particular led to an entirely opposite result, and we are not able to corroborate Ramazzini's assertions in the slightest degree.

On the contrary, it seems to us more than probable that the fumes found in oil-works possess certain curative influences, as, for example, they are able not only essentially to reduce bronchial catarrh, but also to prevent it. Individuals who enter the works weak in body, narrow-chested, and greatly disposed to catarrh, soon become sensibly stronger and able to

withstand outside influences, such as change of temperature, etc.

These favorable changes, which, as we often have opportunities of observing, are produced in the systems of workmen during their employment in oil-works, we believe may be ascribed solely to the influence of fumes of oil.

Whether these observations which we have communicated may perhaps be of value, in a therapeutic point of view, we leave undecided.

The influence which the fumes of volatile oils exercise upon workmen manifests itself in quite a different way from that first described. While we take it for granted that the technical part of the process of manufacturing them is understood, let us observe that in this branch of industry there are still other influences besides those in question which are pernicious to health, and which require consideration, and it is possible that in this way the poorer state of health of the workmen can be accounted for. But the vapor of volatile oils by itself alone is not unimportant, even if our investigations have not been made to their usual extent, and furthermore have been confined to a few works in Leipzig, still they have assuredly taught us that, 1st. There is nothing to be perceived here of the favorable (?) effect of the fumes of fat oils; and, 2d. That certain conditions of ill-health, if they are not developed by, yet owe their origin to, the fumes of volatile oils. These appear to relate chiefly to the nervous system, and are soon discovered in general lassitude, headache, nausea, etc.

We can state nothing further concerning the relative frequency of these diseases among workmen, except that in the works visited by us, they certainly appeared very rarely. According to statements of workmen, the state of affairs seems to be essentially the same in other works which, for easily understood reasons, were inaccessible to us. Further investigations on this subject seem to be urgently needed.

THE EFFECTS OF FUMES OF TURPENTINE ON WORKMEN.

Roche, Ueber Vergiftung durch Terpentin-dämpfe, l'Union, 36, 1856.—Marchal de Caléil, Vergiftung durch Terpentin-dunst, l'Union, 32-35, 45, 1856, und Ibid. 150, 1857.—Liersch, Zur Vergiftung durch Terpentin-dunst, Casper's Vierteljahrschr., Bd. XXII. S. 232, 1862.—Husmann, a. a. O. S., 423, 1863.—Chevallier, Des dangers qui peuvent résulter du séjour dans les localités où l'essence de Térébenthine ou d'autres produits analogues se trouvent en expansion, Ann. d'hyg. publi. II, Sér. xx., p. 95, 1863.—Eulenberga, a. a. O. S., 453, 1865.—Schuler, Die glaserische Baumwollenindustrie, Vierteljahrschr. f. öffentl. Gesundheitspflege, Bd. VI., Heft i., S. 103. Braunschw., 1872.

Among the so-called soft resins and balsams which produce the solutions of resin in volatile oils, there is none better calculated to interest us than turpentine. It is not only because it has found a widely extended use in manufacture and art, so that it figures in numerous trade-industries, but also on account of the influence which the handling of this substance exerts upon the health of the workmen;—a highly interesting study, to which attention was called half a century ago.

Patissier was the first who, in 1822, gave it as his opinion that people who were obliged continually to breathe the fumes of turpentine were apt to suffer from various disorders, especially coughs and attacks resembling colic.

Soon afterwards a few, then numerous observations

corroborated this opinion, and gradually, on every side, the conviction was created that the fumes of turpentine exercised an evil influence on the system, and were perhaps even directly poisonous.

Although Marchal de Calvi never entered upon casuistic discussions, and although their number was by no means inconsiderable, yet the question would not have been soon decided, had not trustworthy observers (Chevallier, Lévy) established that they had discovered a remarkably fine condition of health in works where turpentine fumes abundantly prevailed, and that no traces of colic, nervous troubles, diseases of the respiratory organs, etc., were there to be found. After the path of physiological experiment on animals had been trodden (by Liersch) without obtaining any other decided result than that the fumes in question exercised an unmistakably evil influence on small mammals, even so far as to cause death in consequence, it seemed to the author to be eminently proper, departing from the usual custom, to use human beings themselves as objects of experiment, and to study the effects of the various kinds of inhalations.

In order to decide rightly upon the causes of ill-health arising from the breathing of fumes of turpentine, we must distinguish the effects produced upon the system by inhalations of a comparatively great quantity of turpentine, lasting but for a short while, from those of long-lasting, often-repeated inhalations of but comparatively small quantities of turpentine.

Inhalations lasting but for a short time have the following effects, as the author has observed them in his own person, as well as in a number of workmen: While at first they accelerate the respiration and circulation (pulse 92, breathing 26, in a minute), there soon follow slowness of breathing and later slowness in the movement of the heart. After the inhalation has lasted several minutes, dull headache, tingling in the ear, an inclination to vomit, appear. After the inhalation is concluded (gauze-mask, 20-25 drops of the oil of turpentine, inhaled from 10 to 12 minutes), considerable lassitude, nausea, sickness, and inclination to vomit remain; the odor of violets in the urine was not noticed. From these symptoms it follows that inhalations of short duration, in which a comparatively small amount of turpentine is absorbed by the system, always exercise an evil influence on human beings (of course excepting cases where it is employed therapeutically), and at first the breathing and the movement of the heart will be affected, and with larger doses the brain, and perhaps the spinal marrow also. Stupor occasionally precedes a "stage of exaltation."

The influence which long-continued inhalations (lasting uninterruptedly for an hour at a time and often repeated) exercise on the organizations of workmen we may state from observations made by us on twenty-one workmen, as follows:

1st. In a quantity of cases (about twenty-five per cent.) the fumes act harmfully, principally on the organs of respiration. Some weeks after beginning work a cough appears, accompanied by pain in the breast; the workmen become thin, and (provided that their labor has been uninterrupted) show after some months all the symptoms of a chronic destructive process in the lungs.

In these cases the opinion of Lombard is undoubtedly correct, that pulmonary consumption often occurs in consequence of breathing the fumes of drying oil and varnish.

2d. In a few cases a lasting pernicious effect upon the canals of the stomach and intestines is produced.

We think that many of the assertions made as to

this should be received with caution, because the employment of turpentine often supposes the simultaneous action of lead upon the system (varnishers, painters, etc.), and the symptoms resembling those of colic which then appear, such as constipation, with severe pain in the stomach, may be more readily ascribed to the influence of lead than to that of turpentine.

In the twenty-one cases examined by us, no one complained of serious disorders of the digestive canal arising from the breathing of fumes of turpentine, yet the possibility of such a connection is not to be questioned.

Schuler (compare Lit.) has noticed cases of that nature.

The uropoietic system is sometimes sympathetically affected. Ischuria, as well as hæmaturia (Harris and Colton), although rare, have been several times observed after inhalation of turpentine.

3d. As to what concerns the effects on the brain and spinal marrow, these inquiries, in view of the symptoms just described, must be of little importance, for even if most workmen, at the commencement of their labors, suffer from headache, *muscæ volitantes*, *tinnitus aurium*, etc., yet these are symptoms which, unless they increase so much as to cause anxiety, soon disappear.

4th. In about ten per cent. of all cases, where the mere inhalation of the fumes of turpentine was under question, we noticed absolutely no pernicious effects whatsoever caused thereby. Among our workmen were two (one house-painter and one color-grinder) who had worked for a long time in an atmosphere of turpentine without being in the slightest degree affected. Here belong the observations of Lévy, and the (not very numerous) cases of people inhabiting rooms freshly painted in oil without any injury to their health.

If we now connect together the results of our observations, it will be found that long-continued, oft-repeated inhalations of fumes of turpentine but slightly concentrated, often cause no evil effects whatsoever; should they however do so, they will affect the lungs most frequently and severely, less frequently the stomach, intestines and kidneys, and the brain and spinal marrow never.

NOTE.—The fumes which asphalt—a black shining resin, made by gradual oxidation of petroleum—creates in its manufacture, were for a long time thought to be prejudicial to the health. In the work of Krauss and Piehler (*Encyclopädisches Wörterbuch der Staatsarzneikunde*, Bd. I. S. 158) we find an article expressing itself somewhat in that sense; and also in a treatise on the boiling of asphalt in the open air (*Archiv der Deutschen Med. Gesetzgebung*, III. 24), we read something similar. Nevertheless this is not the case; the fumes which arise in boiling asphalt (for the repairing of pavements, etc.), cannot be considered as injurious to health, as observations in English and Scotch establishments have taught us. Even in the case of the workmen who are employed at the kettles, and who are most exposed, there is too small an amount of irritation produced by the fumes of asphalt on the organs of respiration, to cause any deterioration of the health. On the other hand, we have frequently observed, as for instance at G. M. & Co.'s works at Glasgow, where one hundred workmen are constantly engaged with asphalt, that these fumes exert a healthful influence on bronchial catarrhs, which have sprung from causes occurring at other times, and that, in consequence of this, patients suffering from protracted catarrh have been ordered by their physicians to try an atmosphere of asphalt. Let it be remarked

in passing, that their labor, which is performed for the most part in the open air, is not only consistent with good health, but rather contributes to the fine physical condition of the workers in asphalt.

THE NORMAL MAN.

By EDWARD H. SIEVEKING, M.D.*

WERE insurances effected upon every member of the community indiscriminately, and did every company take its due proportionate share, the risk and the result could be calculated with absolute certainty, as the duration or prospect of life of each member of the community can be accurately determined. But the nature of our social relations makes it necessary that the lives taken by insurance companies should be selected lives, and that they should approach as nearly as possible to a standard of perfect health.† Although in all well-regulated States the statistics referable to the entire population are reliable even to minute details, the individual is subject to accidents which cannot be foreseen or calculated, and therefore, as only a limited number of people appreciate the value of life insurance, and there are always many who would be willing to benefit themselves to the detriment of the insurance company, it is necessary that the latter should be on its guard against involuntary deception or actual fraud. A company that took no precautions as to selecting average lives, would, as has been repeatedly the case, soon find its assets incapable of covering its liabilities. And one of the first conditions of successful life insurance business is, that there should be no doubt as to its being at any time able to fulfil its engagements towards those who have invested their money in premiums with a view to securing for themselves or their successors a stipulated benefit.

It is equally to the interest of the insurer and the policy-holder that every guarantee should be obtained that the latter offers all the conditions of good health, which means that he possesses no hereditary taint, and that his organs and functions are in a condition to enable him to bear the wear and tear of life without unnecessary detriment. He should approach as nearly as possible the ideal or typical man, the limit of whose age may reasonably be assumed to lie somewhere between 70 and 80.‡ Practically it is impossible to insure perfect health in a large number of insurers, though Dr. Fleming and others show that in the aggregate their rate of mortality is lower than that occurring among the general population. The influences that we are all subject to, owing to the hereditary impress we receive before birth, the neglect of sanitary laws, the friction we undergo in our passage through life, the labor and anxiety associated with existence, impair in the individual, to a great extent, the standard of perfect health, which theoretically may be attained. For this deviation the tables of insurance premiums are calculated to make due allowance; for if there

were not a proper margin for the accidents of life, no insurance business could be safely conducted, and it is, even with that condition, necessary to have large averages, in order to secure permanence and stability.

Before proceeding to the consideration of those elements which impair the prospect of life and diminish the working capabilities of our organism, it may be well to devote some space to the examination of the conditions which constitute perfect health, and of the means at our disposal to determine their existence. It is the departure from these conditions that constitutes the real difficulty of the medical referees of life insurance associations, who are bound to reverse the legal theory that every man is innocent until he be proved guilty, and to assume that every candidate for insurance is more or less un sound until his physical health is conclusively established.

We cannot regard the individual as self-contained. From the earliest history of man the influences imparted by progenitors to their descendants have been recognized; and though such influences may be neutralized or modified by training and education, they will ever imperatively demand a large share in the estimate of individual quality and character. The Mosaic account of the origin and development of the Jewish race has a red line of genealogical doctrine running through it, which presents features of the greatest interest to the student of mankind; while the "*Potes creantur fortibus et bonis*" of Horace is only one of the many instances of a recognition of the same principle by profane writers of antiquity, which has received larger and more scientific treatment by philosophic inquirers of recent times.

For the purposes of life insurance it is necessary to determine the existence and the character of hereditary influence from three aspects. The evidence obtainable may be derived from preceding generations, from collaterals, and from descendants. It has been too much the custom to pay regard only to the vital power of progenitors; but, important as this point is, we shall find, when discussing special morbid taints, that the health of collaterals offers very valuable indications as to the health of an insuree, which are not afforded or not accessible when the former alone is examined. The condition of descendants, in the nature of things, does not so frequently assist in determining the health of their predecessors, because, though theoretically of similar import, the age of insurers generally militates against this element becoming an item in the calculation of their vital power. Apart from the actual health of the progenitors, physiological conditions come into play, that frequently determine the viability of their offspring, some of which at least are readily ascertainable. To these belong the relative ages of the parents at the time of the insuree's birth. Great disparity of age is justly regarded as exercising a prejudicial influence, even though other points are favorable. Blood relationship, again, which in this country is not a bar to marriage in degrees that physiologically are objectionable, leads to the production of a sickly offspring, which may not at the time of insurance have exhibited any failure of power, but which nevertheless would be less capable of resisting morbid influences, to which they must sooner or later be subjected. It is this power of resisting disease, the *vis unita*, to which in all cases the medical referee's attention requires to be specially directed. The actual malady or morbid taint is comparatively easy of detection, but the gauge that is to test the insuree lies in the means of estimating his ability to undergo the heat and burden of active life,

* An extract from his work entitled, *The Medical Adviser in Life Assurance*. London, J. & A. Churchill. 1874.

† For details connected with, and in illustration of, this train of thought, the reader will do well to refer to an admirable treatise by Dr. J. G. Fleming, of Glasgow, entitled *Medical Statistics of Life Assurance*. Glasgow, 1862. The work is unfortunately out of print, and we have had much difficulty in obtaining a copy for reference. In a careful analysis of the deaths and causes of death occurring in thirty-six years in the Scottish Amicable Society, Dr. Fleming places before his readers numerous interesting and important conclusions, some of which we shall take the opportunity of reproducing in our pages. This agrees with the scriptural threescore years and ten; but it is to be observed that in Genesis (vi. 3) the days of man are promised to be one hundred and twenty years. Flourens and Buffon are both of opinion that the natural term of existence is one hundred years.

and to ward off or bear with impunity the noxious influences which he cannot altogether escape.

In the increasing intercourse among the nations of the world, and the intermarriage between different races, considerations may be expected to arise, which, with the spread of life insurance to the dependencies of Great Britain, will merit future discussion. The deterioration of race in various parts of the globe has already attracted attention, and it is an acknowledged fact that the burgher population of Ceylon, descended from the earlier Dutch settlers, no longer presents the sturdy characteristics of their forefathers. As yet, fortunately, we possess no analogous declension in any British community; but the locality of birth, even where the parents are healthy, already deserves the attention of the medical referee in the examination of English lives. Whether, in the course of time,* a change in the habits, and the adoption of hygienic measures not yet appreciated, may modify the effect of climate, remains to be seen; but for the present it is an undoubted fact that the healthy children of healthy English parents, born in tropical regions, after a few years pine away, and, unless sent to temperate zones, lose the vigor which is their inheritance. The longer their return is delayed, the greater will be, *ceteris paribus*, the impairment of vital power, which, apart from actual disease, will tend unfavorably to modify this susceptibility to disease, and to diminish their prospects of longevity.

As regards temporary residence in various countries, it is questionable whether, in the present state of social intercourse, and with the improved methods of communication and sanitary appliances of all kinds, it can be considered as affecting life insurance prejudicially. Messrs. Bailey and Day† show, in opposition to Dr. Guy, that the members of the peerage enjoy a high average duration of life, and remark that the male lives of that class enter the army and navy in large numbers, travel extensively, and are more exposed to what assurance offices consider extra risks than the middle classes. They infer that differences of climate have less effect on human mortality than differences of occupation and position in life, and that, as the offices do not attach much importance to the latter, they might relax somewhat in their estimate of the former. We willingly adopt the corollary without the reason assigned, for we hold that offices ought to be more particular than they are in considering the influence of occupation on the expectation of life.

Physically, as well as morally, the child is undoubtedly "the father of the man." Everything, therefore, that aids in the normal growth of the infant, materially affects its future well-being. Hot-house plants, and plants over-stimulated by rich manure, are the exact prototypes of children reared in a manner calcu-

lated to anticipate the normal periods of development. The laws of nature are not difficult to read that bear upon this matter; and were it possible to go into the question of early training of our applicants for insurance, we should doubtless be able to fix, with greater certainty than we now possess, their future chances of life. I allude more particularly to the feeding of infants,* to the prejudicial influence of hand-feeding, adopted for various reasons to which it is unnecessary to allude here, in lieu of the only physiologically correct food for infants, the maternal milk. During the later periods of childhood, the employment of artificial stimuli of all kinds, physical, emotional, and intellectual, largely impairs brain-growth, muscle-growth, blood-growth, either by a development of one part of the organism at the expense of another, or by directly stunting the entire process of nutrition.

We need scarcely dwell longer on the aspects of childhood in reference to life insurance at present. Although some offices present an attractive feature with reference to early insurance, by which the premiums are returnable if death occurs before the age of 21, this very arrangement renders as close an investigation into the antecedents of the child less necessary than it becomes during the periods of life after growth is completed, and when applications for insurance are most largely made. But when manhood is established, the question of the extent to which, within the limits of health, variations of structure and function may exist, become of paramount importance; and it is here that we particularly look for a standard of comparison by which to determine the departure from the typical man, without recognizing a positively morbid condition.

The remarks that follow are chiefly the result of observations made upon members of that somewhat complex race to which the modern Briton† belongs; and as he is not regarded as inferior to any of his contemporaries, whatever is true in him may be applicable to mankind at large.

The period of complete manhood is fixed by law at 21; but physiologically this is certainly not universally correct, for although development may be regarded as accomplished in every respect at this age in the healthy English female, and vertical growth may have terminated even in the male, a man's vital power cannot be regarded as having attained its maximum development until about the age of 30.‡ For some years after the youth has ceased to grow, in the ordinary sense of the word, the dimensions of his chest, the great index of vital power, continue to expand, and numerous are the instances derived from military experience, showing that recruits at the age of 20 are unable to undergo the fatigue of active service that is borne with impunity by men of a more mature age§. They are literally not as yet well knit

* That such an anticipation is reasonable is borne out by facts already at our disposal: thus it is found that although, according to the sanitary report of the Bengal Presidency for 1871, the death of European children in the plain of India, amounts to 91 per 1,000, the mortality at a school in Rajpootana, in existence since 1851, on Mount Abu, has only been 8 per 1,000. The site of the school is 4,500 feet above the level of the sea, and enjoys a mean temperature of 60° F. In order to show the contrast between the ordinary mortality of English children brought up in England and India respectively, we annex the following tabular statement of their death-rates, compiled by Dr. Fayer (*Brit. Med. Journ.*, May 3, 1873):

	England.	India.
Under five years.....	67.58	148.10 per 1,000.
Five to ten years.....	8.81	17.73
Ten to fifteen years.....	4.98	11.51

We experience some doubt as to these numbers being correct, as the mortality for the children in England is manifestly too low; but Dr. Fayer's authority stands too high to doubt the general results to which the table points.

† Upon the Rate of Mortality amongst the Families of the Peerage.—*Insurance Magazine*, July, 1861.

* Those who wish to study the laws governing the nutrition and development of the child, are particularly referred for valuable information to Dr. Edward Smith's elaborate work on *Health and Disease*, as influenced by the Daily, Seasonal, and other Cyclical Changes in the Human System. London, 1861.

† This term is used advisedly, because there are observed differences between the three chief divisions of the inhabitants of Great Britain: when, if the term, Englishman were employed here, it might lay the writer open to the imputation of wishing to ignore features indicating a physical superiority of the Scotchman or the Irishman. For the purpose in view, such a distinction would be unnecessary.

‡ Quetelet (*Sur l'Homme et le Développement de ses Facultés*, Paris, 1855) shows that the growth of man cannot be regarded as universally complete at the age of 25; see his *Tables de Mesurement* taken on inhabitants of Bruxelles, vol. ii, p. 13. Quetelet also gives tables showing the completion of female growth at 20, and the completion of male growth at 30.

§ For detailed information upon this point, the reader is especially referred to Professor Aitken's work, *On the Growth of the Recruit*: 1862.

together. Several important bones are not perfectly consolidated, and it may be specially mentioned that the sternum, which has to bear so great a strain in labored respiration, and is specially taxed by the weight of the soldier's knapsack, is not converted into a single plate of bone until after the thirtieth year. It is not until the sixth quinquennial period of life that our leading anatomical authorities find that the following events, connected with the consolidation of the skeleton, took place:—1. Completion of the vertebral column; 2. Completion of the sacrum; 3. Coalescence of the third with the second piece of the sternum; 4. Completion of the ribs; and 5. Coalescence of the haunch-bones with their crests.

The average height of an Englishman brought up under favorable circumstances is 5 feet 9½ inches, which is notably above that of the average Belgian, Frenchman, or Italian. The height of the average English female appears to be about 5 feet 2 inches.* It would be difficult to fix the limits at which height and health are incompatible. The downward range is certainly larger than the upward range, which appears due to the fact that the vital organs, the heart, and the chylipoietic viscera do not keep pace in development with the muscular and osseous systems of persons exceeding the normal elevation. We more frequently meet with people of diminutive stature, with a perfectly equable development of external and internal organs, who, for purposes of life insurance, would offer every reasonable guarantee for their viability, than with men and women materially exceeding the average stature, in whom some invalidating element in the organs of sanguification, circulation, and innervation may not be traced. *Ceteris paribus*, the small person is more easily nourished, and if, at the same time, the respiratory function is well carried on, which we shall shortly see is one of the most assured signs of vigor, he is on the whole better adapted for the warfare of life than his overgrown neighbor, to whom, possibly, he may look up with envy.

We will next examine the bearing of the weight of the individual upon health. Here we find, normally, a progressive increase from birth to the decline of life, which must not be regarded as identical with development, as we have seen that the full growth of the body reaches its acme in the third decennium of life. The increase of weight that takes place at a later period is due to the accumulation of fat under the skin and in the cavities of the body, and, as is well known, very commonly assumes morbid proportions, which often affect the life insurance value of the individual. From birth† the male sex exceeds the female, both in size as well as weight, and this prevails throughout life excepting, according to Quetelet,‡ at the age of 12, when the weight of both is the same; but it appears, according to the same authority, that the female attains her maximum of weight at a later period of life than the male.

According to Liharzik,§ the normal growth of the human body is completed at the end of the twenty-fifth year. He estimates the mean height of a "growing lad" at 18 years at 163 centimetres, or 64.17 inches, and that of a man who has completed his normal growth at 68.9 inches.

The average weight of a young Englishman of 21 is 151 lbs., but the table in ordinary use to determine

the normal height and weight of applicants for insurance is given for the age of 30, at which there is already an increase upon the former estimate; it will also be seen that the average increase per inch of stature above 5 feet is 5½ lbs., although the range of variation at different heights is greater than might have been supposed *a priori*.

Although the standard supplied by the table in general use may be regarded as a valuable indication of the individual's health, it must not be relied upon alone as a test of his suitability for insurance. Considerable variations occur within limits that do not impair the prospect of longevity; but where they are marked, greater care is requisite to determine the value of other points that bear upon the viability of the person under examination. Such variations depend upon race, employment, age, habits of life, sex, and temperament, which, from the absence of sufficient data, it would be impossible to formularize, but which, nevertheless, are roughly taken into consideration in estimating the value of a life. We all know that a Scotchman does not yield in bodily or mental vigor to the Englishman, yet experience teaches us that the average weight of the former is less than that of the latter.* Dr. James Forbes, when Professor of Natural Philosophy in Edinburgh, examined 800 students with reference to their physical development, distinguishing the natives of England, Scotland, and Ireland. He found the law established that development in every respect increases between 14 up to 26 years of age, but that the increase became slower as the age advanced. Our Scotch friends will be pleased to hear that, tested by Regnier's dynamometer, Scotchmen were superior to Englishmen in tractile power. This being measured by pounds, gives for

Englishmen at the age of 20 to 55,	366 to 384 lbs.
Scotchmen "	374 " 404 "
Irishmen "	397 " 413 "

Sedentary occupations, with an ample food-supply, tend to increase the weight, while it is reduced by employment involving continued open-air exercise and a tax upon the muscular system. An undue diminution of weight would be regarded with more suspicion early in life, as indicating impaired nutrition, and taken with any symptom, not by itself adequate to raise a doubt, that tended in the same direction, might justify rejection. On the other hand, an abnormal elevation of weight when manhood is established, though compatible with health if the occupation and mode of life be healthy, may imply a tendency to fatty degeneration, or to apoplectic affections where the concurrent circumstances are not equally favorable. In all these questions a certain latitude is unavoidable, and what is technically called circumstantial evidence must guide the inquirer in arriving at a conclusion. Dr. Purdon, in a recent pamphlet on life insurance, following Dr. Brinton,† allows a variation of 20 per cent. as compatible with health. This may be exceptionally true, but, practically, it is found where early deaths occur from constitutional disease that a smaller variation than this implies ought, at the time of insurance, to have attracted attention and commanded an increased rate, although no other indication of a hereditary or constitutional taint existed. Our own experience leads us more and more to regard the table as a valuable aid in determining the value of an applicant's life, and we regard with suspicion any material departure from the law it appears to involve.

§ Law of Increase, by F. B. Liharzik, M.D.; 1862. See also Aitken's Growth of the Recruit, and Dawson in *Statistical Journal*, March, 1862.

Any sudden change of weight demands still more careful consideration than a habitual departure from the normal standard. It may, as in an obese person, be the result of an illness that restores a healthy state of things, but it is more frequently the forerunner of disease; when it takes the form of reduction, we look for some morbid taint that induces wasting, as consumption; where it runs in the opposite direction, the prospect of life may be affected by alcoholism, by degeneration of the vessels, leading to cardiac, renal, or cerebral mischief, or by some analogous impairment of the nutritive powers.

Of all the points bearing upon the present health and the future prospects of an individual, there is probably none that exercises a greater influence and more deserves our attention, than his respiratory power as indicated by the development of his chest and its contents. It is fortunate that we possess more perfect means of gauging the power of the thoracic viscera, than are applicable to any other viscera of the body. We can not only measure the external dimensions of the chest and determine the physiological movements of its walls, but we are able to watch the process carried on within, by the stethoscope and by percussion, by the spirometer, and by the sphygmometer, with results that amount to almost absolute certainty. In the ordinary inquiries necessary for life insurance, it is scarcely practicable to bring all these methods of research to bear upon every candidate for insurance. But there can be no doubt that, were we not afraid of frightening the customer, or were time no consideration, a more careful application of the various tests of pulmonary capacity would prevent many lives from being passed as normal that now become claims at an earlier period than the medical examiner and his Board of Directors had reason to anticipate. Respiration and life may be regarded as synonymous, and we find that vital power may be measured by the manner in which the functions of respiration are carried on. Hence the stress that medical men, and even popular opinion, lays upon the value of a well-developed chest, which affords an indication of what Mr. Hutchinson was the first to term the vital capacity of the lungs. In ordinary quiet respiration the thorax is neither fully expanded, nor fully emptied of the contained air. To measure its entire capacity—*i.e.*, to determine the whole amount of air which it is capable of taking in and discharging in one respiratory act—it is necessary that a forced inspiration and a forced expiration should be made. Even after the latter act a portion of "residual air" remains in the lungs, which is entirely independent of the will, and always present in the chest. Mr. Hutchinson terms the air of ordinary respiration "breathing air;" that of forced inspiration "complemental air;" and that of forced expiration "reserve air." The following table shows how widely previous observers had differed as to the quantity of air belonging to each of these divisions. They regarded

Residual air as ranging from 40 to 360 cubic inches,	
Reserve air	77 170 "
Breathing air	" 3 100 "
Complemental air	" 119 290 "
Vital capacity	" 190 560 "

These discrepancies were due to Mr. Hutchinson's predecessors not having had regard to a variety of collateral circumstances which ought to be taken into account in estimating the process of respiration. These are especially the power of the muscles concerned in respiration, the circumference of the chest, the height and weight of the individual, the pulse, the number of respirations, and the age.

For a description of the methods, and especially of the spirometer, an instrument for measuring the air expelled during expiration, as well as for many details of great interest, we must refer the reader to the original paper by Mr. Hutchinson. It will suffice for the purpose of the present work to extract some of the chief practical results which he has attained.

The mean results of spirometrical measurements of the vital capacity of 1,923 men, belonging to different classes of society, arranged according to height, together with their mean weights, are compiled in the following table, from which it will appear that there is a definite increase of vital capacity closely proportionate to the increase in height:

Mean Vital Capacity of 1,923 Men belonging to different Classes of Society.

Under 5 ft.	155 cubic in.	92-96 weight in lbs.
5 ft. 0 in. to 5 ft. 1 in.	175	115-52
5 " 1 " " 5 " 2 "	177	124-23
5 " 2 " " 5 " 3 "	189	127-86
5 " 3 " " 5 " 4 "	193	138-01
5 " 4 " " 5 " 5 "	201	139-17
5 " 5 " " 5 " 6 "	214	144-93
5 " 6 " " 5 " 7 "	221	141-29
5 " 7 " " 5 " 8 "	228	152-59
5 " 8 " " 5 " 9 "	237	157-76
5 " 9 " " 5 " 10 "	246	166-10
5 " 10 " " 5 " 11 "	247	170-86
5 " 11 " " 5 " 12 "	259	171-45
Over six feet	276	218-66

The mean for all heights being 217 cubic inches.*

When vital capacity is compared to weight, without reference to height, we fail to find the same progressive ratio of the respiratory power; thus the mean vital capacity of 147 men weighing 11 stone was 225 cubic inches; while that of 12 men of 14 stone only showed an increase of 8 cubic inches; so that, if there is, as we believe, a correlation between vitality or vital power and vital capacity, the man of lower weight has, *ceteris paribus*, the better prospect of longevity.

The vital capacity is found to increase from the age of 15 to 35, whereas from 35 to 65 it is decreased in the progression of 19, 11, and 13 cubic inches. It is remarkable, that although there is an exact relation between the circumference of the chest and weight, with which it increases in the exact arithmetic progression of 1 inch for every 10 lbs., Mr. Hutchinson was unable to find any such definite relation existing, as might be reasonably inferred, between the circumference of the chest and vital capacity. This result is so much opposed to the teachings of anatomy and vital dynamics, that although we cannot doubt the correctness of Mr. Hutchinson's observations, we think there must be some underlying fallacy dependent upon unobserved influences, or upon an insufficiency in the number of cases examined. Some of the points in his investigations have been confirmed in a remarkable manner by those of Dr. Balfour,† to whose researches we shall have an opportunity of alluding again, when we examine the bearing of spirometry upon chest-disease in connection with life insurance.

Very few remarks on the organs and functions of the body that we have not yet alluded to will bring to a close what we have to say in this chapter on the subject of the average man. There are no special tests by which we determine the healthy condition of the brain, or the abdominal viscera, as bearing upon life insurance. The absence of any morbid taint, which will form the subject of future chapters, must be taken as negative evidence of health, which is otherwise in-

* The weights in the above table are the results obtained from a different and larger number of men than those examined for their vital capacity.

† Contributions to the Study of Spirometry, by J. G. G. Balfour, M.D., F.R.S.—*Medico-Chirurgical Transactions*, 1890.

dictated by those evidences of normal development which we have recently discussed.

The decline of life commences at periods which vary with the variations of hereditary and acquired vigor of the individual. Any exhausting influences that sap the powers of innervation or nutrition in youth or manhood will cause a premature senility, which, without actual disease, impairs the prospect of life of the individual. As a general rule, it is found that persons who have borne the battle of life well, and have passed the climacteric unscathed, are good subjects for insurance. The higher rates are, of course, calculated for the probable duration of life, but the casualties from unforeseen disease are smaller than occur during the earlier decennia. Women have passed the dangers incidental to their sex, and men are no longer exposed to temptations and dangers which beset them in the heyday of youth and early manhood.

Miscellaneous.

LONGEVITY.—Sir Duncan Gibb, M.D., LL.D., then read a paper upon "Longevity at Five Score Eleven Years." He said he had brought forward nine examples at previous meetings of the association of persons who had overstepped the century by several years, and now his tenth instance was that of a female still living at Tring, in Hertfordshire, who attained her hundred and eleventh birthday in April last. Tables were quoted containing 84 instances of persons whose age extended from 107 to 175; 40 of these were under 130, and 44 above that age, and the author considered that three-fourths of the total number might be taken as correct. The proof of that was the instance he brought forward of Mrs. Elizabeth Leatherland, now alive and in her 111th year, her baptism being recorded in the register of the parish of Dover, in Kent. This was confirmed by the drowning of her son and his family, and other persons to the number of 37, at Hadlow, in Kent, in 1853, in the hop country, by a catastrophe mentioned and described in the papers of the time. Her son was then fifty-nine, and if now alive would have been eighty, his birth occurring when his mother was twenty-nine or thirty. Other corroborative circumstances were stated, clearly establishing the great age of the old dame, who was of gypsy descent. The author then described her condition, the result of a careful personal examination at Tring, in October, 1873. She walked with the aid of a stick, was short in stature, bent with age, complexion brownish, countenance a series of thick folds, and she had several sound teeth. She chatted away continually in a clear, distinct voice, and was in possession of all her faculties, though somewhat impaired. She was a little deaf, and took snuff; her skin was as soft as velvet, and her hair quite gray. She was thin, and the muscles of her neck stood out in bold relief. All her internal organs were in perfect health—lungs, heart, etc.—and her pulse was as regular and as soft as in a girl of eighteen. In fact, the changes of old age as met with in persons from seventy to eighty had not taken place in any of the tissues of the body, being thus similar to the nine other cases examined by the author. She was, of course, feeble; but, taking all things together, that did not prevent her reaching to her present exceptionally great age. Her age, the author said, taught us two lessons—one was the absence of small changes for the most part in centenarians, which was the chief reason of their attaining to such a great age; the other the occurrence now and then

of instances wherein even six score years is reached, if not more. To ignore all past cases of extreme ultra-centenarian longevity because we cannot get at their proofs at the present day, he considered unphilosophical and unscientific, for there existed as conscientious and painstaking inquirers after truth then as exist now, whose statements and recorded facts must not be wholly ignored, as every honest investigator well knows.—*The Doctor.*

RECENT ACTION OF PHYSICIANS IN GERMANY.—One of the principal tasks of the German Medical Association, during its recent session at Eisenach, June 10, 1874, was to remove, if possible, the grounds for the unpleasant relations which have hitherto existed between the medical examiners and the life insurance companies. As is well known, this feeling of dissatisfaction had reached such a pitch that a number of medical societies, especially those of the Grand Duchy of Baden, passed resolutions refusing out-and-out to furnish family physicians' certificates to life insurance companies. By mutual concessions on the part of the companies as well as of the physicians, it was decided at Eisenach to abide by the following rules:—

1. The written consent of the applicant was invariably to be obtained before calling upon the physician for a certificate; and this consent was to be so worded that the physician would feel himself at full liberty to testify without reserve regarding the applicant's past and present physical history.

2. The printed questions of the certificate were to be framed in such a way that the physician could answer them without having an interview with or examining the applicant.

3. The physician was invariably to send his certificate directly to the main office of the company, and under no circumstance to deliver it to an agent or any third party.

4. This certificate was to be considered by the company as a confidential communication from the physician.

5. The regular fee (5 reichsmark = $\$1.25$) for this certificate was to be paid in all cases by the company. Upon this basis peace has at last been restored between the companies and the physicians.—*Deutsche Versicherungs-Zeitung.*

In the meantime a Committee appointed for that purpose is preparing a form of application and medical examiner's report, which, if adopted by the Chamber, will prove an important step toward collecting valuable medical statistics. Our only regret is that a blank similar to the one now under discussion was not put in use years ago, as in that case we should now be able to work out the answers to many interesting medical questions.

INEBRIETY AND INSANITY.—According to the most recent reports of the Scotch Insane Asylums, out of 615 cases of insanity, 149 (24 per cent.) were demonstrably due to the immoderate use of alcoholic drinks. These figures show how great an importance life insurance companies should attach to moderation in the habits of those whom they propose to insure.—*Deutsche Versicherungs-Zeitung.*

THE CHAMBER OF LIFE INSURANCE.—No decision has yet been reached on the different medical questions which have been brought before this body for consideration. An adjourned meeting will be held during the present month, when the discussion of these questions will be resumed.

Original Lectures.

AN OUTLINE OF THE PHYSIOLOGY OF
THE NERVOUS SYSTEM.*

By E. C. SEGUIN, M.D.

GENTLEMEN:—In thinking of a subject to present to you in an introductory lecture, it occurred to me that a good one would be a sketch, very much condensed, of the anatomy and physiology of the central nervous system, to serve as a basis upon which we can, during the winter, build up a knowledge of diseases of the brain. I shall be very brief upon the individual heads of the lecture, wasting no time upon matters which are not capable of bearing a logical relation to pathology.

Before entering upon the subject proper, I wish to say a few words, intended to give you a clearer idea of the relation of medical to general knowledge. I mean to warn you against the error which it must be said some of the books in your hands tend to strengthen and perpetuate, viz., the separation of physiology from pathology, and the confounding of the latter with pathological anatomy. If we look at the matter from an extra-medical or philosophical point of view, we are led to classify our knowledge of the animal body into two categories: statical and dynamical knowledge. In other words, we study the animal organism and its parts in a state of rest, and in a state of activity; we observe the form and constitution of parts, and determine their properties and functions.

The study of the human body and its parts in a state of rest is called anatomy, in the broad sense of the word, making it to include chemical and microscopical analysis. Anatomy is spoken of as normal (with many subdivisions) when it describes the healthy parts and tissues; as pathological or morbid when it treats of the changes produced in tissues and parts by disease.

Our dynamical knowledge, embracing the study of the properties and functions of the parts we have anatomically analyzed, is called physiology; and this must, like anatomy, be separated into two great subdivisions—physiology, strictly speaking, and pathological (or morbid) physiology, or pathology. The activities we observe in abnormal (pathological) states are not different in kind from those which pervade the organism in health; nor are the laws of derivation and utilization of these activities different from the laws which operate in the normal body. By close analysis we find that in diseased states, as in health, physical and chemical laws govern the frame, and that essentially the results of their operation are the same. It can, I believe, be demonstrated with all but mathematical exactness, that the great law of conservation and correlation of force is supreme in the disordered and in the perfect animal organism. There is and can be no entity of disease, no demon. Even therapeutics can be brought into accord with this conception of medical knowledge; for our medicines and remedial agents are only means by which we aim to act upon the human body in such a way as to modify the shape or constitution of its parts, and to alter the mode of activity of its tissues and organs. And although the *modus operandi* of most medicines is obscure as yet, I think it not rash to say that medicinal agents do not act in any super-

natural or occult way, but by the laws of physics and chemistry.

The study of the physiologist, and of the pathologist as well, begins with the nutrition of simple tissues, single cells, or even masses of protoplasm; and upon such a study, as a basis, there is built up the more complicated and elaborated knowledge of the activities of the human body which the practical physician needs so much at the bedside.

A consideration of what I have said will, I trust, lead you to admit two propositions: first, that we physicians are in reality naturalists, studying what we call disease by natural and scientific methods; second, that the most excellent physician must be the man who (contrary to a vulgar prejudice), together with a practical turn of mind and a sympathetic nature, has the greatest amount of scientific knowledge at his command.

I have thus apparently gone out of my way in order to help you in viewing this lecture as a logical whole, an imperfect attempt to give you a guiding plan in your studies of diseases of the nervous system.

The subject of the lecture is naturally divisible into three parts.

1st. A study of the elementary parts of the central nervous system—their anatomical attributes and physiological properties.

2d. A study of the organs and apparatuses in the central nervous system, and their functions.

3d. A summary of the chief modifications of the properties and functions which constitute the symptomatology of disease.

1. The part comprising the nervous centres may be classified as follows:

- A. Bindweb (neuroglia).
- B. Bloodvessels and lymphatic spaces.
- C. Nerve fibres { myelinic.
- { amyelinic.
- D. Nerve cells (ganglion cells).

A. The bindweb, gentlemen, is the framework in which lie the strictly nervous elements of the nervous system; it incloses and supports nerve fibres, nerve cells, and bloodvessels. Its histological composition is that of a fibro-connective tissue, according to the latest observations. In it we meet with bundles of connective-tissue fibres, with exceedingly delicate fibrillae of fibrous tissue, and with more or less altered cells lying often at the point of meeting of the fibrillae. The fibrous fibrillae are more immediately in relation with the nerve-fibres and cells, while the connective tissue, constituting the septa and the cortical layer of the spinal cord, are united at the periphery with the pia mater, or innermost membrane of the three surrounding the brain and cord. The bindwebs of the brain and spinal cord are similar in kind, but the cerebral fibro-connective tissue is much the more delicate. The statements that there is a "granular matter" in the neuroglia, or that it is a sponge-like tissue, I believe from personal observations to be based upon inexact observations. At any rate, it suffices for our purpose to know the bindweb as a form of connective tissue, containing nuclei which may be the starting-point of proliferation changes tending to truly pathological or to reparative changes.

B. The bloodvessels of the nervous centres are very abundant, and are in many respects peculiar. The capillaries are by far more numerous in the gray matter of both encephalon and spinal cord than in the white substance. The larger vessels all reach the nervous organs through the pia mater. The rarity of anastomoses between the arteries in the cord and brain is a most striking feature, and is closely related with

* A lecture introductory to clinics upon Diseases of the Nervous System, delivered at the College of Physicians and Surgeons, New York, on Saturday, October 2d, 1874.

pathological processes. The non-capillary vessels are remarkable for the relatively extreme development of their muscular coat. The greatest peculiarity presented by these vessels, however, consists in their having an outer sheath, constituting a canal separated from the vessel by a small amount of fluid. All the vessels of the cerebro-spinal mass are thus inclosed. These so-called perivascular canals are made up of very delicate connective (structureless?) tissue, and contain a fluid very analogous to lymph. The perivascular canals are an extension into the parenchyma of a vast system of lymphatic spaces which surround the nervous centres, the so-called sub-arachnoid space in the meshes of the pia mater around the brain and spinal cord. This arrangement has been known for several years; and we now know, by the recent investigations of Ranvier and Axel Key, that the same sub-arachnoid or lymphatic space extends outward with every cerebral and spinal nerve to its termination. You should imagine the nervous system—brain, spinal cord, and their nerves—as floating in lymphoid fluid, contained in a delicate connective-tissue envelope. Even in the eyeball and internal ear these lymph spaces have been demonstrated. We are only beginning to appreciate the bearing of these important anatomical discoveries to pathological processes. It has been stated that nerve cells, in the cerebral convolutions especially, are surrounded by a similar lymphatic space—an extension of the one described—but this is, I am convinced, an error of interpretation, the space seen having been produced by the shrinkage of the cells under certain modes of preparation.

c. Nerve fibres. Several classifications of nerve fibres are in use, but the simple one of two classes—myelinic and amyelinic—will suffice for us physicians. By the term myelinic nerve fibre is meant a complete nerve fibre, one consisting of three parts—a central body or axis cylinder, a surrounding mass of fatty substance, the myelin, and a structureless enveloping sheath (the membrane of Schwann). In some parts of the nervous system the last element is absent. The amyelinic fibre is simply a naked axis cylinder. You see from these definitions, that the essential part of the three is the axis cylinder, the other two, which may be called insulating, are superadded. The amyelinic fibres are met with in the gray substance mostly, but are also abundant in the sympathetic nerves. We find myelinic nerve fibres, without the membrane of Schwann, and varying infinitely in size, in the white columns of the spinal cord, and in the white substance of the encephalic mass, constituting the bulk of these parts. There are also such fibres, though minute ones, in the gray substance of the cord and brain. The peripheral parts of the nervous system, all the cerebral and spinal nerves, and a part of the sympathetic, are made up of the second variety of myelinic fibres—those which have the three parts.

A peculiarity of nerve fibres is that they extend independently of each other, *i.e.*, not anastomosing, from their origin to their distribution, from nerve-cells in the central nervous mass to peripheral organs; and this isolation of nerves, together with their insulation, explains a physiological attribute to which I shall call your attention. I should add that forty years ago it was believed that nerve fibres extended from the brain to the outer parts of the body, and that the spinal cord was chiefly a bundle of nerves. Progress has strongly tended to take this supremacy away from the brain, to show us the importance of the spinal cord as a centre; and we now believe that nerve fibres once in the spinal cord run only a comparatively short distance before uniting with nerve-cells.

n. nerve cells are the noblest elements of the nervous system; those which possess the power of generating force in the modern acceptance of the phrase, *i.e.*, the property of evolving nerve force out of chemical activity. They are found in greatest number in the brain, spinal cord, and sympathetic nervous system—aggregations of them constituting gray matter or ganglia. Nerve cells, wherever found, consist of organized matter, call it protoplasm if you will, not inclosed in any cell membrane, sending out prolongations or processes of various shapes and lengths, containing a globular body called the nucleus, which itself incloses a smaller body termed the nucleolus. These nerve cells vary in size, in shape, and in the number of their processes. The largest ganglion cells are met with in the anterior gray horns of the spinal cord in its lumbar and cervical enlargements. In the ox, cells taken from these localities are almost visible to the naked eye. In the floor of the fourth ventricle (medulla oblongata) and in certain parts of the base of the brain large cells are also found. The smallest cells recur in the gray matter of the cerebral convolutions, and in parts of the medulla oblongata. As regards shape, four subdivisions may be recognized: polyhedral, pyramidal, oval, and round. The first are met with in the same location as the largest cells; the pyramidal are nearly restricted to the cerebral convolutions; oval cells are found in the median and posterior parts of the gray matter of the cord, and in the medulla; round cells in the sympathetic and in the ganglia of the posterior roots of the spinal nerves. With respect to the disposition of their processes, cells are distinguished as multipolar, bipolar, and apolar. I do not believe in the existence of apolar nerve cells. Under the name of multipolar cells we include a majority of ganglion cells; those of the cerebral cortex exhibiting from three to six processes, the large cells of the medulla and spinal cord showing a great many—eight, twelve, or more. Bipolar cells are rarely seen in preparations from the human nervous centres. The separations of cell processes into two classes was an important progress. A multipolar cell sends out one stout, thick process, which extends a long distance, not subdividing, ultimately forming, with the addition of myelin, a nerve fibre. The same cell also throws off an indefinite number of processes of unequal size, which rapidly subdivide, growing smaller and smaller. The former is the "cylinder axis process;" the latter are the "protoplasmic processes," and their destination is unknown. It has been claimed that the number of processes and the size of cells afford an indication of their special functions, but that is not believed to-day. I should add that the communications between cells which you will find figured in books do not exist; and that the communication of nerve fibres with nerve cells has been demonstrated, though a very few times.

These elementary structures, while alive and forming a part of the animal body, possess certain physiological properties, some common to all, others the special attributes of individual parts. The most common of these physiological properties is that of being osmotic, *i.e.*, of allowing fluids to pass through them. This property is possessed in a very high degree by capillary vessels, by arterioles, venules, and the perivascular sheaths—the escape of material from them to the tissues, and *vice versa*, being very rapid and free. The hindweb, also, has the osmotic property in a high degree, and thus serves as an aid to nutrition as well as a mechanical support. Nerve fibres and nerve cells are undoubtedly osmotic, but to a much less degree. Wherever it exists, this important

process is under the same laws; it is only possible when liquids of different density are on either side of the membrane: its rapidity is increased by motion, pressure, heat, and chemical action, all of these being found in the living nervous centres.

Chemical changes of a very complicated sort are going on constantly in the cells and nerve fibres of the central nervous system, constituting the essence of nutrition. In a state of health the acquisition of new material by the tissues is so balanced with the separation of effete matter, that, in spite of great internal activity, the parts are maintained in an uniform (not mathematically equal) condition. We should never forget that this chemical action in myriads of parts cannot take place without producing other correlative effects, such as nerve force, heat, and electric currents.

Nerve fibres possess certain special physiological properties. In the first place, they conduct the impressions they receive, in both directions, from the central organs to the periphery and *vice versa*. This conduction is not by any means instantaneous or even very rapid, as it takes place in isolated nerve fibres at the rate of less than sixty yards per second, whereas the speed of electricity is 464,000,000 yards; that of light, 300,000,000; that of sound, 332; that of a cannon-ball, 552. In the living body the rate of transmission is from forty to forty-five yards. This conduction is done, furthermore, in a perfectly isolated way by individual nerve fibres: there is no interference between fibres on their way to and from the central organs. Nerve fibres are excitable, that is, respond to stimuli—mechanical, chemical, and electrical—by motor manifestations or by sensations when the motor or sensory filaments are experimented upon. This excitability is quite independent of the nervous centres, and is inherent to the nerve, as is shown by the fact that a nerve continues to react to stimuli for three days after its separation from continuity with the nervous centre.

Nerve cells have properties whose existence we learn in part through reasoning by exclusion, after having ascertained the properties of nerve fibres, and in part by direct experimentation. In the first place, certain nerve cells have the power of furnishing force (motor impulse) to nerves and muscles; this is called motricity by some authors. Another property of nerve cells is sensitivity, that is, the property of transforming impressions received from without by and through the sensory nerves into a sensation. That nerve cells possess a power over the nutrition of parts non-nervous, we now incline to believe; but we hardly yet dare name and define this property. But nerve cells have, I believe, yet one physiological property, viz., that of retaining impressions made upon them; a property for which I now propose the term *retentivity*. I have for some time believed that nerve cells (and other cells to a degree) do in all parts what it is acknowledged they do in the cerebral convolutions—they possess memory, or the property of registering or retaining impressions. That this is probable is shown by the fatality of numerous actions occurring a second time and oftener. The occurrence of a sensation will give rise to a flow of ideas associated with the sensation, and this under normal conditions will be repeated whenever the sensation is renewed. An action of the class, called reflex or sensori-motor, is, after its first performance, fatally repeated whenever the same initial sensory irritation occurs. A bolus of mixed foods passing down the alimentary canal provokes in a necessary or fatal way the action of various muscular, vascular, and glandular organs. The well-

known experiment of placing a drop of acid near a frog's anus, after decapitation, illustrates my view of the possession of memory by the nerve-cells of the spinal cord; for in this experiment the hinder legs of the animal are drawn up and moved in an apparently intelligent manner, in such a way as to remove the irritating acid. Three years ago, in spring lectures given here, I explained this phenomenon by saying, that the frog having during its life often performed this act for the same purpose, its occurrence after cerebral death takes place by necessity, because the same sensation is transmitted to the spinal cord. Additional proof of the correctness of this theory is to be obtained from a study of the mode of acquisition and retention of complex co-ordinate movements, such as walking, dancing, piano-playing, etc. Motricity, sensitivity, and retentivity are therefore the chief special physiological properties of nerve cells.

Let us now, gentlemen, resume our statical, or, if you please, anatomical study. The various nervous elements which I have sketched for you are combined in the living body in such a way as to constitute organs and apparatuses. The term organ I would apply to such parts as are the seat of performance of relatively limited and less important functions, while by apparatus I understand a combination of organs serving for the evolution of important and comprehensive functions. The spinal cord, medulla oblongata, pons Varolii, cerebellum, and cerebrum may be named as the central nervous organs, made up as follows: The cerebrum consists of a superficial or cortical layer of gray matter, *i.e.*, of tissue made up of nerve cells, and both kinds of nerve fibres (myelinic and amyelinic), arranged in a somewhat complicated way. This gray matter rests upon the white substance composed of myelinic fibres, which extend downward and inward to certain basal gray bodies or ganglia, the optic thalamus, and the corpus striatum; or the white substance may be described as radiating from these bodies toward the peripheral gray matter, which latter is arranged in folds called convolutions or gyri. The cerebellum has an analogous structure, with variations—the corpus dentatum as central gray body, and white substance radiating thence to the peripheral convolutions. The pons Varolii is made up of white substance on its outer and anterior parts, with masses of gray matter within. In the medulla oblongata we find an analogous structure, white matter at the periphery, and gray matter in the centre and posteriorly. The floor of the fourth ventricle contains a series of most important ganglia (masses of gray matter). The spinal cord has the same structure throughout its length—a structure best described upon a transverse section. Such a section is seen to consist of symmetrical halves, each containing a central gray mass and peripheral white matter. The gray matter is divided into anterior and posterior masses, the so-called horns, of which the anterior is the larger. The posterior horn reaches out to the margin of the organ, but everywhere else there is white substance outside of the gray horns. The shape of the gray horns and the relative proportion of white and gray substances vary in different parts of the cord, but that does not immediately concern us. From the spinal cord, symmetrical on either side, are the roots of nerves; the posterior roots being attached to the cord just inside of the posterior horn, the anterior roots issuing from the anterior mass of white matter. Upon the posterior root, just before it joins with the anterior root, we see a small swelling which is a mass of gray matter—a ganglion. The white peripheral matter is usually subdivided in each half of the spinal cord into two

parts—the antero-lateral columns, and the posterior columns—the dividing line between them being the posterior gray horn, where it strikes the periphery of the organ. A microscopic central canal runs the entire length of the spinal cord, continuous with the large openings, called the ventricles in the encephalic masses. Just at the junction of the spinal cord and medulla oblongata, in front, is seen a limited spot where bundles of white substance cross the median line, being myelinic fibres extending from the anterior column or pyramid of one side of the medulla to the antero-lateral column of the other side of the cord, constituting the so-called decussation of the pyramids.

The encephalic nerves all terminate in parts below the hemispheres and cerebellum. If I add that histologically and morphologically every part beneath the cerebrum, cerebellum, and opto-striate bodies belong to the spinal cord, it will be truthful, and of great help in our physiological and pathological studies. Ever since I began lecturing here, four years ago, I have taught this natural division of the nervous centres into the spinal axis, cerebellum, and cerebrum. Accepting this classification of the centres, we can also say that with the exception of the olfactory, all nerves are spinal, which philosophically is perfectly true.

I will now call your attention to certain great functions of the central nervous system—functions which involve the entering into activity of large tracts of nervous tissue extending over one or more of the organs just enumerated. I allude to the conduction of sensations, the transmission of motor impulses, the so-called reflex action, and co-ordination of movement.

In the first place, about the conduction of sensations. How are sensations formed in the spinal gray matter transmitted upward so as to be put within reach of the higher sensibility we call consciousness? To this question only a very partial answer is possible, mainly with reference to the direction of conduction. It is quite surely ascertained that a sensation originating in an irritation of the right lower extremity is perceived by the left cerebral hemisphere, and the left half of the pons Varolii. In other words, the sensory nerves, or better, the sensory paths, all cross the median line somewhere in the spinal axis. We owe chiefly to the experimental inquiries and pathological observations of Brown-Séquard the demonstration of two most important facts in this connection: (1) That these paths cross the median line (decussate) almost immediately after entering the cord, and then extend upward in the opposite half of the organ to the seat of consciousness; (2) and that it is the central gray matter, not the posterior columns, which contains these paths. This almost horizontal decussation has been shown to take place at the origin of every spinal nerve; in other words, sensory decussation is complete throughout the spinal axis. There seem to be good experimental and pathological reasons for believing that the perception of sensation (their appreciation by consciousness) takes place in the pons Varolii; though cerebral action must intervene in the most complete perception, that including recognition of cause of irritation. I cannot leave the subject of transmission of sensations without adding a few words about a great law, a proper understanding of which is of great help to us in diagnosis, I mean the law of reference of sensations. By reference of sensations we mean the fact that when a sensory nerve is irritated at any point, at its termination (normal way), its middle, or at its origin in the spinal axis, the resulting sensation is felt in the parts to which the nerve is distributed. To illustrate: If I touch the table with my two outer

fingers, I correctly refer the sensation to the vicinity of the pulp of these fingers; if I strike the ulnar nerve behind the elbow, the greatest sensation is felt in the tips of the little and ring fingers, which this nerve supplies, and if I could irritate the spinal origin of the ulnar nerve, or parts in physiological relation with it higher up, the sensation would still be felt in the district supplied by the nerve. You all are aware that persons who have lost limbs by amputation feel the absent member a good while; and they do so by virtue of this law. This law of reference of sensations holds good throughout the sensory tract (æsthesodic tract), from the special senses down.

In the second place, as regards the transmission of motor impulses from the nervous centres outward. Experiments and pathological observations have taught us that in the apparatus for motor manifestations (kinæstodic tract) there is also a crossing over of paths. The motor fibres, or better, paths which transmit impulses to the right leg traverse the median line, though in a very different way from the sensory paths of the same limb. The right half of the spinal cord contains, throughout its length, the motor paths for the right limbs and right side of trunk; no decussation takes place until the lower edge of the medulla oblongata is reached, when all the motor paths cross the median line and enter the left side of the medulla to extend upward to the cerebrum. In the medulla and the pons Varolii the motor paths cross the median line rather higher up than the origin of the motor nerves. The importance of using the word paths instead of nerves, in the present state of our knowledge, is shown in this connection, since physiology and pathology teach that there is a crossing over, while anatomy seems to demonstrate that all motor nerves (anterior spinal roots) have their nucleus of origin in the corresponding half of the spinal cord; the right sciatic nerve springing from the right anterior horn of the cord, the right hypoglossal and facial nerves from nuclei in the floor of the fourth ventricle on the right side of the median line.

In the third place, the all-pervading function of reflex action—sensory-motor, excitomotor phenomena. The following definition of a reflex action is perhaps sufficient in a theoretical sense: it consists in the transformation, by nerve cells, of a sensitive impression (with or without consciousness) into motion, chemical action, or ideas. The parts essential to the performance of a reflex action consists of a centripetal (sensory) nerve to transmit the excitation, a ganglion cell to transform it into nervous force, and a centrifugal nerve to carry the nervous impulse to the muscle, gland, or cerebral convolutions. The results of the activity of such an apparatus are motion (common muscular, or vascular), secretion, ideation. From this definition you can readily imagine that reflex actions occur in nearly every part of the body, in small segments of it as well as in large portions. A heart cut out of the animal's body will continue to beat some time in response to irritations. Contractions may be obtained by irritating a small portion of intestine removed from the body, and a small segment of the spinal cord will suffice to give reflex movements in the muscles supplied by that piece of cord. Reflex actions take place in all parts of the nervous system (spinal axis, cerebrum, sympathetic system), and at all times; and it is through this kind of action that the most important bodily functions (including in part, certainly, cerebration) are produced. There is a tendency to make all active nervous phenomena of reflex nature, denying the existence of spontaneity in the animal frame, and I must admit that a good deal can be said

in support of this extreme view. It would be quite out of place for me to enter into any details about individual reflex actions. I only ask you to remember that many mental manifestations are reflex in character; that respiration, circulation, nutrition, many acts of our life of relation (walking, etc.), are under the control of the law of reflex action; and that many diseases are produced by just the same mechanism.

Lastly, concerning co-ordination of movements. It has been thought, and that within twenty-five years, that there existed a "faculty" of co-ordination (what "faculties" have not been invented by fertile brains!) by the exercise of which our movements are regulated and made perfect. Such a view I need hardly tell you is quite opposed to present physiological and psychological notions. Simple experiments performed long ago show the absurdity of this creation of the theorizer. If the cerebellum or cerebrum be removed from an animal, it is noticed that in the animal deprived of cerebrum there is no impairment of co-ordination at any time: in the case of injury to the cerebellum inco-ordination occurs, and lasts for quite a while; but as shown by Dalton, Lussana, and Weir Mitchell, this disorder ultimately ceases. I have already referred to the experiment of putting nitric acid upon a frog's anus after decapitation, with the effect of causing perfectly co-ordinate movements resulting in the removal of the acid: which movements are so perfect as to have led one German physician at least to admit a consciousness and volition of the spinal cord. These experiments show that co-ordination is a function of many parts of the nervous centres. Another way of studying this function is by watching the physical education of an infant. At first his motions are utterly purposeless and inco-ordinate, but by degrees he acquires the power of moving groups of muscles in a definite way, and at length comes to prehend, to stand, to walk, to speak; and when older he may learn to eat, to play on the piano, to do astonishing feats of hand-skill. By analyzing this progress we reach the conclusion that parts of the nervous centres are educated by repetitions of sensory impressions and of volitional motor impulses, leaving their impress upon groups of cells (so-called centres) which have the property I propose to call retentivity: the cells acquire the "habit" of acting in an automatic, necessary way. It is, furthermore, important to notice in this connection the fact that it is impossible for us to move one muscle alone by a volitional impulse; in other words, the simplest act is co-ordinate. For example, the external rectus muscle of the right eye cannot be made to contract without simultaneous contraction of the internal rectus of the opposite eye; in willed flexion of the hand the extensor muscles contract as well as the flexors. The best theory of co-ordination, to my mind, is that which, denying all direct (continuous) connection between the cerebrum and individual muscles, admits the existence of educable or educated groups of motor cells in all parts of the spinal axis, which groups act as wholes upon the reception of a volitional impulse. We will to grasp a pen, and, after having learned, we do it without giving any attention to the details of the movements. The necessity of watching movements which should be performed in an automatic way is a serious symptom of disease.

To resume, there are four generalized functions in the nervous system.

1st. Sensation and perception are executed by means of paths which decussate almost horizontally in the spinal axis; the conduction being by the gray matter, but by the white columns of the cord; coarse sensibility with doubtful consciousness has its seat in the

pons Varolii; perfect perception and appreciations is possible only with the help of the cerebral mass.

2d. Motion is executed through motor impulses, which, starting from the opto-striate bodies (from cortex of cerebrum also?) traverse paths which decussate almost opposite the motor nerves as far down as the lower margin of the medulla oblongata, where the paths for the trunk and limbs decussate in a bundle, to remain, below this point, in that half of the spinal cord whence arise the nerves going to the muscles.

3d. Reflex action is the result of a transformation of an irritation from the periphery into nervous force by a nerve cell, transmitted centrifugally by a second nerve. That all nervous phenomena are of reflex mechanism is not to be too positively denied.

4th. Co-ordination is no faculty, but a function of every portion of the motor tract of the spinal axis from the origin of the third cerebral nerve down.

There is not time for, nor had I had the intention of, entering into an analysis of the restricted functions of the organs composing the nervous centres. Even Hitzig's and Ferrier's most interesting researches into the possible motor functions of the cerebral convolutions I must pass by, intending to speak of them in the course of remarks upon the cases which we shall study together this winter.

There are a few pathological laws logically allied to the physiological propositions enumerated above, which I want to submit to you.

1st. Any disease of any part of the nervous centres may produce two kinds of symptoms, which we should always attempt to distinguish: these being symptoms of irritation, consisting, according to the location of the lesion, in exaltation of ideas, delirium, in numbness, pain, and in spasmodic movements; and symptoms of destruction of parts, loss of mental power, anaesthesia, paralysis. Brown-Séquard was, I believe, the first to insist upon the exceeding importance of distinguishing these two classes of effects.

2d. It should be borne in mind that irritating lesions may cause the second class of symptoms by producing an inhibitory (arresting) effect upon centres near or distant.

3d. Ischemia of the nervous centres produces extreme irritation symptoms, delirium, spasms, pain, and numbness, followed by loss of function of parts.

4th. The effects of hyperaemia are not satisfactorily known.

5th. A want of equilibrium in the circulation of both hemispheres is a common cause of vertigo.

6th. Almost any lesion of the nervous centres may disturb the nutrition of distant (non-nervous) tissues.

7th. A generalized lesion of the convolutions of the brain produces, first, exaltation of mind and emotions, followed by abolition of the faculties, and a false general paralysis.

8th. A lesion of one cerebral hemisphere gives rise to symptoms (paralysis, numbness) in the opposite side of the body and face. The localization of the lesion in the left hemisphere about the fissure of Sylvius, is exceedingly likely to abolish language spoken and written; while lesions of the right hemisphere produce more severe palsy, set the emotions free, and endanger life more.

9th. A lesion of the centre of the pons Varolii will produce general paralysis, with probably anaesthesia and changes in the bottom of the eyes.

10th. A lesion in one-half of the pons Varolii will produce palsy with (probably) anaesthesia in the opposite side of the body.

11th. Lesions of the cerebellum when in one lobe

produce an incomplete hemiplegia on the opposite side, with marked eye and stomach symptoms.

12th. A suddenly produced lesion of the centre of the medulla oblongata will probably kill the patient at once by arresting the respiration.

13th. A lesion localized in one-half of the medulla oblongata will give rise to hemiplegia and anesthesia on the opposite side.

14th. A lesion at the base of the brain, not on the median line, will produce a crossed palsy (as first indicated by Romberg) ; palsy of body on side opposite lesion, and palsy of one or more cranial nerves on the same side as the disease.

15th. Pressure anywhere within the skull may affect the nutrition of the optic nerves.

16th. In lesions of the cerebral hemispheres accompanied by coma (apoplexy), the eyes are together turned and fixed toward the side of the lesion, and away from the palsied side.

17th. A lesion occupying the whole thickness of the spinal cord, or its gray matter, will give rise to palsy of all parts below the lesion, *i.e.*, below the distribution of nerves issuing from just above the lesion; and such a paraplegia is necessarily attended by anesthesia, and increased reflex movements in palsied parts.

18th. A lesion in one-half of the spinal cord (hemisection, Brown-Séquard), at any point will produce paralysis with hyperesthesia on the same side as the lesion, and anesthesia on the opposite side.

19th. A lesion involving the posterior columns of the spinal cord produces neuralgia and ataxia of movements.

20th. A lesion affecting the lateral columns of the spinal cord will cause a paralysis accompanied by contracture.

21st. A lesion of the cells of the anterior horns of the cord alone will produce a palsy (no anesthesia), accompanied by extreme wasting of muscles, and loss of electro-muscular reaction. Any part of the spinal axis may be the seat of this disease.

22d. A lesion (destructive) of nerve trunks gives rise to a paralysis with anesthesia, and rapid loss of electro-muscular reaction.

23d. A lesion in the cerebrum and the opto-striate bodies may produce secondary lesions in the spinal cord and nerves.

24th. A lesion of the spinal cord may cause secondary lesions upward and downward in the cord, and in nerves.

25th. Lesions of nerve trunks may produce secondary lesions of the spinal cord.

accomplished physicians, it is but just, frankly to give the facts and figures on which they are based. Let us gladly appeal to numbers. From the report of Dr. Aigner of his European tour, it appears that, doubtless from our vast emigration, the dispensaries of New York are the largest in the world.* The writer proposes to discuss the general treatment of pleurisy, and the use of croton-oil and the tincture of iodine as substitutes for fly-blisters, in this lowly field. His experience was mainly during several years of service as physician to the class of "Diseases of the Chest and Throat," in the New York and Eastern Dispensaries. These investigations were commenced more than twenty years since. They were principally in the first of the above institutions, which was the most venerable and extensive.

Many present will remember a quaint old brick building that then stood on the site of the present elegant edifice in Centre street, near the Five Points. A stone on the south end celebrated the date of its erection, in the last century, by the inscription, "*New York Dispensary, 1790.*" From many causes this noble charity furnished the greatest "annual crop" of pleurisy that we have ever seen. It was built, as if in honor of our Dutch ancestors, over an ancient skating-pond. Even as early as our day it was surrounded with great, filthy tenement-houses. These were filled to overflowing with weary, destitute emigrants of all nations, who were often fed on cheap refuse provisions, and lodged on cold floors with a scanty covering. The sanitary condition of that low region was awful. In some respects it was doubtless worse than that of St. Giles, London, or Cowgate, Edinburgh. At midnight in winter, it seemed like the valley of death. It was near Cow Bay, and the haunts of sin and misery. And it had underground dance-houses, with small, red windows, lit up as with Satanic flames. Here all human colors mingled in revelry, and drunken men staggered forth as if from a Turkish bath, reeking with perspiration, to sleep and sicken on frozen sidewalks.

The multitude of sick relieved by this long-established institution for our young country, was almost incredible. Its reputation had grown among all classes from its foundation, owing to the labors of many of the best physicians of your city.† From a volume of printed Annual Reports, kindly furnished by the treasurer, which we hold in our hands, we learn that during the seven years and a half of our service there, commencing with the spring of 1852, that including vaccinations, dentistry, and all its departments, it actually averaged the enormous number of over forty thousand patients yearly. For the reasons given, its percentage of chest diseases was very large. It seems from these records that within six years of strict classification, previous to the close of 1859, during which, with the exception of a few weeks, the writer divided equally with another physician the class of "Diseases of the Chest and Throat," there were entered twelve hundred and forty-eight cases as "pleuritis." This was an average of two hundred and eight annually. The male side, which we happened to have,

ON THE GENERAL TREATMENT

OF

PLEURISY, AND THE USE OF "CROTON-OIL PAINT" AS A SUBSTITUTE FOR FLY-BLISTERS.

By JOHN W. CORSON, M.D.,

ORANGE, N. J.

(Read before the New York Med. Library and Journal Association, October 23, 1874.)

CAREFUL statistics from great charities have helped to fix the real value of many remedies. When life is at stake we dare not lightly risk new things. In presenting any fancied improvements before so many

* See Annual Report of the New York Dispensary for 1863. St. Bartholomew's and other hospitals in London have very large "Out-Door Departments," but the regular dispensaries of European cities are much smaller than ours.

† Among many other well-known names, we notice on the "consulting" list, those of Drs Hosack, Post, Stevens, Willard Parker, Gilman, Bulkeley, Watson, Linsly, and Markoe; and as Attending Physicians or Surgeons, Drs. A. C. Post, Gurdon Buck, J. A. Sweet, G. F. Shady, L. E. Taylor, Purdy, James Crane, Van Kleeck, McCready, Clements, Bridson, J. O. Stone, Purple, Halstead, Elisha Harris, Stephen Smith, Bishop, Eager, Gomez, A. B. Mott, Theband, Pulling, Cameron, O'Rourke, Aigner, W. C. Corson, Kennedy, Harrison, Kelly, Murray, and many others.

would naturally rather excel the female department from greater exposure. Deducting one-sixth for the district service, this would give for our personal share, as the basis of these observations, over five hundred cases of pleurisy. To be safely within bounds, this estimate does not include the extra patients sent to our Saturday "Chest Clinique" for students, nor those of three years on the district, nor the results of three years of attendance during this period in the same class in that worthy charity the Eastern Dispensary.

From differences in the severity of the winters, or other causes, the numbers with chest affections varied. These fluctuations may be illustrated by the following table, with the result in each year, taken from the Annual Report of the year following:

NEW YORK DISPENSARY—VARIATIONS IN SEASONS.

Four prevailing Diseases of the Chest, for Six Years previous to January 1st, 1860.

Year.	Pleurisy.	Pneumonia.	Phthisis.	Bronchitis.
1859 (Rep. 1860).....	306	119	1,936	4,667
1858.....	250	192	1,286	4,374
1857.....	144	106	1,225	5,465
1856.....	131	132	865	4,057
1855.....	235	226	639	3,126
1854.....	182	274	638	1,890
Totals.....	1,248	1,109	6,719	23,529

It will be seen that "bronchitis" largely heads the list, while the sad array of consumptives comes next. As proof of care in diagnosis, there were recorded in this term a "total" of 1,175 patients with "pleurodynia," or "muscular pains" of the chest. Those interested in sanitary studies may make a more accurate comparison of these changes, with the aid of the following table, giving the entire attendance for this period:

PATIENTS OF ALL CLASSES, INCLUDING VACCINATIONS, ETC.

1859 (Rep. 1860).....	44,627	1856.....	40,225
1858.....	47,032	1855.....	59,554
1857.....	41,223	1854.....	46,052
Total.....	258,753		

Among these poor we soon learned to dread the exhaustion of large fly-blisters. Even with the hardy subjects which they seemed to benefit, they were soon cut down to the standard of four inches square, or less. One or two only were used at intervals of a few days, and they were soothed with an anodyne poultice before dressing.

In the latter half of the management of these Dispensary cases, there was found a far better substitute for blisters. It was the alternate application of iodine and croton-oil. We commonly changed to these last when the tape-line showed slight enlargement or "bulging;" when inspection proved that the intercostal spaces were beginning to flatten, and when the dulness on percussion was more completely "deadened." The ribs over the effusion were then painted with several coats of the tincture of iodine in large brown patches, five or six inches square, every second or third day. These stains were rubbed over with two or three drops of croton-oil—perhaps once a week—just sufficient to maintain moderate pustulation. And the soiled fingers were at once washed with soap and water. When the space thus gently irritated was healed, the process was repeated or the location was changed. And thus we kept painting and rubbing till the effusion was gone.

The excellent results which we shall presently mention were hardly due to these appliances alone; for as every sensible practitioner knows, counter-irritation

in any form is only a valuable auxiliary to internal treatment. And this last was equally mild. Even at that early day, among these poor emigrants, we never either bled or purged in pleurisy. As a rule, latterly, we avoided antimony, mercury, veratrum viride, and aconite. We did not deny their valuable services as arterial sedatives, and as excellent substitutes for blood-letting in inflammation, with stronger patients or in private practice, in this brain-weary age. But with these weaker constitutions we feared that they would help to thin the blood or palsify the impulse of the feeble heart. We were not quite original. It is but a just tribute to say, that this caution was due in part to the previous teachings of that admirable chest physician, Skoda, during a few months in the hospital at Vienna.

In the acute stage, as is well known, we were liable to be consulted at two different points in its progress. There might be fever; a rapid or full pulse; thirst; a furred tongue; with difficulty of breathing; a sharp pain in the side, and a dry, teasing, cough, accompanied by the physical signs of stiffness in the chest movement and the "friction sounds" of the "dry period." Or a little later these febrile and rational symptoms might be associated with marked dulness on percussion, and the absence of respiration from the effusion of the fluid. And one was relieved of the fear of pneumonia by the freedom from tenacious or bloody sputa. In either case, our first effort was to make the patient thoroughly comfortable. It was before the blessed day of hypodermic injections. We generally resorted to a safe anodyne, added to a diaphoretic or diuretic, and sometimes to both. It is scarcely necessary to add that there is little or no risk with a mild narcotic in these painful chest affections, when the face is not livid, and there is a warm glow upon the surface of the body. In our later experience the following soothing combinations, among others, were often used:

R. Pulv. Doveri.....	gr. xx.
Pulv. potassæ nitrat.....	gr. xx.
Pulv. opii.....	gr. ij.
Pulv. sacchar. alb.....	ʒ i.
Ol. anisi.....	gtt. ij.
Spirit. cinnamon (tinct. ol.).....	gtt. iij.
M. et div. in pulv. No. vi.	

Take one powder in moistened sugar every four waking hours till quiet.

In mercy a saccharine aromatic was added to cover the mawkish taste of these powders. Some of our friends present will recognize this addition as a concentrated imitation of that very convenient preparation, the "oil sugar" of the German pharmacopœia, composed of one drop of essential oil to thirty grains of sugar.*

In milder cases, or later in the disease perhaps, we treat thus:

R. Liquor ammoniæ acetat.....	ʒ iij.
Spirit. ether. nitr.....	ʒ iij.
Tinct. hyoscyami.....	ʒ ij-ʒ iv.
Spirit. gaultheriæ (tinct. ol.).....	gtt. xij.
M.	

Take a dessert-spoonful in sweetened water every four waking hours. When convenient, this was given with some grateful fruit juice, or with lumps of ice dissolved upon the tongue. If the fever was very high, half a drachm or more of the nitrate of potass, in solu-

* See Article "Oelzucker," editor, 1850. [With a refinement worthy of German civilization, it makes the mouth water with such "delicacies for the sick," as the syrups of cinnamon and raspberry.

tion, was substituted for the acetate of ammonia. When the hyoscyamus failed to quiet the pain, a little morphia was sometimes administered.

Within the last few years we have changed to milder external applications at the commencement. We have resorted to a plan equally serviceable and safe in pains of the chest or abdomen. Over the aching side there has been at first laid a blood-warm mustard plaster, half meal or flour, folded between cloths, and applied for twenty or thirty minutes, till the surface has been well reddened but not blistered. The mustard has been followed by a piece of flannel wet with laudanum or spirits of camphor. This again has been pressed home to the ribs by a comfortably hot bag of three or four quarts of meal, oats, or better still, *wheat bran*. If musty, from being long kept for the purpose, it may be sprinkled with cologne. It is generally heated in a deep dish, in a stove, oven, or range, and poured into a soft pillow-case, to be lightly applied and renewed as it gets cooled. We think "dry heat" is much more safe than moist. The "bran bag" may be kept warm much longer if covered with sheets of cotton wool, enveloped with brown paper, or more perfectly still, with "*oiled silk*." This sort of domestic Turkish bath is commonly used, for several hours at the onset of the disease, first to quiet pain, and next to excite a gentle perspiration, and thus relieve congestion of the lung.*

All this gentleness was to save strength. We waited till the early acute symptoms had passed before venturing to apply a blister. The diet was rather liberal. Milk, eggs, toast, bread and butter, plain vegetables, fruit, and the lighter forms of animal food were gradually allowed; for it was evident that prostration would soon follow.

In the chronic stage it was found convenient to compare the good effects of squills, digitalis, the acetate of potass, and other diuretics, by the following test, available for the first fortnight or more of the effusion. It was to listen directly over the upper border of the fluid—while the patient distinctly counted—for that piercing, trembling echo of voice, the "Egophony" of Laennec. Or in its absence, there was usually marked "bronchophony" without the vibration. One or the other was commonly audible at this period, if carefully sought at a point nearly opposite the middle of the scapula, or upwards or downwards about two inches from the spinal column behind. A black mark, an inch long, was at once made over this penetrating line of voice, with a moistened stick of *nitrate of silver*. And this dark stain remained perhaps for ten days or more, as a fixed landmark for daily careful observations, to measure the rise or fall of the fluid within. For these changes corresponded with the shiftings of the intensified sound of voice. This mark was also a useful guide in estimating any variations in the respiratory murmur or dullness on percussion. And it told the story, when fortunate, of gradual cure. We do not know the author of this excellent device. At least two accomplished friends have used it for years.

These physical signs were all made more clear by another simple expedient. The patient was directed to cross both arms and grasp, not these but the *high-est points on the shoulders as far back as he could reach*. He then pulled them steadily and firmly forward, so as to separate the shoulder blades, and hold them

fixed as widely apart as possible behind. This process might be aptly termed *uncovering*; for it partly laid bare the ribs under both scapulae and stretched and thinned the thick muscles in their rear. The writer had occasion to commend this improvement on the old position in a paper read before the Academy of Medicine, and published in the *New York Journal of Medicine* for March, 1859, "On the Management of the Shoulders in Chest Examinations." In consumptive patients it was also a great assistance in searching for obscure groups of tubercles at the apex of the lungs behind. We add a sketch.

— Nitrate of Silver Mark; .Egophony or Bronchophony; "Uncovering the Chest behind."

By many experiments with the "nitrate-of-silver test," aided by this expedient of "uncovering," we came at length, as a rule, to prefer the iodide of potassium in steady moderate doses, as the most uniformly successful tonic diuretic of the list. Others might produce a greater temporary increase in the quantity of urine; but this proved, as we fancied, the best absorbent to liberate the compressed lung. To use an agricultural figure, it excelled the others in its power of *under-draining*. It had also the power of preserving, and sometimes even increasing, the appetite for food. While we were mildly blistering or painting or rubbing for weeks together outside, we gave internally, at the same time, about five grains or even less of the iodide of potassium three times a day. This salt, as well as some of the preparations of iron, will produce a slight amount of *ecorroy* in most sensitive subjects, which we have found relieved by a merely nerve addition of hyoscyamus or conium. The following prescription, variously modified, was a favorite with us as a mild diuretic in chronic pleurisy:

R. Potass. iodid.....	ʒi-ʒiv.
Tinct. hyoscyam.....	ʒij.
Tinct. cort. aurant.....	ʒi.
Spirit. gaultheriæ vel	
Cinnamoni (tinet. ol.).....	gtt. xij.
Aque ad q. s. ft.....	ʒiv.

M.

Take a dessert-spoonful three times a day in a wineglassful of sweetened water between meals. This mixture was sometimes made more diuretic by adding three or four scruples of the best extract of taraxacum, or more laxative and tonic by combining with it a

* The heated "bran bag," applied twice or three times a week at bedtime to the loins, by increasing cutaneous action has served us materially in the treatment of certain affections of the kidneys.

fluid drachm of the tincture of *nux vomica*. In tedious recovery the appetite was occasionally encouraged by qualifying the above combination with two or three drachms of the tincture of columbo, or an ounce of the tincture of calisaya bark.

We watched the more delicate of those pallid, emaciated patients with pleuritic effusion with deep interest. Until complete restoration to health there was always a lingering fear of future consumption. In some respects we happened to anticipate the recent views of Niemeyer and others as to the *occasional* agency of inflammation—especially in weak or scrofulous subjects—as the starting-point of tubercles. And these apprehensions stimulated all possible preventives. At the close of the treatment we recommended warm flannels, plenty of milk and meat, and other varied diet; ventilation in sleeping, and careful yet free exercise in sunlight and air. Sometimes the lost flesh was restored with cod-liver oil. And the ears were closely inspected to see if they needed *iron*. These were as interesting as the webs of frogs to young microscopists. Like the pulse, they were examined while free from excitement. And we have never seen a surer sign of the want of iron in the blood of a calm patient than a *pale, waxy ear*.

To favor those grand restoratives sleeping and eating, special pains were taken with the prescriptions. Medicines were always given by preference during "waking hours." Sugar was not so essential as water. Salts, acids, alkalies, and chemicals generally were thought to disturb the stomach less when pretty largely diluted. The interval "between meals" was commonly selected as the best time for the starch and other elements of partly digested food to combine with the iodide of potassium and some other substances.

An early accident directed our attention to another aid in building up these pale, wasted subjects, slowly recovering from pleurisy. Many years since, while on duty as physician to the Brooklyn City Hospital, the writer began a series of observations for a projected paper "On the Relative Agreement of Medicines with the Stomach." Fits of flatulence, tender spots, and furred tongues were counted till he was weary. The task of thus comparing all the bitter things of the materia medica proved too great. It was never finished. But the effort led to new views of the importance of their pleasant administration. On careful examination it appeared that digestion itself was often temporarily interrupted by the nausea from unpalatable drugs. In actual danger we never dared to fiddle with any kind of inert practice. With the prevailing exhaustion of this overworked age we were always generous in supporting agents. But in this it became a rule to conciliate the sense of taste—that jealous guardian to the stomach—with savory disguises. In fact it was simply bribing the porter. When their doses were made agreeable the poor seemed to eat the meagre fare of the sick-room with a keener relish. And if they thus recovered more rapidly, there was an actual saving in expense to a benevolent institution in adding a little sugar, a few drops of spicy tincture, or inexpensive aromatic essence. They would thus need less medication. We remember that dyspeptic consumptives used to profess to be attracted from other dispensaries by our "more pleasant" cod-liver oil spiced with a drachm to the pint—or less—of the very cheap oil of sassafras. As a general rule we observed that, as in the cookery of health, the stomach in sickness was best pleased with the more delicate compound flavors. In illustration we may mention that our most satisfactory recent improvement of cod-

liver oil, in private practice, has been to add to the ordinary full bottle of oil a teaspoonful of a mixture of one part of the oil of pimento or "allspice," one part of the essence of cinnamon, and two parts of the tincture of orange-peel.* This kindly practice perfectly charmed children. And then it was only humane. Where the hundreds of millions of earth instinctively craved "seasoning" in their food, it was hard to deny them "condiments" in their medicines. So we have continued ever since this early experience to flavor from principle, in the firm belief that the sick are thus better nourished.

The success of this gentle plan in this serious malady among these poor emigrants was a constant surprise to us for years. We can hardly account for it still. In the main features of this mildness our worthy colleagues agreed. As the figures show, more than half the credit was due to their skill. We may give some facts. Statistics in a crowded dispensary can never be so perfect as in a well-organized hospital. Their weak point is the termination. Making in honor due allowance for the number of grave cases sent to the hospital from the dispensary and the "results" lost, as well as for the transient patients who would stray to the country, its death-rate from pleurisy was still very favorable. Probably the item of mortality was better kept than many others. For where cases became so serious as to be fatal, they were always attended at their homes by the district physicians. These were salaried officers, appointed usually after faithful services, who reported the losses from each disease monthly. In six years, and over twelve hundred cases, there were only recorded six deaths from pleurisy, or less than a half per cent. With the drawbacks we have mentioned, it may be more safe to estimate the loss in round numbers at one per cent. Again, we were on the lookout all this time, publicly and privately, for suitable subjects for Dr. Bowditch's comparatively safe operation for empyema, with a small trocar and pump, near the inferior angle of the scapula behind. And we only ventured to puncture eight times. With the recent improvement of the admirable aspirator of Dieulafoy, we should have probably operated much more frequently. In mild weather and moderate attacks the average time for the absorption of the fluid was about six weeks. This term was doubtless apparently extended by our caution in retaining patients under treatment longer than usual during convalescence. Unless the pulse ran for days over a hundred and twenty, we were pretty certain that the effusion was not purulent. Very curiously, our percentage of recoveries for some years was decidedly better in the dispensary than in private practice. Could it be that these wanderers from the fields and cottages of Europe had an elastic hardihood of constitution denied, with all their comforts, to our own brain-working citizens?

Returning to our process of economizing blisters by alternately painting and rubbing with the tincture of iodine and croton-oil, it may be remarked that it had three defects. It was filthy, tedious, and uncertain. The sick citizens of the Sixth Ward were very modest with cologne and croton water. In their misfortunes they were sometimes dirty. We speak mildly. And this solemn anointing—this benevolent staining of the white fingers of a young physician over ribs already browned and scarred—kept the crowd too long in waiting. Pure croton-oil rubbed outside had its freaks. It behaved well in a dozen patients perhaps, and then, without any warning, it ran wildly over a whole side like an eruption of small-pox; or in sleep it mounted

* Pimento as a delicate carminative has been introduced into three of the formulae in the British Pharmacopœia.

to the face, with a capital imitation of erysipelas. Nothing but firm faith in its virtue made us endure these drawbacks. We longed for something better. It came. About four years since, in private practice, we discovered that sulphuric ether not only dissolved croton-oil in the tincture of iodine, but also greatly improved it as a counter-irritant. This combination could be cleanly and rapidly applied with a camel's-hair pencil, even by a nurse. It dried quickly, saved the fingers, and was very certain. Within twenty-four hours it commonly produced, on a red, even surface, a thickly dotted pustular eruption, smaller in size, less painful, and much better defined than that from croton-oil alone. The medical virtues of the iodine were retained, and even its dark stain on the skin helped accurately to measure the application. Thus improved we have found it, after a pretty extensive trial in different diseases, more generally serviceable than any other counter-irritant that we have ever used.

The curative action is the same; but in actual experience it is far more convenient than the alternate painting and rubbing of twenty years ago. In appearance it perfectly resembles both the tincture of iodine and Lugol's solution. It should be very carefully labelled. With "paint" staring him in the face, on the bottle, a worthy neighbor was so fascinated with its beautiful violet color, not long since, that he mistook it for the tincture of rhubarb, and took a teaspoonful of it to cure his diarrhoea. He was moved, down to his very boots. When you remember that a single drop of croton-oil will commonly produce five or six painful evacuations from the bowels, you can estimate the force of ten drops fired with forty of the tincture of iodine. He doubtless felt like a man with the nightmare, who dreams that he has swallowed the screw of a steamship in rapid motion. In fact, he got up a fearful imitation of Asiatic cholera, from which he fortunately recovered, much wiser in the study of purgatives. Excuse this playful illustration of a very serious matter—a mistake in taking medicines. To prevent such accidents, we advise you always, in writing this prescription, either to leave verbal directions with the druggist, or add a postscript, "Please write 'Paint' distinctly at the top." An intelligent lady patient one day called it "croton paint." "Liniment" will surely lead to blunders. "*Paint*" is just the word. With a slight addition for safety, let us commend this suggestion in a name to the grave committee of the next Pharmacopœia, and propose that it be first elegantly rendered "Pigmentum Croton Tiglii," and then be plainly translated "Croton-Oil Paint."* The quantity of sulphuric ether added should be double that of the oil, to make a perfect solution. If the ether is not pure, there will remain a little oil undissolved at the bottom. It is better always to shake the mixture before applying. From many experiments we have preferred two forms varying in strength. We give the formula:

MILDER CROTON-OIL PAINT.

B.	Olei croton tiglii.....	℥ i.
	Ether. sulphur. fort.....	℥ ij.
	Tinet. iodin.....	℥ v.

M.

Apply two or three coats at a time, with a camel's-hair brush, over a small surface once a week. This is most useful for children, females, or sensitive males.

STRONGER CROTON-OIL PAINT.

B.	Olei croton tiglii.....	℥ ij.
	Ether. sulphur. fort.....	℥ iv.
	Tinet. iodin.....	℥ ij.
	Potass. iodid.....	℥ i.
	Iodini.....	gr. x.

M.

Paint, as above, over the side, back, or loins. It is richer in iodine and better adapted to less susceptible subjects.

With increased confidence from experience, these combinations have superseded blisters entirely in the majority of cases of pleurisy that we have treated within the past three years. We now apply them within forty-eight hours after the effusion. With two patients, not long since, one a lad of twelve years, just returned in the spring with an invalid from Florida, and the other a young lady of sixteen, after the exhibition of the iodide of potassium and repeated "paintings" alone, without the aid of blisters, the fluid was absorbed within a month.

As we have just intimated, our observations have extended beyond pleurisy. We have a collection of cases of affections of the eye, ear, bladder, and spine, as well as examples of whooping-cough, pleurodynia, muscular rheumatism, and sciatica, and other diseases, which we have gradually gathered from domestic practice and the "Dispensary Department" of the Orange Memorial Hospital. These show a wide range of usefulness of the "paint" as a counter-irritant. But we cannot trespass on your kindness with them now; we hope in future to present them through some proper channel.* It was most generally serviceable, perhaps, as a help to gentle expectorants in ordinary mild bronchitis, or, as it is familiarly termed, a "neglected cold" of a week's duration. And with the aid of tonics, nourishing diet, and *double flannels*, it often helped to alleviate the "winter cough" of the aged. Our favorite location for "painting" in these bronchial difficulties was each side of the spine, in the hollows between the shoulders. It caused here the least annoyance in both sexes, was protected in sleep and with nursing women, and seemed to afford most relief from being nearest the roots of the nerves concerned in coughing.

We close with a few precautions. On account of the danger of exciting either eczema or ulcers of the leg, we avoid applying croton-oil in any form below the hips. We here substitute the pure tincture of iodine. In affections of the eye and ear, a mere line of pustules can be concealed by the hair of the temple, or behind the mastoid process. Elsewhere, with both forms of the paint, we commonly cover a space of from one to five inches square—less in children and females, or along the spine—and more in males, or over the loins or the sides of the chest. From two to four coats at a time are applied with a camel's-hair brush, on the average about once a week. If this fails to pustulate within forty-eight hours, the surface is rubbed thoroughly with the finger till well reddened, and the paint is reapplied. When it spreads uncomfortably, or is more painful than usual, these symptoms may be promptly relieved by brushing over the eruption with equal parts of glycerine and laudanum, and then covering it with a soft piece of linen moistened with olive-oil.

* Since writing the above, we perceive that in the excellent Pharmacopœia of the Hospital for Diseases of the Throat, London, edited by Dr. Morell MacKenzie, there is a class of "Pigmenta" or "Local Applications."

* An abstract of these cases will be published as an Appendix with this paper, in a small volume, by Wm. Wood & Co.

still only a mass of cells. The author advances another argument, much less convincing. He says that when the ventricle has contracted it forms a solid mass that the current of blood could never force open, hence this mass must open spontaneously. But it has never been asserted that the stimulus of blood produced the relaxation, diastole, opening of the ventricle, but that this having occurred spontaneously, the blood excited the muscle to a new systolic contraction. The author has made some new dissections of the mammalian heart, prepared as follows: The ventricular cavities are stuffed with bread crumb or bran, and the organ is then boiled four to six hours (eight to ten for ox or horse). It is then soaked in alcohol for about a fortnight, when the fibres will be found to separate with great facility. By this method the author succeeded in demonstrating seven layers of muscle—three internal, three external, one central. Of the three outer layers, the first is nearly vertical, the second oblique, the third more oblique, the central layer completely transverse. The internal layers return by a similar, but inverse gradation, to the vertical direction. The fibres of corresponding external and internal layers, *i.e.*, one and seven, two and six, etc., are continuous in the left ventricle at the left apex, and in the right ventricle, along the track of the anterior coronary artery. This successive embrace of the layers explains alike the rolling movement and powerful action of the ventricles. The blood is literally wrung out from them.

The author describes minutely the *musculi papillares*, and shows that between them run three spiral grooves, two directed to the under surface of the bicuspid valve, the third to the aorta. On the beginning of the systole the blood is moulded into three spiral columns, of which two force upward the bicuspid valve, and effect its closure, the third is projected out of the aortic orifice. As the contents of the ventricle diminish, the *musculi papillares* contract, and draw down the valve in a conical shape, so as to diminish the size of the cavity. The movements of the heart are not intermittent, for a continuous wave of motion is at all times passing over it, but its parts move and rest in succession. The opening and shutting of auricles and ventricles alternate like that of the bodies and sphincters of other hollow viscera. This, indeed, is easily seen by any one on a frog, whose heart, as Beau long ago observed, may be observed as readily as a book is taken off a shelf to be read.

The arrangement of the muscular layers of these various hollow viscera accords with that just described for the heart; and the author is ingenious in finding further homologies with the trunk and limbs of vertebrate animals. In the thorax the pectorals and deltoids run vertically, transversely, and at various degrees of obliquity, the intercostals, beneath, cross each other as in the letter X, while the serrati run at right angles to both. A similar arrangement is conspicuous in the abdomen. The posterior muscles of the thorax may be traced in the same way. Eliminating the element of bone (which, as the author observes, is only introduced high up in the ranks of life, and is secondary, therefore, to fundamental conditions), we have in the thorax and abdomen two hollow muscular masses, of which one opens when the other closes, and which are closely allied to the auricles and ventricles of the heart. The diaphragm descends when the thorax opens, *i.e.*, draws in air and blood, just as the mitral and tricuspid valves descend when the auricles are in diastole and aspirate blood. The heart in the thorax pulsates as it were within a larger heart.

The arrangement of the muscles on the limbs is like

that of the trunk muscles, analogous to those of the heart. In the arm the biceps represents the longitudinal fibres, the supinator longus and flexor carpi radialis the slightly oblique fibres, the pronator radii teres and flexor sublimis the oblique fibres, and the pronator quadratus the transverse fibres. Throughout this succession of increasingly complicated combinations of muscular movement, the author finds recurring the original type presented by the sarcoic element, and consisting of alternate widenings of the mass in directions at right angles to each other. Upon these spontaneous "vital" amoeba-like movements, centrifugal or opening when extended transversely, centripetal or closing when in a longitudinal direction, depend not only the functions already described, but the peristaltic movements of tubes with muscular coats, whose fibres run at right angles to each other (intestine), or at right angles to elastic fibres (arteries). A wave of motion passes over these tubes as in the earthworm, the heart, affecting successive segments at successive times. When in any segment the circular fibres broaden and shorten, the longitudinal fibres lengthen and narrow, and both the centrifugal and centripetal actions concur in elongating the tube, which shortens again by a reverse action. The whole constitutes the peristaltic or vermicular motion.

In describing the conditions of circulation, the author is, moreover, too exclusive in rejecting the intervention of physical laws and analogies to circulation in elastic tubes. The experiments of Marey, Leandrus Kirchoff, and others, have too well established this analogy for the larger arteries, where muscular fibre does not come into play.

The description of this central chapter has exhausted our space, so that we can do no more than refer to those preceding, where the author passes in review the circulation in plants, in vertebrates, and the human fetus, and to those which follow, the first containing elaborate descriptions of the valves of the vascular system, based on original dissections, the last devoted to a more cursory review of the nerves of the heart in mammalia. We will, however, quote the most original suggestion in regard to the circulation of plants, namely, that the tubes containing sap are arranged in a series of siphons, one extremity of each siphon terminating in a surface of evaporation, either at the leaves or at the roots.

From the above extracts we need hardly say that these lectures contain much novel and interesting matter. There is, as the author himself observes, some redundancy, and many pages only useful to the novice; but they are easily forgotten in following the personal researches of the brilliant lecturer. His antagonism to many commonly received doctrines only renders the discussion of his own views more animating.

THE TREATMENT OF SYPHILITIC DISEASES BY THE MERCURIAL VAPOR BATH. By JOHN W. FOYE. Boston: Williams & Co. 1874.

THIS is perhaps a modern curiosity of literature. Without apparent object, unless perhaps it is his desire to be an author and to parade his book before a public to which he panders, it is difficult to understand why he thus takes excerpts from the books of Parker and Lee, and with his own unoriginal interpolations forms a volume which is noticeable for its want of smooth continuity. Not an original idea is given; even all of the advantages of the treatment are not evidently appreciated by the author, and his book is as unuseful as it is unnecessary. It is an example of the modern *vacathes scribendi*. Its contents are long familiar to all by the writings of those who have more

authority, or by observation of the treatment of syphilis, which certainly must be more extended and clear than that of the author, as, judging from the book, it could scarcely be less.

A TREATISE ON THERAPEUTICS, COMPRISING MATERIA MEDICA AND TOXICOLOGY. By H. C. Wood, Jr., M.D. Philadelphia: J. B. Lippincott & Co.

To the student of medicine and to the practising physician a thorough work on therapeutics is certainly one of the greatest necessities which they experience. Indeed, this want cannot be exaggerated, and to fill it have many men tried with good intention, but without success. After looking over works on therapeutics in either of the three great languages, one turns away disappointed, as there are essential deficiencies in all. What appears so simple is really so difficult, and it is given to very few men to possess a peculiar fitness to write upon therapeutics. The reasons are obvious: Want of proper experience, proper mental training, a mind not carried away with theories and hobbies; indeed it is very doubtful whether one man will ever in a thorough manner compass the subject. The tendency of to-day is to divest works of this class of the irrelevant and dull details of materia medica, and to devote more space to therapeutics proper, and this is certainly a step in the right direction. As a judge of books, we must say we took up this work with a kind of prejudice, in consequence of the long and somewhat verbose and desultory preface which we find in it. It seems to us that if an author wants to prove the necessity of his work, or his peculiar fitness for it, or again, his general plan of handling his subject, he can do it at much less tedium to his readers. To review a work of this kind is almost to review a dictionary; so we shall, rather than consider details, speak of its general scope. It must be said in justice to the author that his studies and experience are such that he is more than some others fitted for the task of writing a work on therapeutics, leaving out unnecessary detail of facts. There is in the work much useful information, showing long, painstaking observation. There is no evidence of blind reliance on certain drugs, or certain modes of practice. Starting with the physiological action of drugs, in the study of which the author has long labored, we find the action in pathological conditions clearly traced, and any section can be read with profit. Though there are points in the work which will admit of criticism, it must be confessed that, as a contribution to therapeutics pure and simple, it has reached nearer the mark than any work now before the public. There is an evidence of much labor of its author to familiarize himself with what others have done, and in the main he gives their views fairly and fully. Taken as a whole, it is a work which can remain on the desk and be consulted from time to time with benefit, which gives good therapeutic advice in a practical way.

CARDIAC THROMBOSIS IN DIPHTHERIA. (DE LA THROMBOSE CARDIAQUE DANS LA DIPHTHERIE.) By BEVERLY ROBINSON, M.D. Paris, 1873.

This brochure is a well-written contribution to a subject which has not heretofore been largely or carefully studied, and which, from its importance, well merited a full consideration. It is handled by the author in a very thorough manner, and his work gives evidence of much clinical research. The numerous cases which are incorporated in the book are well reported and are of much interest. The author draws up his conclusions in the following clear, aphoristic form:

1. Cardiac thrombosis is a tolerably frequent complication of diphtheria.

2. The elastic fibrinous coagula entwined in the valves, or which adhere to the walls of the heart, are formed before death.

3. They are often developed before death in children who are far from having become extremely weak. They have several times been recognized when the child appeared to be convalescing, and there was indication of a coming cure.

4. They give rise to very grave symptoms, which make their presence suspected.

5. Their diagnosis is important in the double point of view of prognosis and treatment, as their existence renders the fatal termination of the disease almost certain, and renders useless, in some cases at least, the operation of tracheotomy.

6. The polypoid clots are frequently the proximate cause of the grave condition of the patient, and which is not due to its disease itself.

7. Death may occur in a sudden manner immediately after the occurrence of this formation, or even after a longer or shorter state of suffering.

The work is interesting to all who desire to familiarize themselves with the complete clinical history of diphtheria, and an acquaintance with its contents may perhaps avert unnecessary operations of tracheotomy. On the cover and title-page the author is put down as Robinson Beverly, a transposition which is to be explained probably by the unpardonable carelessness peculiar almost to the French in quoting names of foreigners. The present work is by a New York physician, and was his inaugural thesis, submitted to the Faculty of Medicine of Paris.

A PRACTICAL TREATISE ON THE SURGICAL DISEASES OF THE GENITO-URINARY ORGANS, INCLUDING SYPHILIS. By W. H. VAN BUREN, M.D., and E. L. KEYES, M.D. New York: D. Appleton & Co. 1874.

To those who endeavor to keep themselves well read in the branches treated of in this work, the necessity of its publication has been felt quite seriously of late years. In these days of multiplicity of authorship it is a fact of some satisfaction to a writer that his theme is one which is so interesting and important as to warrant its elaboration into a volume. So much material progress has been made within the last few years in the study of the genito-urinary diseases and syphilis, that the works which were before the public were rendered almost obsolete. The necessity for the work being conceded, it certainly is a matter of profound satisfaction to the profession, as indeed it was of vital importance to them, that it was undertaken by men who by their position are so eminently fitted for it. For many years the name of the senior author has been identified with the careful study and practice of these diseases, and he has been justly looked upon as one of our foremost, if not the foremost, surgeons of the branch. His fitness to undertake the work is undeniable, and in it he has associated with him a gentleman who has long made these diseases a special study, and who has already communicated papers of great value on these topics. It is rare that authors are so eminently fitted for a task, and considering the extent and importance of the present one, the fact is very auspicious. The portion treating of diseases of the penis is very concisely written, practical in character, and in the matter of treatment clear and simple. In few works are the diseases of the penis so well treated of in so small a space. The chapter upon Urethral Fever is especially well written, and contains the recent views advanced regarding the condition. Perhaps one of the best portions of the book is that treating of stricture. The condition is well described in all its phases,

the necessary instruments are designated, and the treatment is laid down in a manner at once simple and practical. Indeed, in these days when urethrotomy is pushed to an incredible degree, when, according to certain theories, which it must be confessed are undemonstrated by practice, every man should be cut at the meatus until he has a hypospadias, and his urethral canal should be, by means of dilatation and remorseless cutting, rendered almost if not of the size of his œsophagus, it is refreshing to read such words of cheer as are contained in this volume. It shows that every surgeon of genito-urinary diseases does not vie with Reybard of old in the depth and number of their incisions of the urethra. On the contrary, here we have clearly set forth what gradual dilatation will do, how to do it, when and how to use urethrotomy and division. Such chapters as these certainly must have a salutary and perceptible effect upon the growing fashion to incise the urethra. The various diseases of the other organs, and their treatment, are well described, and any person can read the chapters devoted to their consideration with great satisfaction and profit. We would say that the chapter upon *Maladies Involving the Genital Function* is one of the best in the book—one which is usually treated of in a mawkish, sentimental manner, but which here is written in a markedly philosophical way, and supplemented with practical, sensible details. On the whole, the portion of the work devoted to genito-urinary diseases is admirably written; not being verbose it is terse, without being vague it is clearly practical. Chancroidal ulcers and their complications are fully described; their treatment is given at length, and their differentiation from syphilitic ulcers is brought out in a table of exceptional clearness of detail. The various chapters upon syphilis show a thorough acquaintance with its manifold forms, which are well described. Perhaps exception might be taken to the classification of the dermatic lesions adopted by the authors as being founded on an unscientific basis; yet as the efflorescences are so well described, any shortcomings in their classification are readily looked over. The important subject—treatment of syphilis—is well handled, and its careful perusal will be of benefit in inculcating sound therapeutic doctrines. The chapter upon the *Nervous Affections of Syphilis*, as might be expected, considering the valuable contribution the authors have already given us, tersely and admirably written, and contains information of much importance. While as a whole the work is of great value from the fact that the personal experience and knowledge of its authors is given, they have enriched it very materially by adding the views of others. Indeed, a book rarely appears in which the author is as familiar with what others have done in every branch as there is evidence of in this volume. Besides this, there is an undercurrent of candor in stating the views of others, which may well be largely imitated. All things considered, the authors have given us an invaluable work, clear and not in the least obscure, true and practical, such an one as can be consulted with profit, in which treatment and principles of treatment are clearly laid down. In seeking helping hints as to practice, one noticeable feature will be found to be the directness of statement, from which the reader gleans definite ideas rather than desultory unsatisfactory hints. The work certainly fills a void not filled, and much felt, not only in English-speaking countries but also on the continent.

THE PHYSIOLOGY OF SCEPTICISM AND PHENOMENALISM.
By JAMES ANDREWS. Glasgow: Jas. Maclehose, 1874.

THE little work bearing the above title shows fruit of

the highest intellectual labor. Without a preliminary word the author enters upon his task, and ends by giving us fifty-eight pages of "solid sense," if we may use this expressive adjective. Mr. Andrews' essay is logical and concise, and from the excellent impression it has given us we unhesitatingly say that it is the best book we have yet seen upon the subject of which it treats.

After defining the word "phenomenon," he says: "The word 'phenomenon' in this essay is used to signify that which appears to be, but is not what it appears. Thus, in a dream I appear to see and hear, and move about transacting business as if I were awake. This is appearance only—phenomenon. . . .

"In the existence of phenomena lie the justification and necessity of metaphysics. The fundamental problem of metaphysics is, how are phenomena in general possible? We are deceived; there is no blinking the fact. We cannot look, listen, or move without being deluded; appearing to see, hear, or move, while we neither see, hear, nor move. The fact is undeniable—how is it possible?"

"The answer of scepticism is, that the problem is insoluble; its practical conclusion is, that the appearance is as good as the reality; the belief, persuasion, or delusion of knowing is quite as good as really knowing; sometimes a great deal better, therefore take things easy. You cannot get rid of appearances; you cannot distinguish realities when you suppose you have found them different from their phenomena; it is therefore indifferent which you get."

Ancient and modern metaphysics are compared and analyzed, so far as their relation to the subject is concerned. The phenomena of consciousness, the existence of delusions, the various conditions of the will coexistent with a disturbance of some of its agents of conduction are discussed in a very scholarly manner, and a thoroughness entirely Scotch.

It will hardly do the little book justice to discuss its merits in this small space allotted to the reviewer; it is well worth reading and studying. In conclusion, Mr. Andrews adds: "We might go on indefinitely, explicating all the great problems of philosophy by the same method; but meanwhile enough has been said to show in general how phenomena are possible, and with a demonstration of their possibility, scepticism and phenomenalism, as systems, 'disappear.'"

THE PHILOSOPHY OF SPIRITUALISM, AND THE PATHOLOGY AND TREATMENT OF MEDIOMANIA. Two Lectures by FREDERICK MARVIN, M.D., Professor of Psychological Medicine and Medical Jurisprudence in the New York Free Medical College for Women. pp. 68. New York: Asa K. Butts & Co. 1874.

IN striking contrast to Mr. Andrews' book just noticed, is that which bears the above pedantic title. "It is a sad thing that in the nineteenth century one can find occasion to write such lectures as these," says the author in his preface. We quite agree with him, and sympathize with his readers.

After a rambling chapter or two upon spiritualism, which are nothing more nor less than a *réchauffé* of what has been written by others for years upon this fruitful subject, we are brought to the second part of the book, the study of *mediomania*, discovered by the author. *Mediomania* is hardly more than a common form of melancholia dished up with a dash of hysteria. Dr. Marvin cites the cases of several individuals, principally spiritual media, who have been treated by him for emotional excitement. It is unnecessary to say more.

The whole style of the book is exceedingly bom-

bastic, and some of the passages are written with such a reckless poetical license that we must give a few specimens of the author's language.

On page 60, we are told "many a noble friendship has been destroyed, and many a rash deed performed, for want of sufficient pepsin to effect the digestion of a certain article of food in a given time."

On the same page the author has presented us, in a rude wood-cut, with some rare post-mortem appearances which he has discovered, as characteristic of this important disease (?), viz., broken uric acid crystals.

The crowning sentence of the book would do credit to the most enthusiastic sophomore. He says on page 62, in speaking of *protean insanity*, "She enters by the gateway of the cerebro-spinal system and rides upon the lightning of the motor nerve; she enters the arterial channels, and floats on the shining discs of blood down long generations."

Reports of Hospitals.

BROOKLYN CITY HOSPITAL.

NOTES OF PRACTICE AND PECULIARITIES IN TREATMENT.

As a dressing the surgeons are very partial to styptic cotton, especially for chronic ulcers; first scarifying the surrounding tissues, apply layer of the cotton, and strap over this. The rapidity of cure sometimes is wonderful. Besides the power of healing, its antiseptic properties are good.

As a general local application for chancre and syphilitic eruptions, the following is used with marked success:

Ungt. zinci oxide,

hydrarg. chlor. mite, aa;

while for internal use the ward prescription is,

Hydrarg. binoid gr. ij.

Potass. iodidii ʒ ss.

Syr. sarsap. co.,

Aqua, aa ʒ ij.

M.—ʒ i. t. i. d.

Iodoform locally applied after cauterizing a chancreoid seems to have a good effect. Oleate of mercury in the treatment of orchitis is used with benefit. Applied locally to the indurated testicle, absorption is often rapidly promoted, though its irritating effect to the skin is not pleasant.

As a treatment for specific bubo, ungt. hydrarg. locally applied, alternated with

Tr. iodine ʒ iv.

Glycerine ʒ ij.

M.—Painted over the indurated glands.

In simple bubo glycerine externally has been used with good results.

In phagedenic bubo, ferri et potass. tart., internally and externally, is exclusively used.

Internal urethrotomy is employed in most cases of stricture, with, as yet, no unfavorable symptom.

Hydrate of chloral has been used satisfactorily as an antiseptic lotion, gr. xx. to Oj.

An interesting case of *hydro-hematocoele* was admitted to the hospital. The patient was tapped for hydrocele in a New York dispensary. According to his statement he was cut twice, the first one being a dry tap, the second bringing blood. He was then sent home. Considerable hemorrhage; picked up in the

street; brought to this hospital showing signs of excessive bleeding. Scrotum eighteen and a half inches in circumference, four (4) times the size it was before the operation, and bleeding from two incisions. Hemorrhage controlled by pressure and cold applications. Few days after admission scrotum laid open, when it was found that the tunica vaginalis had not been pierced; the blood external to the sac.

EXOSTOSIS OF HUMERUS.

Patient, while playing ball, noticed for first time a hard lump upon the arm, inner aspect of deltoid. Imagining a dislocation, went to his family physician, who corroborated the patient's diagnosis, calling in consultation one or more physicians. Worked hard for a half hour (more or less) in the vain attempt to reduce their dislocation. Then sent him to the hospital, where an exostosis was diagnosed, with no dislocation, the patient having perfect use of his arm.

POLICE CASES.

Man found unconscious upon the street; been drinking. On admission, inequality of pupils and complete coma. Head carefully examined. No external marks of violence.

Autopsy.—Fracture of skull, with rupture of middle meningeal.

Young man fell from wagon, striking upon head; slight contusion back of cranium; comatose; inequality of pupils, etc.

Next day convulsions set in; had continued for two days, when wet cups were applied to back of neck, attended with their immediate cessation.

FEMORAL HERNIA.

Patient male, age 19; has had reducible hernia for several years. Upon admission, swelling in left groin. Tumor painful, inflamed, and tense. Vomiting.

Taxis employed ineffectually; patient etherized; sac aspirated; and taxis being employed reduction took place.

Interesting feature is femoral hernia in male.

CUT THROAT.

The patient was a man who made quite an extensive incision above the thyroid cartilage; the edges of the wound were brought together and carefully stitched, as is the custom; but in this special one we saw the effects of pressure upon the larynx by pent-up secretions; fortunately the stitches were cut in time.

DELIRIUM TREMENS.

Treatment in these cases very unsatisfactory; probably the most reasonable way is to give potass. bromide grs. lx., followed in an hour by chloral hydrate grs. xx. every fifteen minutes until three doses are taken. If sleep is not produced discontinue medicine and give plenty of nourishment, leaving the patient to wear it off.

ACUTE DYSENTERY.

Ice-draw injections, with suppositories of morphia and bismuth, submitted internally, sometimes produce a rapid cure.

COLLES' FRACTURE (DOUBLE).

Treated with anterior and posterior straight splints, compresses over both deformities; result in this case very good.

Esmarch's method employed in amputation of thigh for compound fracture of femur with extensive necrosis and an immense pyogenic surface. Patient was nearly moribund; union of flaps by first intention, and is now rapidly recovering.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, October 28, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

INTRA-CANALICULAR ADENOMA OF THE BREAST.

DR. SATTERTHWAITE presented a diseased breast, which had been removed by Prof. H. B. Sands. The history was substantially as follows: The patient, a lady forty-five years of age, was married twenty-three years ago, and is the mother of three children. The first was an eighth-month child, and died at the age of three months, but as her physician recommended her to "keep her milk," she used a breast-pump. This gave her pain. Shortly after, she struck her breast against a door, and soon afterwards noticed that her milk was bloody. She nursed her second child without special inconvenience, using both breasts, but noticing that the right breast—the one in question—was somewhat larger than the other; it was also painful. About ten months before the birth of her third child there was a discharge from the nipple, as if, she said, from a blood-blister. She nursed the third child without difficulty, but there was always more or less pain in the right breast. About fifteen or sixteen years ago she first discovered lumps in her breast. Five or six years ago she noticed growths rising from the nipple. These were cauterized and disappeared, but afterwards returned. They were again cauterized, and again disappeared. When the breast was removed it was small and flattened; but there was a small hardened mass about the base of the nipple, while rising from it there was a growth of a pale pink color, resembling exuberant granulations and about three-quarters of an inch in height. Near the periphery of the gland there was a small firm nodule. On cutting vertically through the nipple and examining the tissue microscopically, these growths could be traced down into dilated milk-ducts, and one was found to spring from the wall of the duct about three-fourths of an inch below the nipple. The outer portions of these excrescences were papillary in character, but nearer the point of attachment they contained a very considerable amount of true gland structure, similar to what is found in the healthy breast. The name of adenoma seemed therefore appropriate, though it was proper to add that there was also a large amount of fibrous tissue about these glandular structures. As they also originated and grew in the ducts, they were therefore intra-canalicular. The tumor had been diagnosed as an adenoma by the operator prior to its removal. The firm nodule spoken of before contained glandular tissue, though it was less in amount than the fibrous tissue that surrounded it. From the history of the case it would appear that the trouble commenced during the first lactation. The discharge of a serous fluid during the last pregnancy would seem to favor the view that there had been dilated ducts or cysts in the breast, which discharged their contents at that time. It was well known that growths of this kind were apt to be associated with these changes in the breast. It was exceedingly rare for such a growth to project through the nipple, at least no instance of this kind had been found in the books.

UNREDUCED STRANGULATED FEMORAL HERNIA.

DR. SATTERTHWAITE also presented an artificial anus, which, together with a portion of the small intes-

tine connected with it, had been removed from a patient at the Presbyterian Hospital. The history was as follows: M. E., 40, single, was admitted into the hospital on the evening of the 9th of September, 1874. She stated that two and a half weeks previously she had an attack of vomiting and purging, which lasted several days, when the purging suddenly stopped while the vomiting continued. At this time she discovered a tumor in her left groin, but she felt no special anxiety about it as it had often appeared before and had disappeared again. The tumor, however, remained, giving her great pain, and had acquired increased size. During the week previous to admission she had a discharge from her bowels, following a dose of castor-oil. The vomiting continued until admission. When seen by the attending surgeon, Dr. Gurdon Buck, there was a flattened tumor in the left groin, about five inches in circumference, and soft in the centre, where the skin was also moist and discolored, and crepitation could readily be felt by palpation. Three days later an opening formed at a point a little below and opposite the middle of Poupart's ligament.

Fæces were discharged through the opening, though never so abundantly as by the rectum. The patient was much exhausted by the sloughing which took place about the artificial opening, and she gradually sank and died seven days after admission. At the autopsy it was clear why there had been no continued constipation. The portion of intestine that was involved—the ileum, about four feet above the ileo-cæcal valve—proved to be engaged in the femoral canal, but only at its periphery, that is, at the farthest point from the attachment of the mesentery. The amount of tissue actually lost by the intestine could not have been greater, probably, than a twenty-five cent piece, and consequently the calibre of the intestine was very slightly diminished, and the fæces could pass quite readily to the rectum. There was acute enteritis, but no peritonitis, and there were no adhesions between the folds of intestine. Around the ileum, where it was attached to the femoral opening, there was a slight reddening; but there were no other signs of inflammation further than those already mentioned.

RUPTURE OF BLADDER FROM KICK IN PERINEUM.

DR. MASON presented a bladder removed from a boy aged eleven. This patient, six days before his admission, was kicked in the perineum by a playmate. He complained of some pain, and for some hours afterwards was unable to pass his urine; then the bladder was evacuated voluntarily several times during the remainder of the day on which the injury had been received. After this, again, he had retention, which condition continued for forty-eight hours, necessitating the use of the catheter. This operation was performed twice daily, until admission to the hospital. During this period of six days no pain was complained of, and no bloody urine had shown itself.

Dr. Mason saw him for the first time July 10. He was then running about the ward, and only complained of an inability to pass his water without assistance. A very careful examination was then made, which resulted negatively in the direction of a diagnosis. There was no pain on pressure above the pubes; no sign of any injury about the perineum, and a number 12 bougie (French scale) was passed with ease. A silver catheter of larger calibre was also introduced without difficulty, and drew off some clear urine. But the daily use of the catheter became imperative, the urine being sometimes clear, sometimes turbid, sometimes of dark color, and not unfrequently was of an offensive odor. On the 12th of July some blood

made its appearance in the secretion, coincident with which was a complaint of pain in the hypogastrium. A poultice was then applied to the bladder, and the organ was washed out. July 19, while in a warm bath, a small quantity of urine was passed voluntarily.

During the afternoon of July 20, without any notable change in the vesical symptoms, the patient rolled his head upon the pillow, became drowsy, the pupils became dilated, the face somewhat cyanotic, and he fell into a drowsy state. This condition lasted, however, for half an hour, when he awoke and seemed to be as bright as usual.

July 25. He was suffering from more pain, and the house-surgeon, in attempting to introduce a catheter, felt for the first time an obstruction. Dr. M., who also saw the patient on that day, had a similar experience. Rupture of the bladder was then for the first time suspected. Dr. M. passed his finger into the rectum, for the purpose of assisting the passage of the catheter, when, to his surprise, he encountered a swelling in the neighborhood of the ramus of the ischium. The patient was then etherized, and the bladder was opened the same as for the operation of lithotomy. Bloody urine flowed out, and the organ, which had been very much distended, collapsed at once. Passing the finger into the bladder, a soft and enormous swelling was felt.

The operation was performed at 5 o'clock, July 25. At nine o'clock that evening the bladder became again distended, when the house-surgeon introduced a catheter and relieved him. The catheter was used daily until the 22d, when the patient was again etherized for the purpose of examining the wound. The finger being passed into the wound pushed something before it.

July 26. Dr. M. passed Thompson's urethral dilator into the wound, and a metallic catheter was left in the bladder. This instrument gave rise to so much pain that it was removed, as was also the case with a flexible catheter which had been employed subsequently.

July 27. The patient complained of more pain, and the abdomen became tympanitic. Relief from these symptoms was obtained by warm applications.

July 28. A large quantity of pus was discharged from the wound, attended with a feeling of a good deal of relief. From that time until death the urine flowed freely through the artificial opening. On the 8th of August he was attacked with diarrhoea, to which he finally succumbed. A few days before his death he also had a good deal of cough, and developed the usual symptoms of pleurisy.

The autopsy was made the day following by Dr. Delafield. The right lung was the seat of recent pleuritic adhesions. The right kidney, ureter, and pelvis of kidney contained pus. The entire organ was enlarged, and there was a general infiltration of pus through its substance. The wall of the bladder was thickened; its mucous membrane covered with pus, and in its lower and posterior portions there was a large rupture. One of the torn edges infiltrated with pus projected into the cavity of the viscera. There was also a rupture of the urethra just in front of the neck of the bladder. Besides this there was some pelvic peritonitis; the anterior portion of the rectum was bound down, so that Douglas's cul-de-sac was bridged over and filled with urine.

The reasons why the urine flowed freely after the lateral section and the use of Thompson's dilator, and not afterwards, were quite apparent on autopsical examination. Passing the finger through the wound, one portion of the rent was seen to fold directly over

the neck of the bladder, and to be covered with granulation tissue.

Dr. Mason remarked that some two years ago he had had occasion to operate upon a patient by lateral section two days after rupture of the bladder. In that case the patient's life was saved. He was convinced that had there been any difficulty in evacuating the bladder on the day of admission, which difficulty would have necessitated a rectal examination, the real nature of the case would have been easily detected, and the operation would have been performed to better advantage.

FIBROMATA OF THE LOBULE OF THE EAR.

DR. KNAPP exhibited two fibromatous tumors, removed by operation from the lobules of the ear of a negress, which tumors had been occasioned by the wearing of ear-rings. One of these growths was the size of a nutmeg, the other that of a hen's egg. They were composed of connective tissue. In removing the larger tumor the flaps were made from the superior surface of the growth. These were curved in shape, with their convexities downward. The external flap was longer than the internal one, and when both were brought together to form the lobule the wound was on the internal aspect of the latter.

PERSISTENT WHEEZING RESPIRATION AND ENLARGED BRONCHIAL GLANDS.

DR. LEWIS SMITH presented the thoracic organs removed from an infant, aged five and a half months, that died in the Infants' Asylum. The attention of Dr. S. was called to this case about the first of September. He was informed at that time that this baby had had a wheezing respiration for a week. The temperature was normal, the respiration somewhat accelerated, and the pulse was 90. The wheezing occurred in inspiration and expiration, and appeared to be produced in the larynx or in the trachea. The mother of the child having phthisis, and a careful examination of the throat of the child revealing nothing unusual, the conclusion arrived at was, that there was an enlarged bronchial gland pressing either upon the bronchial tubes or upon the trachea. This wheezing respiration continued throughout the life of the child, and its persistency was one of the main confirmations of the diagnosis. At first the lungs were sound, but in the course of a week or more febrile symptoms set in, tubercles became developed, and, with an attendant diarrhoea, terminated the life of the patient October 20.

At the autopsy several bronchial glands were discovered undergoing cheesy degeneration. The largest of these was located nearly at the point of bifurcation of the trachea, but pressing mostly upon the right bronchus. The mesenteric glands were also cheesy. Tuberculous deposit was found in both lungs. The spleen contained a few small tubercles, as was also the case with the liver. The brain was not examined.

ACUTE NEPHRITIS—COMA.

He also exhibited a pair of kidneys removed from an adult female, aged 34, who having been a subject of syphilitic disease, but having at the time no manifestations of the disease, became suddenly comatose, and died in thirteen hours after. He did not see the patient during life.

At the autopsy the brain was found normal; the kidneys were, however, intensely congested, and presented the general gross appearances of acute Bright's disease. Associated with this condition there was found albuminous urine in the bladder.

The Society then went into executive session.

NEW YORK SOCIETY OF NEUROLOGY
AND ELECTROLOGY.*Stated Meeting, October 19, 1874.*

THE PRESIDENT, DR. MEREDITH CLYMER, in the Chair.

A MEMORIAL notice of the late Dr. Jeffries Wyman, a Corresponding Member, by Dr. S. G. Webber, of Boston, was read by the President.

A memorial notice of the late Dr. Francis Edmund Anstie, of London, a Corresponding Member, by Dr. Alfred L. Carroll.

The special order of the evening was a paper "On the Combined Administration, chiefly Hypodermically, of Chloral, Morphia, and Atropia," by Professor Roberts Bartholow, M.D., of Cincinnati, a Corresponding Member.

COMBINED ADMINISTRATION OF CHLORAL, MORPHIA,
AND ATROPIA.

Dr. Bartholow began by stating the desirableness of further knowledge of the reactions which ensue when remedies affecting the nervous system are conjointly administered. He had to offer to the Society a condensed summary of the results obtained from the simultaneous administration of chloral, atropia, and morphia.

Chloral differs from morphia, when injected subcutaneously, in the more decided systemic effects and the less local impression on the sentient nerves. As regards the systemic effects, the action of chloral is very much the same when administered hypodermically as by the stomach. The chief danger is an arrest of the respiratory movements. Chloral does not exert any chemical action on atropia when the two are held in solution together, for dilatation of the pupil of a cat takes place when the combined solution is instilled into the eye. Dilatation of the pupil also happens when they are administered hypodermically together. An apparent antagonism is observed as regards their action on the heart when the solutions of chloral and atropia are placed in contact with the heart of a frog when in position in the chest, after division of the medulla, or when the heart is removed. The action of the heart is further found to continue much longer when a lethal dose of chloral is administered together with atropia. In rabbits the same result is produced by the conjoined administration of the two agents.

Atropia is found to prolong the chloral narcosis several hours in rabbits, and diminishes the sensibility to pain. In man the excitant action of atropia hinders the occurrence of the chloral narcosis, but rather deepens the sopor when it at last supervenes. The effects of atropia last much longer, and are, apparently, in no way prevented by chloral.

Morphia deepens in every way the effects of chloral. Dr. Bartholow found, in the course of some experiments on himself, that many of the unpleasant effects of morphia are modified, as regards the wakefulness caused by the latter, but are not modified as regards the subsequent nausea, vomiting, vertigo, and constipation. When the two agents are administered conjointly, a much less quantity of chloral is necessary in order to produce sleep.

These agents act much more happily when administered simultaneously. Chloral causes sleep, morphia relieves pain, and atropia prevents or lessens the depression in the respiratory and cardiac movements caused by the other two, whilst it contributes to their cerebral effects.

These physiological studies are confirmed by the therapeutical results. The combination of chloral, morphia, and atropia is adapted to those cases of *insomnia* caused by pain, or in which chloral and morphia alone merely increase the cerebral excitement, as in *hypochondria*, *puerperal mania*, etc. This combination is also indicated in cases of fatty and irritable heart.

When pain is to be relieved, chloral is not so serviceable alone as in combination with morphia and atropia. The local administration—that is, the insertion of the medicament at the site of pain—is more effective than the merely systemic impression. This is especially the case in *tie-douloureux*, *sciatica*, and *coxydynia*, which are much more effectively treated by injections practised into the neighborhood of nerves which are the seat of pain. The combination of a local irritant and benumbant with a systemic anodyne is more curative than either used singly.

In cases of *muscular spasm* the author of the paper had obtained excellent results from the combined use of chloral, morphia, and atropia, and he especially called attention to the efficacy of these agents in the cramps of cholera. Many cases of spasmodic asthma and hay-fever had been benefited by their conjoint administration.

The paper was discussed by Drs. W. H. Draper, A. McLane Hamilton, Putnam-Jacobi, Beverly Robinson, and Bartholow, after which the Society went into executive session.

ACADEMY OF MEDICINE.

Stated Meeting, November 5, 1874.

DR. AUSTIN FLINT, PRESIDENT, in the Chair.

ACUTE AND SUBACUTE SPINAL PARALYSIS.

The paper for the evening was read by Dr. E. C. Seguin, upon "Acute and Subacute Spinal Paralysis" (inflammation of the kinesodic tract of the spinal cord).

This is a rare form of myelitis, which has only been recognized and described within the last few years.

The affection has received a variety of names, as follows: "Acute Anterior Spinal Paralysis," "Subacute General Anterior Spinal Paralysis," "Spinal Paralysis," "Myelitis of the Anterior Horns," "Acute Spinal Paralysis of Adults," "Affection of Adults like Infantile Spinal Paralysis."

The author of the paper preferred the terms "Acute and Subacute Spinal Paralysis," or inflammation of the tract, a name based upon pathological considerations.

The paper was a most systematic and exhaustive *résumé* of the history of the cases which have been already reported, together with a report of the cases which have fallen under the author's observation; and also the semiology, diagnosis, pathological anatomy, etiology, prognosis, and treatment of the affection.

From an analysis of the cases reported, it appeared that there were present *disæsthesia*, slight temporary *anæsthesia*, paresis affecting the extremities; and in rare cases face, eyes, tongue, and throat, not affecting the respiratory muscles and those of the abdomen, back, bladder, or sphincter ani.

Muscular atrophy of the paralyzed parts. Strong tendency to spontaneous recovery. The course of the affection may be acute, subacute, or chronic; the majority of the cases being of the first variety.

Diagnosis: *Positive*, from paresis affecting muscles

of rational life; atrophy and loss of electro-muscular contractility; *negative*, absence of spinal epilepsies, bed-sores, or disturbance of sphincter ani muscle.

The disease resembles infantile spinal paralysis in a most remarkable way.

Pathological anatomy: Granular degeneration of the ganglionic cells of the anterior horn of gray matter.

By far the greater number of cases have been males. Exposure to cold, or "catching cold," is a frequent cause.

Prognosis, as regards life, very good; relating to the paralysis, only moderately good.

The rapidity of the atrophy and loss of electro-muscular contractility are guides to prognosis. Treatment, same as in acute myelitis and congestive condition of the cord.

In the chronic form, treatment for the purpose of restoring vitality to the muscles.

The author of the paper inclined to the opinion that we have in this disease, which affects adults, a form of paralysis identical with infantile spinal paralysis; and with that view suggested the following formulated view of the affection:

Inflammation of the motor tract of the spinal cord.	In adults.	{ Acute. { Subacute. { Chronic.
	In children.	{ Always acute.

MEDICAL LIBRARY AND JOURNAL ASSOCIATION.

Stated Meeting, Nov. 6, 1874.

DR. J. C. PETERS, PRESIDENT, in the Chair.

ON OVARIOTOMY.

THE paper for the evening was read by Dr. B. F. Dawson, upon special points in Spencer Wells's "Ovariectomy Operations, with Remarks upon the Operation in General."

The following were the points specially referred to, and were brought forward by the author of the paper for the simple purpose of eliciting opinions from the profession regarding their value and practicability:

The *first* point was: Mr. Wells never permits more than seven or eight persons to be present at any of his operations. A larger number is very likely to impede the movements of the operator, etc.

Second. No person is allowed to be present who is likely to carry about with him infectious germs. Strangers are therefore obliged to sign a paper to the effect that they have not been near any case of contagious disease, or anywhere where they would be likely to get any infectious germs.

Third. Perfect quiet and avoidance of all excitement, both before and after the operation. No one is allowed to be present until the patient is anesthetized, and no one is allowed in the room after the operation has been completed, except the immediate attendants of the patient.

Fourth. The anæsthetic now employed by Mr. Wells is bichloride of methylene. Mr. Wells is of the opinion that many cases have proved fatal from the vomiting which is liable to follow the administration of ether and chloroform, and it is possible that this is a prominent reason for using the methylene.

At this point the author of the paper made some general remarks relative to the use of this agent, and

arrived at conclusions as follows, viz.: nausea and vomiting are much less likely to follow its administration than the administration of ether or chloroform; there is seldom any bronchial irritation; and the rapidity with which the anæsthesia can be produced, the absence of all vapors of the agent in the room, and the quickness with which the patient recovers from its influence, are all elements in favor of its adoption; certainly in favor of giving it a thorough trial.

Fifth. Mr. Wells always secures the patient to the table with straps. All movement is thus restrained, and the patient is prevented from impeding the operation.

Mr. Wells is exceedingly careful to prevent any blood from entering the peritoneal cavity. When the cyst is emptied the abdominal walls are at once pressed together by the hands of an assistant, and the edges of the wound brought to look upward. A large double sponge is placed in the abdominal cavity, to absorb all fluids while the pedicle is being secured and the stitches introduced through the abdominal parietes. Each suture, after its introduction, is given to the hands of an assistant, who sustains the edges of the wound until all the sutures are introduced; then the sponge is withdrawn and the wound closed, exercising the greatest precaution with regard to thoroughly closing it about the pedicle. He uses the clamp.

The patient is placed in bed always in the same room, in which there is a grate, and even in warm weather there is a small fire. The room is darkened.

Dr. Sims remarked that he was not willing to accord to Mr. Wells the palm of being the most successful operator for ovariectomy; but chose to bestow that honor upon Mr. Keith. With regard to limiting the number of spectators, and being sure that none of them carried any infectious germs about them, he took to himself the credit of inaugurating Mr. Wells in this very precaution. He called the attention of Mr. Wells to the importance of this precaution in the year 1866, and was glad to hear that he was active in its thorough enforcement.

Dr. Sims remarked that he acts altogether upon this principle, and insists upon it most rigidly, and is thoroughly satisfied that in this particular Mr. Wells is right.

In hospital practice it cannot be carried out.

With regard to bichloride of methylene, he was not at all disposed to accept it as an anæsthetic. As to its safety, he did not think it one whit safer than chloroform. It slows the pulse, it is true, and he had thought this an advantage in some instances.

With the experience we have he does not think we have a right to say that it kills only one in five thousand; for it is to be very much doubted if it ever has been administered that number of times. He was not of the opinion that it should be used by every ovariotomist.

As far as strapping the patient down is concerned, he saw no necessity for it. As to closing the wound very tightly about the pedicle, that is a matter of great importance. Probably every operator is very careful about that part of the operation, and he could not see how any operator could very well do otherwise.

He had *always* been opposed to the clamps, but today entertained somewhat different views upon that question than formerly.

Dr. PEASLEE remarked that he, as far as he was individually concerned, admired the spirit of having the ideas of one man, especially of one who is an acknowledged leader in any department, given to us for consideration, as had been done in the paper for the even-

ing; but, as far as possible, he had acquainted himself with all the methods of operating which had been practised by all operators, and had given to the profession the result of no one man's experience, but the result of *all* men's experience. With regard, however, to the particular points presented in the paper, he might say that so far as exclusiveness, admission of spectators, etc., was concerned, he believed it to be very judicious. It would be far better, no doubt, for our patients, could this precaution always be taken; but we cannot do that in hospital as we can in private practice.

He fully agreed with Mr. Wells that the patient should be anesthetized before she is brought into the presence of either instruments or persons who are to be present at the operation. The precautions with regard to quiet after the operation are also very proper.

He thought it hardly necessary to fasten the patient to the table; still it might happen, but exceedingly seldom, that it would be of service. It might be so, perhaps, if the anæsthetic should produce vomiting or something of that kind, which would have a tendency to discontinue the operation.

With regard to the admission of persons who have been in any way exposed to infectious influences, we certainly cannot be too careful. The peritoneal cavity has immense power for absorption, and that being the case the least particle of infectious material in the atmosphere about the patient may expose her to great risks, and should be carefully guarded against. In every case of ovariectomy the abdominal wall should be hermetically sealed. If a drainage tube be used its connections, *in every particular*, are to be air-tight. Every open tube introduced into the peritoneal cavity is an invitation to septicæmia. He believed that this position can be maintained, and receives the support of the profession.

He did not wish to be misunderstood; what he meant to say was: A tube is not an invitation, but an *open tube* is an invitation to septicæmia. It is the admission of air that is objectionable.

With regard to the kind of anæsthetic to be used, he did not see how any one could defend the use of chloroform in ovariectomy at the present time. The question with regard to chloroform was, he thought, that it should be entirely rejected. As between ether and methylene, he was inclined to use ether, and was not disposed to resort to anything else. There is a great objection to both ether and methylene if they are not administered in a proper manner. Ether should be administered simply to the production of anæsthesia and *not* asphyxia. If the patient is asphyxiated, the chances of success are very much diminished. When the anæsthetic has been carried to the point of producing stertorous breathing, it should at once be stopped, and the patient held at a point somewhat short of that.

Dr. Dawson remarked that *pure* methylene was scarcely liable to produce vomiting.

Dr. PALLEN remarked that the subject of treatment of the pedicle seemed to be worthy of a few moments' consideration.

Mr. Wells treats all his cases with the clamp.

Dr. Peaslee uses the ligature, and drops the pedicle within the abdominal cavity.

Dr. Keith sears the pedicle.

Dr. Sims formerly used the silver-wire ligature, and dropped the pedicle within, and latterly has adopted the method of securing the pedicle by means of an iron wire, and retains it outside.

Dr. Dunlap, O., ligates the pedicle and drops it within.

Thus we are left in considerable doubt as to the best method of treating the stump.

Septicæmia and peritonitis have followed all these methods. It seemed to him that the best method is that latterly employed by Mr. Keith, namely, *searing* the pedicle; yet there are very many cases which he should dislike to trust to this means, on account of enlargement of blood-vessels which is sometimes present, and the consequent liability to hemorrhage. Would it not be well, then, to withhold any absolute opinion with regard to the treatment of the pedicle, and be governed by the peculiarities of each case? For one case may be much more prudently treated in one manner, and another case in another manner. At his next operation he proposed to first crush the vessels and then use the cautery, which he believed would effectually guard against the occurrence of hemorrhage. With regard to anæsthesia, may we not well ask, Whether the vomiting which may be present is always due to the anæsthetic employed? May it not be due in some cases even to commencing septicæmia? or may it not be due to the shock of the operation at times, etc., etc.? These are questions we are not now able to answer, but they are worthy of consideration.

Dr. PEASLEE remarked that when the patient had taken no food for three hours previous to the administration of ether, he had never had vomiting ensue. Still he thought he should use the methylene at his next operation. He also expressed his preference for the ligature (catgut) in the treatment of the pedicle. If compelled to use the clamp, that devised by Dr. Dawson seals the abdominal cavity more perfectly than any which he had seen.

Dr. SIMS remarked that to-day he was satisfied that the practice of securing the pedicle with a silver wire, and returning it to the abdominal cavity, is wrong. That was the plan, however, which he adopted for twenty years; but he had been led to abandon it for the reason that secondary hemorrhage had followed its use in two cases, in which he had seen the *post-mortem*, and he abandoned its use at once. As soon as the silver wire was dropped, he resorted to the method of treatment adopted by Dr. Peaslee at once, and continued that up to a certain date. One day he had a somewhat broad pedicle to deal with, and he introduced a double ligature; and tied one-half of the pedicle with a silk thread, and the other half with the catgut ligature. At *post-mortem* examination he had found to his horror that the end of the stump was in a *sloughy* condition. From this case he hesitated with regard to the use of the ligature and return of the pedicle to the abdominal cavity. That sloughy state of the distal end of the pedicle was immensely suggestive. Now, to-day, he was of the opinion that securing the pedicle with the iron wire, which answers all purposes of a clamp, and keeping the pedicle outside, is the best method of management. With this view he had very much to retract of what he had said concerning the clamp in former years.

I now feel satisfied that the method introduced by Baker Brown will finally be accepted as the best, and that is the use of the actual cautery. When we get instruments perfected for applying the cautery, he believed it could be accomplished with great safety and certainty.

He proposed to have made a clamp with a gutter, so that when the pedicle was cut off even with the upper surface of the clamp, an extensive surface would be left behind for the application of the cautery, and when such a large surface of the stump had been well seared, it would be returned to the abdominal cavity.

He believed that a clamp could be constructed upon this plan, which would give sufficient surface for the cautery to act upon to prevent all possibility of secondary hemorrhage.

DR. SELL believed that every ovariologist should go to his operations prepared for any emergency, and then use his own judgment as to whether he would adopt one or other method of treating the pedicle. He remarked somewhat at length upon the percentage of mortality attending the various methods of treating the pedicle, and concluded by saying that he was simply prefacing himself, as he proposed to review the subject in a paper at some future date.

DR. PEASLEE remarked that he used the ligature because he had never had it *slip or give*, if the precaution had been taken to leave the stump undisturbed after the application. He had never had a case die from hemorrhage when the ligature was properly applied and the pedicle left undisturbed, and had never seen any indication of sloughing where the ligature has been applied. But if these accidents do sometimes occur, the same thing occurs after the use of the clamp and other methods.

ARMY NEWS.

Official List of Changes of Stations and Duties of Officers of the Medical Department, United States Army, from November 5, 1874, to November 18, 1874.

CUYLER, J. M., Surgeon.—Detailed as member of Army Retiring Board, to assemble in New York City, on 16th instant. S. O. 240, A. G. O., Nov. 5, 1874.

HASSON, A. B., Surgeon.—Granted leave of absence for 20 days. S. O. 224, Military Division of the Atlantic, Nov. 12, 1874.

MOORE, JNO., Surgeon.—Detailed as member of Army Retiring Board, New York City. S. O. 240, c.s., A. G. O.

HARTSUFF, A., Assistant Surgeon.—So much of S. O. 233, c.s., A. G. O., as relates to Assistant Surgeon Hartsuff, is revoked. S. O. 244, A. G. O., Nov. 10, 1874.

DE HANNE, J. V., Assistant Surgeon.—Assigned to duty as Post Surgeon at Fort Mackinac, Mich. S. O. 220, Military Division of the Atlantic, Nov. 6, 1874.

WILSON, A. D., Assistant Surgeon.—To report in person to the President of the Army Medical Board, New York City, for examination for promotion, and, upon its completion, to the Commanding General Department of Arizona for assignment to duty. S. O. 243, A. G. O., Nov. 9, 1874.

WOODRUFF, E., Assistant Surgeon.—Assigned to duty as Post Surgeon at Fort Niagara, N. Y. S. O. 220, c.s., Military Division of the Atlantic.

Medical Items and News.

AMERICAN PUBLIC HEALTH ASSOCIATION.—The meeting of the Am. Public Health Association commenced in Philadelphia, Nov. 10th, and proved of such interest, that it was continued a day over the appointed time. The papers presented were generally of a high order, and gave the most advanced views of the students of sanitary science. The Association is commanding the aid and influence of many of the fore-

most men of the medical profession. They are coming more and more to feel how the subject of Hygiene underlies all artistic methods of treatment.

Prof. Hartshorne ably discussed the causes of the excessive infant mortality of cities. Hospitals and hospitalism was very thoroughly discussed in the papers of Drs. Gross, Billings, Pepper, and Carl Pfeiffer of New York. It was claimed by all that there is great need of new investigation of the whole subject. No one advocated the building of hospitals in their former compact structure, but many of the wards should be in buildings only connected by stairways. One or more wards should always be kept vacant, for transfer from other wards while cleansing is going on. In fact, a thorough house-cleaning system is the great desideratum for hospitals. The paper of Dr. Baker showed careful study of vital statistics, and it is evident that the able labors of Farr, Harris, Snow and others in this direction are beginning to secure accurate classification. The paper of Dr. Hunt especially emphasized the fact that cities are an interruption of the sanitation of nature, and as such art must compensate for the evils art has introduced. The need of air circulation beneath the ground and the importance of drains for pneumatic as well as aquatic service was strongly insisted upon. The small-pox question had full ventilation at the hands of Dr. Toner of Washington, and Dr. Snow of Providence, and the distinction between epidemics and contagions was sharply drawn.

Dr. Busey, of Washington, noted some interesting facts as to the handling of vegetables and as to the laws of their decay. Turnips, for instance, show bacteria sooner than any other vegetable, and the proper condition of each vegetable and the laws of its preservation and decay are susceptible of accurate study.

The paper of Dr. Smith showed most conclusively the bearing of sanitary science upon the advance of the medical profession.

Dr. Sturgis, in a paper on syphilis, furnished a large number of statistics and made careful deductions therefrom.

Dr. Beard, in his paper on hay-fever, disputed the ground that it depended upon locality or upon infusoria. While recognizing dust-pollen, etc., as exciting causes, he claimed it as a species of catarrh or influenza which has its foundation in a nervo-bilious temperament.

The papers of Drs. Fryer and Billings gave some interesting observations as to the climate of the extreme West. Its effect on pulmonary disease was discussed on the basis of statistics, and in reference to the native population. While consumption is a rare disease, it is not true that all stages of pulmonary disease are benefited by the climate. The fact was brought to light that erysipelas occurs in the mountain regions, and amid circumstances where it is very difficult to detect zymotic origin. The evils of crowded school-rooms was ably discussed by Dr. Bell, of Brooklyn, and the important point insisted upon that we are not too much to concentrate our attention upon carbonic acid as the index of foul air. There were several other papers of interest, and the whole meeting was found profitable to those in attendance. The evening addresses of Dr. Osgood, on "The Relations of Health to the Higher Culture," of Prof. Orton, on Geology in its Relation to Water-Supply, and of Gen. Vieié, on Drainage and Sewerage, commanded the full attention of large audiences, as did the excellent closing addresses of Hon. Mr. Eaton and Hon. Mr. Steiner. No time was wasted on side-issues or feasting, and both the papers and discussions are a valuable contribution to sanitary science.

Original Communications.

A BRASS RING LODGED IN THE LARYNX
FOR FOUR YEARS.

REMOVAL BY SUBHYOIDEAN LARYNGOTOMY—CURE.

By GEORGE M. LEFFERTS, M.D.,

SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY, THE DENTIST DISPENSARY (THROAT DEPARTMENTS); LATE CHIEF OF CLINIC TO PROF. STOEHR, IN THE IMPERIAL UNIVERSITY OF VIENNA.

THE following contribution to the surgical therapeutics of the air-passages is made in the belief that the history of the case detailed possesses a sufficient number of unusual points to render it of general interest. These features are the remarkable and unique method of lodgment of the foreign body, the comparatively slight disturbance—both local and constitutional—that it has until lately caused, notwithstanding the length of time that it had remained within the larynx and in its peculiar location, and its very unusual nature—but one of a similar character having been reported among the very many cases on record of foreign bodies within the air-passages.

This one-parallel case is reported* as occurring in the person of a young child who had inhaled a brass ring the size of a shilling. "It remained in the larynx for nineteen days, the symptoms being an occasional cough, attended by a croupy sound and a whistling noise during sleep. Tracheotomy was performed at the end of the period above specified, and the foreign body pushed upwards and seized by forceps at the opening of the larynx."

The operative procedure employed in our case for the removal of the ring is an unusual one, having been performed but five times, and, as far as I am informed, never in this country, and in the present case for the first time carried out for the removal of a *foreign body* from the larynx, although its applicability in such cases is spoken of by several of those who have written upon the subject.

The skilful use of the laryngoscope has almost entirely obviated the necessity of resort to operative measures of like character in the surgical treatment of the throat; but cases occasionally occur where, as in the present one, laryngoscopic treatment is inadvisable or impossible, and where we are compelled to employ other means for the relief of the patient than treatment *per vias naturales*.

The extra laryngeal methods of operating cannot therefore be lost sight of, but must remain now, as well as in the pre-laryngoscopic era, a valuable means of aid at our command, and any additions to our experience of them, no matter how slight that addition may be, will have a certain value.

Finally, the case affords an instructive illustration of the value of the combined methods of diagnosis by means of the stethoscope and the laryngoscope; for although the diagnosis of a foreign body within the air tract had been made in our case, and its location most accurately determined by the ear alone, still the laryngoscope rendered this diagnosis, by demonstrating the fact to the eye, an *absolute* certainty, and supplied, in addition, the details of position, form, and nature of the foreign body, and led to an intelligent appreciation of the indications for surgical treatment—important facts at which auscultatory science could only arrive by inference.

CASE.—A. B., aged six and a half years. Four years ago (August, 1870) the child, while playing in the company of other children with an ordinary, medium-sized, brass finger-ring, broken at one point, placed it in her mouth, and a few moments later suddenly swallowed it. Urgent dyspnea immediately followed; the child became deeply cyanotic, then unconscious, and suffocation seemed imminent, until one of the bystanders, passing her finger deep into the child's throat, felt the ring and pushed it downwards. This act was followed by immediate improvement in the respiration. The child recovered consciousness, and soon afterwards was able to move about at play.

On the physician's arrival, a short time later, various instruments were passed into the throat in order to seize the ring, but without success, and no foreign body being met with during the examination, it was supposed to have passed into the stomach, and further attempts at removal were desisted from.

Cathartics were administered and the evacuations carefully watched, but without finding the missing body.

The child's respiration is stated to have remained good during the remainder of the day of the accident; but the same night the mother noticed that it was decidedly stridulous, and says that it has since remained so. The child, however, slept quietly, and had no attacks of laryngeal spasm. Deglutition was not and has not been affected. The child, immediately after the accident, became partially aphonic, and has continued in the same condition during the subsequent period of time up to within six weeks. A short, hacking cough made its appearance a few hours after the ring was swallowed, and has persisted since that time.

Several physicians were summoned at different times during the few weeks following the accident, and occasional instrumental examinations of the throat were made. (It may be here stated that no laryngoscopic examination had been made previous to the one made by me.) Emetics, laxatives, and cough-mixtures were ordered, and the mother was assured that the presence of the ring within the air-passages was extremely doubtful. The above narration of symptoms comprises the history of the case during the following period of time—nearly four years—up to six weeks ago. Within this time there was no change in the symptoms as described, nor were any new ones noticed, except that the child gradually lost flesh and strength.

Six weeks ago the child contracted a heavy cold. The respiration immediately became seriously embarrassed. The voice was entirely lost, and laryngeal spasm occurred for the first time, principally during the night. The attacks were prolonged and severe; the child becoming relaxed and cyanotic, then gasping for breath, and tearing at the throat with both hands; but the intensity of the spasm passing off in a few seconds, deep inspirations followed, the face assumed its natural hue, and the patient again fell into a natural sleep.

Lately these spasms have increased in frequency, so that she may have from two to six during the course of one night. Any exertion or excitement during the day will increase the number and severity of the attacks at night. A fit of crying alone has often provoked serious and protracted laryngeal spasm. Although the voice has been entirely lost for the last six weeks, and all of the symptoms have pointed to a very serious interference with the function of the larynx, deglutition has not been at all affected. The child does not, nor has not, complained of any pain during the process, and has always taken, with equal facility, solid or fluid food, a curious fact, to be noted when

* Lancet, vol. i. 1852, p. 247.]

the location of the ring in its relation to the laryngeal parts comes to be described.

The condition of the child becoming so serious, the mother was advised by her friends to leave her home in the country and come to this city for medical advice.

She here consulted Dr. J. Lewis Smith, who upon making an auscultatory examination detected the presence of the missing foreign body within the respiratory tract.

The doctor referred the case, as one of unusual interest, to Dr. J. R. Leaming, who, after making his examination, directed the case to me, for the purpose of having a laryngoscopic examination made.

My report having been made, the child subsequently was most courteously referred to me for treatment by Dr. Smith.

At my request Dr. Leaming has kindly made me the following interesting report of the result of his auscultatory examination:

"Auscultation of the chest: Right side front.—Obscure evidence of obstruction somewhere in the air-passages, not brought definitely to the ear.

"Left side front.—Loud whistling of moderately high pitch over the region of the left bronchus, but without local point of intensity.

"Right side posteriorly.—Loud whistling, moderately low pitch, over the right bronchus, extending into the branches so far as to the third or fourth divisions, rising in pitch, but with no point of local intensity.

"Left side posteriorly. Loud whistling over the left bronchus, of moderately high pitch, extending into the branches so far as to the third and fourth divisions, rising in pitch, but without local point of intensity.

"In all other respects the respiratory sounds of the chest are normal.

"Diagnosis.—Obstruction not in the chest.

"Auscultation of the Trachea.—Loud whistling of low pitch over the trachea, but without point of local intensity; no obstruction.

"Auscultation of Larynx.—Loud whistling of high pitch over the larynx, with local point of intensity.

"Diagnosis.—Obstruction in the larynx.

"The seat of the murmur is in the larynx, and is of high pitch. It is consonated in the trachea, bronchi, and branches, the pitch varying according to the size of the tube; consonated sounds in air-chambers assume the pitch fundamental to the chambers in which they are reformed.

"The murmur was not consonated in the true respiratory system."

The result of the laryngoscopic examination confirmed this diagnosis most fully. The mirror showed the left ary-epiglottic fold, together with the false cord of the same side, to have been the seat of old ulcerative action, and to have undergone considerable alteration in form and size from the results of inflammatory plastic deposit, and subsequent cicatricial contraction. The ary-epiglottic fold is greatly thickened, especially posteriorly, but still preserves its general outline and is distinctly recognizable. The false cord below it presents an irregular and nodulated outline, and by its protrusion forwards and inwards, diminishes the normal calibre of the larynx more than one-half, causing thereby a marked degree of stenosis. The surfaces presented to view in this part of the larynx, although they show the evidences of superficial ulceration at points extending deeply into the tissues, have fully cicatrized and present a smooth exterior.

On the right side of the larynx the parts present their normal configuration. The right vocal cord can

be seen, partly obscured posteriorly by the hypertrophied left false cord, lying far below in the laryngoscopic picture, and moving freely in phonation.

The ring lies as shown in the drawing, with about one-third of its circumference hidden by the middle of the hypertrophied and nodulated false cord and ary-epiglottic fold of the left side, which lie above it. It reaches inwards at about the level of the vocal cords, until it overlies to a certain extent the right vocal cord, thus presenting a direct barrier or obstruction across the larynx, and interfering with and modifying in character the respiratory current of air.

Posteriorly it extends upwards and backwards, and, lying against the posterior pharyngeal wall, is thus elevated above and lies free from contact with the left arytenoid cartilage. About two-thirds of the ring are therefore presented to view, being entirely uncovered by the laryngeal parts, and it hangs in position in the same manner as an ear-ring is held by the lobe of the ear.

The ring has undergone but little, if any corrosive action, it is discolored at points, at others the natural metallic lustre is plainly to be seen, and it presents no irregular or eroded surface, a circumstance readily explainable when it is remembered that foreign bodies situated within the larynx are much less liable to become incrustated with various kinds of matter than when they are lodged in the bronchial tubes. In the latter case the foreign body usually becomes invested by inspissated mucus, or even by earthy substances, principally the carbonate and phosphate of lime, in small quantities.

During respiration the natural motion of the laryngeal parts is confined to the right side of the larynx, and the corresponding cord is abducted from the median line; no change, or but very slight irregular movement, being noticed upon the opposite side of the larynx.

In phonation action is again confined to the right side of the larynx, and the vocal cord approaches the median line and passes beneath the hypertrophied mass upon the opposite side. Owing to its presence, the fact of whether or no it meets its fellow cannot be demonstrated. During this process of phonation the ring rises up from its bed, leaves the posterior pharyngeal wall, and stands in an oblique direction to the vertical axis of the larynx. On the completion of the act it falls back into its former position.

The process of deglutition cannot, of course, be practically demonstrated with the mirror; but simple efforts, the mirror being held in the fauces, show that during the act the position of the ring suffers no alteration. Both fluids and solids must therefore pass, to a certain extent, through the ring to reach the oesophagus.

In deciding upon the operative procedures necessary to be undertaken for the relief of the patient by removal of the foreign body, preference was given to the extra-laryngeal to the exclusion of the intra-laryngeal methods, and for the following reasons:—

The age of the child—six and a half years—and its irritable, nervous temperament, increased certainly by the long-continued abnormal state of the respiratory passage, and the consequent constitutional disturbances, and probably influenced by the many examinations and faucal explorations that it had from time

to time undergone, rendered a perfect and satisfactory examination *utterly impossible*, owing to the child's unwillingness to submit to it. It was only after repeated examinations, and much time spent in reassuring the little patient, that the above results were able to be obtained.

The possibility, therefore, of the successful employment of the delicate operative manipulations required in the performance of any laryngoscopic operation,—manipulations demanding not only a *tolerance*, but also an active and intelligent *co-operation* on the part of the patient,—was in this case not to be expected.

Anæsthetics, valuable as they are in the other departments of surgery, render little if any service to the laryngoscopist in such cases as the one under consideration. The difficulty, not only of the examination itself, but much more so in carrying out the necessary instrumental procedures, is increased greatly, and in fact may be said to be rendered insuperable, by its employment in laryngoscopic surgery. As has been already said, intelligent co-operation on the part of the patient with the endeavors of the physician, forms an essential element in the skilful performance of any laryngeal operation. The patient being anæsthetized this co-operation is not forthcoming, and the operation, in a very large proportion of the cases where it has been employed, has entirely failed.

In addition to the reasons stated, other difficulties arising by anæsthesia employed during the performance of operations within the air tract, will suggest themselves to all surgeons, and need not be discussed here.

Then, again, the location and attachments of the foreign body were unfavorable for its successful removal—"per vias naturales," without ample opportunity and time were allowed to carry out the necessary manipulations for its removal in portions (and this has been shown to be impossible). The ring was located too deeply, was covered by too large an amount of firm cicatricial tissue, and included within itself too much of the laryngeal parts to allow of its being seized and forcibly torn from its bed by means of the laryngeal forceps.

The resulting laceration would have been great, and the danger of subsequent inflammatory oedema or tumefaction—a danger intensified by the already existing state of laryngeal stenosis—would have been too serious to have been incurred when other and safer means of removal were available.

Lastly, the indications for operative interference and removal of the foreign body, which by its presence was causing dangerous laryngeal spasm, were immediate.

These considerations deterred me, therefore, from attempting the removal of the ring by the natural passages, and as the best *substitute*, the operation of "sub-hyoidean laryngotomy," or more properly, perhaps, "sub-hyoidean pharyngotomy," was selected.

This method of removal was especially indicated in the case under consideration; the ring being located at the superior opening of the larynx, it could be easily reached through an opening made in the thyro-hyoid membrane, and removed without difficulty or interference with the laryngeal parts proper. The operation is a much less serious one than thyrotomy, and the results in all published cases that I have been able to find, with the exception of one, have been good in its relation to life; while, of course, it presents none of the dangers of interference with the vocal function that thyrotomy does. No important structures are involved in its performance, nor can any large vessels, with care, be wounded; the most liable to this acci-

dent being the superior laryngeal artery and vein, which, however, enter the larynx so far posteriorly and behind the wing of the thyroid cartilage, that injury to them is almost impossible.

The other extra-laryngeal methods for the removal of growths or impacted foreign bodies,—"*infra-thyroid laryngotomy*" and "*tracheotomy*,"—as they are only applicable in the cases where the body to be extirpated is situated in the subglottic region, were not indicated in our case, and are therefore not considered here. The operation of "sub-hyoidean laryngotomy" offers so many advantages, therefore, that it is a matter of surprise that it has not often been performed, to the exclusion of other and much more dangerous methods which have been at times undertaken for the removal of growths, etc., situated either within the valleculæ, at the base of the tongue, on the epiglottis, the ary-epiglottic folds, or even upon the arytenoid cartilages, after the operation by the natural passages has been proved to be, from the nature of the case, unadvisable or impossible, or after attempts at their removal by the mouth have from any cause failed.

Vidal,* Malgaigne, Lewin,† Semeleder,‡ and Langenbeck recommend its performance in such cases as those indicated above, although I believe that it has never previously been done for the purpose of removing an impacted foreign body. Hyrtl§ objects to the operation on anatomical grounds, and states that a view of the interior of the larynx cannot be obtained through a wound in this region, an objection which experience has proved to be erroneous.

In the present case it was deemed advisable to modify the original operations by first performing tracheotomy, and thereby insure the patient a free and plentiful supply of air during the steps of the operation—a procedure rendered doubly advisable by the condition of laryngeal stenosis existing in the case, and the liability to laryngeal spasm (as shown in the previous history), as well as the danger of subsequent inflammatory action reducing still further the calibre of a larynx already diminished more than one-half from its normal condition.

It was proposed to make the presence of the tracheal tube but temporary, and it having subserved its first purpose of protecting the patient from danger during the operation, to remove it as soon as danger from the laryngeal inflammatory process had passed away.

The operation was accordingly undertaken July 7th, 1874, as follows: The head having been thrown backwards over pillows placed beneath the neck, and the position of the cricoid cartilage having been identified, an incision some two and a half inches in length was made over it, in the median line, and extending downwards over the superior portion of the trachea. The skin and superficial fascia being rapidly dissected through, the inner borders of the sterno-thyroid muscles came into view, and after drawing them aside by means of retractors, a few touches of the knife laid bare the cricoid cartilage, and with it the isthmus of the thyroid body lying immediately below, across the trachea,—in this case being unusually large and lying high up. During this dissection several medium-sized vessels were severed, and a halt was here made until they had been secured by torsion. The isthmus was then displaced, partly by pushing it downwards and partly by tearing through its substance, a procedure which I have several times adopted and have never

† Beiträge zur Laryngoskopie. Deutsche Klinik, 1862, No. 13.

‡ Die Laryngoskopie. Wien, 1863. P. 60.

§ Handbuch der topographischen Anatomie. Bd. I, p. 465.

experienced any trouble nor unusual hemorrhage from its laceration, contrary to what I believe to be the generally held opinion. The isthmus being partly removed in this manner, the upper rings of the trachea became plainly visible, and all active hemorrhage having ceased, a hook was placed under the lower edge of the cricoid cartilage to steady the parts.

An incision was then made in the trachea, from below upwards, commencing at about the fourth ring, and continued up to the cricoid cartilage. The tracheal dilator (Trousseau) having been introduced and the lips of the incision held apart, the canula was readily introduced and secured in position.

Spasmodic cough followed, expelling a moderate amount of clear mucus untinged with blood, but ceased after the further administration of ether through the tracheal tube.

The second step of the operation consisted in, first, identification of the position and relations of the hyoid bone, a procedure not unattended by some difficulty on account of the small size of the parts and the close proximity of the hyoid bone to the thyroid cartilage, a limitation of the field of action which renders the performance of this operation upon a child much more difficult than upon the adult.

This point having been satisfactorily ascertained, an incision three inches in length was made parallel with the lower border of the hyoid bone and one-eighth of an inch below it, transversely across the neck, and the skin, subcutaneous cellular tissue, the superficial fascia with the internal fibres of the platysma myoides, the inner half of the sterno-hyoid and thyro-hyoid muscles being carefully divided on each side of the median line upon a director, introduced successively between the various layers, the thyro-hyoid membrane was reached and laid bare without difficulty and with very little hemorrhage, no art-erial branches having been encountered. Two veins which lay across the track of the wound, immediately below the platysma, were of such a size as to render ligature advisable, and having been raised by dissection from their beds, were secured by double ligature and then severed.

The thyro-hyoid membrane being now divided by an incision of less extent than the one through the superficial parts, thus giving a funnel shape to the wound, the cushion of cellular and adipose tissue lying between the base of the epiglottis and the parts external to it, together with the laryngeal mucous membrane to either side of it, were disclosed, the latter being prolapsed outwards as soon as the tense pressure of the thyro-hyoid membrane was removed, and could be seen to be drawn inwards with each inspiration.

The most important and difficult step of the operation now follows—important as regards the danger of wounding the epiglottis, and certainly rendered more difficult by the vagueness of the description given of its mode of performance by Malgaigne and others, and the omission of the consideration of important anatomical points which must influence it.

Malgaigne says,* and his description of the operation has always been considered the classical one, and is the one which has been followed by those who have performed the operation: "After incision of the thyro-hyoid membrane and those fibres of it which go to the epiglottis, the mucous membrane is reached; seize this and divide it also; the epiglottis then presents itself."

Prat,* in describing the steps of his operation, says that he proceeded to divide the tissues, layer by layer, until he reached the thyro-hyoid membrane; after cutting this through, the epiglottis presented itself.

Follin† states that he divided the cushion of adipose and cellular tissue which lay in front of the epiglottis (after cutting through the thyro-hyoid membrane), and lastly, incised the *laryngeal mucous membrane* and opened the cavity of the larynx.

This stage of the operation would, according to these accounts, seem to be indeed a comparatively simple one; but I have not found it to be as described. My dissections and experimental operations upon the cadaver have shown me that after the thyro-hyoid membrane has been divided transversely, a thick layer of cellular and adipose tissue, extending usually from the hyoid bone above to the thyroid cartilage below, forming the cushion of the epiglottis, and lying between it and the parts external, presents itself; to either side of this mass mucous membrane protrudes. This membrane consists of the broad anterior portions of the ary-epiglottic folds at about the point where they join with the sides of the epiglottis—is therefore *laryngeal mucous membrane*, and an incision made through it transversely and directly inwards, or even with the point of the knife directed upwards and backwards, would open directly into the *laryngeal cavity*, not alone by cutting through the anterior extremities of both these folds, but in so doing necessarily dividing also by the transverse incision the cellular and adipose mass lying in front of the epiglottis and between them—would cut through this cartilage at about its middle, or a short distance below that point.

Follin's description of the steps of his operation illustrates this point fully, and demonstrates the danger of such an incision; for by making it he cut across the epiglottis and penetrated directly into the laryngeal cavity.

It is needless to say that this accident is to be carefully avoided. Such an opening into the cavity of the larynx would render, according to several authors, a clear view of its interior impossible, and would certainly defeat, to a great extent, the purposes and advantages of the operation.

How, then, are we to avoid section of the base of the epiglottis? By, after having reached this point in the operation, inserting a tenaculum into the cellular and adipose mass described above, and by means of it drawing the epiglottis forcibly downwards. This puts its ligamentous attachments to the hyoid bone and tongue upon the stretch, draws it away from the former, and leaves an appreciable interval of space between them through which the knife—its point directed upwards and backwards, and kept near the hyoid bone—can be readily passed, and will be found to have penetrated the mucous membrane between the base of the tongue and the epiglottis, the aim of the incision.

The epiglottis being drawn downwards in this manner, mucous membrane will still present itself laterally; but a moment's reflection will show that this is no longer laryngeal. The displacement of the epiglottis has carried downwards with it both ary-epiglottic folds, and the mucous membrane which we now have presenting is a portion of that situated between the base of the tongue and the epiglottis. The incision needs now only to be carried through it on either side, including the few ligamentous fibres

* Manuel de Médecine opératoire. 1871.

* Gazette des Hôpitaux, 1859. No. 103.

† Archives Générales de Médecine. Février, 1867.

which run from the epiglottis to the hyoid bone, and which are seen in the median line; to lay open the pharynx, and to have the epiglottis present itself uninjured to view. A digital exploration by the mouth, made previous to incision of these parts, affords an important aid in diagnosing their relations. The size, form, and ligamentous attachments of the epiglottis, especially in its relation to the hyoid bone, vary greatly in different cases. If the index-finger of one hand, however, be introduced into the mouth, not only the tip, but also the base of the epiglottis can in the majority of cases be reached and felt, should two fingers of the other hand now be placed upon the hyoid bone, a diagnosis as to their approximative relation can be readily made, and will usually be found to be so satisfactory in its results, and will afford so much certainty to the operator during his future proceedings, that it should in no case be omitted.

In carrying out the further steps of my operation especial care was therefore given to this point, which I have endeavored to make clear in as few words as possible, and the importance of which I think merits careful attention on the part of the operator.

The parts immediately below the thyro-hyoid membrane having been exposed as described above, a tenaculum was inserted near the hyoid bone, into this thick cushion of cellular and adipose tissue, and strong traction downwards made to accomplish the purposes already mentioned. To insure still further certainty, a small incision was made into the left lateral projecting fold of mucous membrane, and a director was passed inwards, and then directly across, coming out at a corresponding point upon the opposite side of the wound, and through the projecting mucous membrane at that point. It should therefore lie in the groove or furrow between the base of the tongue and the epiglottis, and a digital exploration by the mouth confirmed the point.

Nothing now remained in order to complete the operation but to incise the tissues lying over the director. This was done, the direction of the knife being upwards and backwards, and the pharynx was opened.

The epiglottis immediately came into view, not, however, being pushed into the wound, as stated by Malgaigne, and was seized and drawn outwards through the incision. A perfect and most satisfactory view was now afforded of the superior laryngeal parts, and the ring was seen lying in the position as previously demonstrated by the laryngoscope.

In order to remove it with as little laceration of tissue as possible, my intention was to have cut through it at two points by means of a cutting forceps, and, having removed the upper fragment, to displace and bring away the remaining and smaller ones by drawing them out through the tissues in which they lay imbedded.

On attempting this, however, and making the firm pressure on the forceps necessary to cut through so thick a substance, the ring was felt to give and rotate slightly. This fact being ascertained, a moment's manipulation with a small forceps resulted in disentangling it from its attachments, and in bringing it safely out through the external wound.

An examination of the ring, in order to ascertain at what point it had been cut through, disclosed the fact that a piece was wanting. An examination of the tissues failing to find this missing portion, and the edges showing no evidences of having been freshly severed, but one conclusion remained, that the whole ring had been removed; that the mother of the child had been mistaken in her description, and that the missing body

was not a finger ring, broken at one point, with the ends bent together so as to overlap each other and fit the finger of the child, as she had stated, but the ring of a watch or locket, thicker, heavier, incomplete, and with bevelled extremities; and this supposition was later confirmed by a jeweller, to whom it was submitted for examination.

Its singular mode of lodgment could now be more readily accounted for, the character of the foreign body giving the key to the explanation. My original view was, that the ring had lodged and become impacted in the left pyriform sinus at the time of the accident, and that it had from thence sunk inwards and downwards, ulceration having occurred as a result of pressure, and granulations formed over it, as the process proceeded, and subsequently cicatrizing; this action having continued until the level of a vocal cord had been reached, and that further ulceration had been delayed by its dense ligamentous character. The only difficulty was in reconciling the facts with the theory. A body of such a size and character as the one in the present case, lodged as I supposed it to have been lodged, would, I think, in a vast majority of cases, have been coughed up or dislodged during the efforts at vomiting, etc., or most certainly have been removed by instrumental interference at the time of the accident, or at least its presence recognized.

After having seen the ring, however, I think that it is reasonable to suppose that having lodged partly across the superior laryngeal opening at the time of the accident, in pushing it downwards, as was done, the left ary-epiglottic fold was caught between the lips of the ring and the latter then firmly crowded downwards, tearing its way into its position, a position which would render all attempts of nature to dislodge it unavailing, and would also cause a diagnosis as to its presence to be much more difficult, unless the laryngoscope had been used.

The corroded and discolored portion of the ring, as shown in the drawing, demonstrates that it must have subsequently changed its position somewhat, and a still firmer hold on the tissues afforded by one of the free extremities having ulcerated its way inwards through and beneath the ary-epiglottic fold and false cord. This same change hid still further the ends of the incomplete ring, and allowed only an unbroken and rounded surface to appear to the eye, representing a complete circle.

In closing the wound I modified somewhat the methods of former operators, and I think with good result. The general practice has been simply to introduce three or four deep sutures, and then to keep the parts in apposition and at rest by flexing the head upon the chest. The method which was carried out in my case was: First, to unite carefully the divided edges of the *mucous membrane* by means of fine thread sutures, the knots being tied so as to lie inwards.

No difficulty was experienced in its accomplishment, and the good result was made manifest by the fact that at no time subsequently, during the process of healing, was there escape of air through the external wound, nor discharge of fluids during deglutition, even though the latter process was at times, by order, forcibly conducted.

This having been done, deep wire sutures, three in number, were then introduced to bring together all of the deeper tissues, the ends being brought out through the external wound, and finally the latter closed by means of the interrupted suture.

The subsequent history of the case was most satisfactory and rapid in its progress towards a cure, and may be summed up in a few words:

On the second day after the operation it was found that upon closing the tracheal tube respiration could not be carried on through the larynx—a condition which I had anticipated—on account of the inflammatory swelling increasing the original amount of laryngeal stenosis, and to provide against which I had opened the trachea.

A laryngoscopic examination showed the cause of this condition to be due to the swelling of the epiglottis and of the tissues lying between it and the base of the tongue, the latter pressing the epiglottis backwards until it covered more than one-half of the superior opening of the larynx. The larynx itself, with the exception of the left ary-epiglottic fold, which was somewhat swollen and hyperemic, was, as far as could be seen, free from any inflammatory action. Deglutition was easy, and unaccompanied by any pain.

On the tenth day the inner tube being closed by the finger, respiration was readily carried on, and from this time until its removal on the thirteenth day, it was worn closed by means of a small cork, the latter being removed during the night and replaced in the morning. The patient's progress towards recovery during this time was rapid, the greater part of the wounds had closed by first intention, and the remaining portions were granulating satisfactorily.

The common complication after tracheotomy, pneumonia, did not here occur, a circumstance that I attribute in great measure to the fact that no blood was allowed to enter the trachea and be drawn down into the bronchi, to remain a local cause of irritation, at the time of the operation, and not to any measures of special precaution against it that were adopted by me. Indeed, I have found that cases in which the air-passages have been opened do not develop pneumonia any more certainly or readily when they are treated without special reference to their surroundings, only using ordinary precautions against exposure, than when extraordinary measures—the high temperature, moist atmosphere, closed room, etc.—are carried out.

After removal of the tube, on the thirteenth day, the patient's respiration was found to be free, easy, and to have lost its stridulous character. The voice had been gradually assuming force and clearness during the last few days, and the tube being now permanently removed, was heard to be clear and distinct, but with a slight intonation, nasal in character.

A laryngoscopic examination made at this time shows that the hypertrophied and thickened portions of the larynx, especially the left ary-epiglottic fold and false cord, have undergone a rapid process of contraction, and at present, although still of a nodulated and irregular outline, approach very nearly their normal configuration and size. This change allows the left true cord, formerly invisible, to be seen, and it is found to present a normal appearance anteriorly and posteriorly, but on its middle superior surface to be covered by exuberant granulation tissue.

Its muscular action in phonation is deficient, and it does not reach the median line during the act; the right cord, however, in its excursion, passes beyond that point, and meets its fellow in close approximation. Subsequent examinations showed that this condition was improving, and approaching the normal performance of the act. The location of the line of incision through the mucous membrane at the base of the tongue could be seen fully cicatrized; the median glosso-epiglottic fold and the lingual sinuses have

disappeared; but the pharyngo-epiglottic folds are intact.

On the twenty-first day, the external wounds having closed, and the voice having steadily improved in force and character since the removal of the tube, the patient was discharged cured.

In concluding this clinical consideration of the operation a condensed report of the other cases in which the same operation has been carried out may not be without interest.

Considerable research through the surgical literature has resulted in finding the reports of but five cases (one of these having been complicated by the performance of thyrotomy subsequently). That my search has not been exhaustive, I am well aware, and shall be glad if any attention that I may have called to the subject will result in placing heretofore unreported cases, especially in this country, upon record, or in bringing to light any which may have escaped notice.

The cases are briefly as follows:—

I. In 1859 Prat* performed the operation for the removal of a tumor situated upon the left side of the epiglottis, after attempts at its removal by the mouth had failed. The symptoms of extreme dysphagia, and some dyspnea which its presence had caused, disappeared after its removal, and the patient died some time later of phthisis. On the autopsy no vestiges of the growth could be found.

II. In 1862 Langenbeck† undertook the operation for the relief of a patient who had previously had a large pharyngeal tumor removed by means of the galvanocautery, the tumor recurring and causing excessive dyspnea. It was again extirpated by the operation of supra-thyroid laryngotomy. The operation was a severe one, the hemorrhage profuse, and the patient died on the second day after.

III. Follin‡ operated, in 1863, for the removal of a number of myxomatous growths situated in the posterior commissure of the larynx and upon the arytenoid cartilages, laryngoscopic treatment having failed on account of the extreme irritability of the pharyngeal parts. The patient made a speedy and complete recovery.

IV. In 1863 Debron§ performed the operation in order to effect the removal of a laryngeal tumor which he supposed that he could reach through an incision in the thyro-hyoid membrane. It was, however, found, during the operation, that the growth was situated partly within the right ventricle of the larynx, and that it extended downwards below the vocal cord; and thyrotomy was done in order to permit of its complete extirpation. The patient died on the seventh day after the operation, from bronchitis.

V. Langenbeck's§ second case, which occurred in 1869, was entirely successful. The tumor, the size of a pigeon's egg—for the removal of which it was performed—was myxomatous in character, and was situated upon the left ary-epiglottic fold, reaching backwards to the left side of the pharynx, and involving the left arytenoid cartilage.

ON SOME OF THE USES OF GALVANIC AND FARADIC BATHS.

By GEORGE M. SCHWEIG, M.D.,

NEW YORK.

I DEEM it the duty of every physician whom circumstances afford the opportunity of making observations that possess physiological or therapeutic value, to lay before his colleagues not only the facts as they have presented themselves to him, but also his views relative to these, in order that from a multitude of opinions may be culled, in the course of time, the truths which are destined to become scientific facts and principles. This seems to me peculiarly requisite where the physiological and therapeutic effects of a new or recent method are involved, to bring which to its proper worth and standard is as desirable in the interests of science as in those of humanity.

I have had for the last year, and still continue to have, occasion daily to supervise the administration of electrical baths (both galvanic and faradic), and I now propose to lay before the profession the outlines of some cases illustrative of their therapeutic value. These cases are by no means especially interesting in themselves. Even if I had cited such, I could not in this connection have afforded them their merited space. If, therefore, my description of cases should appear to some incomplete and superficial, I beg to say to those that I have not made even an attempt to individualize any case, but have cited each one only to serve as an illustration of the effects of a remedy.

I must for the present refrain from a consideration of the physiological effects of the baths, my experience being as yet too limited to serve as a basis for the grounding of physiological facts.

CASE I. Rheumatism.—Mr. F., from the practice of Dr. Alexander Murray, about thirty-two years of age, of robust appearance, large, vigorous frame, had an attack of acute inflammatory rheumatism in the spring of 1873, from which he recovered in a short time. In the winter of 1874 he experienced a second attack, for which he had had treatment for about two months prior to coming under Dr. M.'s care. After treating him by other methods, including local galvanic applications to the affected parts (joints as well as muscles were involved), for two weeks, Dr. M. sent patient to take electrical baths. On May 25th Mr. F. was brought in a carriage. He was not able to walk, and had to be assisted up the steps by two attendants. His arms were in a scarcely better condition, the wrist-joints especially being exceedingly painful and tender. The first and second baths, administered respectively on May 25th and 29th, did not effect much change in his condition. The third bath was taken on May 30th, with the happiest results. On June 1st patient was able to come for his fourth bath alone and on foot, and thenceforth his recovery was very rapid. The seventh bath, taken June 7th, left him perfectly cured, not a trace of the disease remaining. He has been free from rheumatism since. In the first three baths the galvanic current was employed exclusively, the muscles and tendons being in too tender a condition to bear the contractions induced by strong faradic currents. In the subsequent baths both currents were used, according to indications.

CASE II. Constipation.—Emil Miller, a bright child two years of age, was brought July 7th, 1874. He had suffered from obstinate constipation almost from his birth. Had been under the care of several physicians, but had never received any benefit from treatment. Even with the aid of powerful cathartics, given in doses suitable for an adult rather than a child,

defecation took place only once in every three or four days, and was so exceedingly painful as to elicit cries of pain from the child, who had to be forced to the chamber on every one of these occasions. The feces were always hard and lumpy, and lighter in color than normal. A digital examination per rectum revealed considerable flaccidity. My diagnosis was, *paresis of the muscularis of the intestine*. I ordered faradic baths. I preferred these to local faradization for several reasons, to elucidate which would occupy too much space here. On July 12th the first bath was administered, and I must confess that the result was a perfect surprise to me. True, I had expected a cure to take place; but I looked for gradual improvement, and was not prepared for a result such as was here obtained. *From the time the first bath was taken, defecation took place regularly once a day, without pain; the feces became perfectly normal in color and consistency, and the boy has to the present day defecated regularly and normally in every respect.* To insure permanency, however, the baths were at first continued about twice a week, then once a week, but have now been discontinued for some time. No other therapeutic measures, either internal or external, were resorted to in this case, neither was there any change made in the diet of the child.

CASE III. Mercurial Stomatitis.—Mr. S., about thirty-five years of age, came to me for treatment in the fall of 1872. He then had indurated chancre, two buboes, and syphilitic sore throat. He had had the chancre for six weeks before applying to me, but was, as he said, ashamed to consult a physician. Before medication had had time to make any impression on his system, roseola appeared. The syphilis was very obstinate in this patient, compelling me to keep him under the influence of mercury for a long time. In October, 1873, the patient presented himself to me with a very aggravated mercurial stomatitis. The usual remedies, both internal and local, made little or no impression on the affection. On November 11th, I advised patient to discontinue all other measures, and try a course of galvanic baths. He took his first bath on the same day. This was repeated every other day until six baths had been taken, when all symptoms of the disease had disappeared. The descending galvanic current was used throughout.

CASE IV. Locomotor Ataxia.—Mr. W.—act, forty-eight, came to consult me January 12th, 1874. He had then felt the symptoms of locomotor ataxia for about six years. Had been unable for several years to walk without the aid of a cane. When walking he dragged his right leg along in a semicircle, and was able to accomplish very short distances only. There were almost complete anæsthesia and great paresis of the bladder. The same conditions were observable in regard to the bowels. Anæsthesia of both lower extremities existed, complete in every respect in the right leg, almost so in the left. Dyspepsia and general debility and emaciation accompanied the disease. Treatment was begun on January 15th. I prescribed phosphorus and cod-liver oil, and passed a strong galvanic current through the spine for probably ten minutes. January 16th, a galvanic bath was administered. Towards the close of the bath (which occupied twenty minutes) patient thought he felt some sensation in his legs. The baths were taken every two or three days, alternating with strong galvanizations of the spine. While taking his second bath, patient remarked that "his right leg felt warm for the first time in six years." The treatment as described was continued for about six weeks, during the latter part of which the local applications were gradually diminished in frequency, the baths being con-

tinued regularly. Medication was discontinued about this time. About the middle of March Mr. W. was enabled to resume his occupation (paymaster's assistant on Erie Railway). His improvement had been rapid and steady. All the symptoms gradually disappeared, and in the beginning of April the patient was, with the exception of some feebleness consequent on his protracted illness, as well as ever. He continues so to the present day. He still takes two or three baths a month, but has had no other treatment since May. He walks freely without a cane, and talks jocosely of running foot-races. All functions are performed normally.

Although in this case the baths were not employed exclusively, yet they predominated in the treatment; and if the judgment of the patient, a very intelligent gentleman, is to be relied on, a large share of the success is due to the baths.

CASE V. Rheumatism.—Mr. B.—y, æt. twenty-two, came for treatment on August 27th, 1874. Had sub-acute rheumatism, with considerable swelling of ankle-joints. The acute attack dated back six weeks. Locomotion was very painful, and could be accomplished only with the aid of a cane. A galvanic bath on the 27th and one on the 28th of August were sufficient to remove both swelling and pain, enabling the patient to resume his avocation.

CASE VI. Mercurio-Syphilitic Cachexia.—Mr. L., æt. twenty-seven, had primary syphilis about four years ago. Subsequently had inveterate constitutional symptoms, for which he was under medical treatment both here and in Europe. When he had sojourned in the latter country some time, he was pronounced cured by his physicians. He married, and returned to this country in the fall of 1872. A few weeks after his return he fell into a gradual decline, which confined him to the house—and part of the time to bed—for eight months, during the latter portion of which he had discontinued all medical treatment. It was with difficulty that, assisted by his wife, he managed to reach my office. I found him terribly enfeebled; greatly emaciated; sallow complexion. He was much annoyed by rheumatic pains, which I considered specific. His condition was so exceedingly low that I decided to postpone all medication until he should be stronger. I ordered galvano-faradic baths, i.e., the galvanic current in the bath as an eliminative, the faradic as a tonic. The first bath was taken on November 20th, 1873. For one month he took the baths, and nothing else. He was then so much stronger that I felt justified in instituting a mild specific course of treatment, the baths being continued as theretofore. At the end of two months the patient was nearly as strong as ever, was able to resume his occupation, and had gained twenty-seven pounds in weight.

CASE VII. Chorea.—Hugh O.—l, æt. twelve, from the practice of Dr. J. O. Farrington: one of the severest cases of chorea I have ever seen; had been afflicted four years. Was sent February 5th to take electrical baths. Between that date and March 23d, took seventeen baths, steadily improving. Internal medication was attended to by Dr. F. The boy made a complete recovery.

CASE VIII. Impotency.—Mr. F., from the practice of Dr. Caro, a robust gentleman, æt. thirty-six, full of muscular vigor. Had had syphilis, the symptoms of which had disappeared under Dr. C.'s treatment. For two years the power of erection, as well as sexual appetite, had become extinct, if we except an occasional imperfect spontaneous erection on waking up in the morning, and even this was of rare occurrence. Ordinary medication proving inadequate, Dr. C. sent

patient to take electrical baths. From March 7th to July 16th Mr. F. used the baths, averaging about two weekly. He was then, and still remains, perfectly restored.

CASE IX. Hysteria.—Mrs. A., from the practice of Dr. Kremer, æt. 28, married, sterile, was sent by Dr. K. to take baths on June 12th, 1874. Intense pruritus, transient flushing and heat of the entire surface, with pricking sensations and headache, were the more prominent symptoms. Six galvano-faradic baths effected a complete and permanent cure.

CASE X. Specific Syphilitis of Knee-joint, with considerable Effusion in and around Joint.—Mr. C., from the practice of Dr. Sheppard, æt. about 35. First saw patient at his house on Nov. 9th, 1873, in consultation with Dr. S. and Dr. Hutchinson, of Providence, R. I. Had been on mercury and iodide of potassium for a long time. When I first saw him, he had been incapacitated from work for about a year. Had been unable to leave the house for three months. The affected joint was very much enlarged, with little or no motility, the condition being practically the same as true ankylosis. It was decided to substitute tonics for the specific treatment, and to administer galvanic baths. On Nov. 11th the first bath was administered; another on the 15th, and a third on the 19th. Considerable improvement in motility was then apparent. Two more baths, taken respectively on the 23d and 29th, effected some reduction in the size of the knee. The baths were continued to January 3d, 1874, when the effusion had become almost entirely absorbed, and the joint perfectly mobile. The patient then had been for some time taking daily walks, massaged. He now (Jan. 3d) walks without any difficulty, has regained his normal vigor, and is practically well.

CASE XI. General Neurasthenia of a Hysterical Type.—Mrs. E., from the practice of Dr. Krebich, æt. about 28, married, of an exceedingly nervous temperament, had suffered from great nervous irritability and prostration since her last confinement (about a year previous). Was sent by her physician to take galvanic baths, April 21st, 1874. Cases of this kind are too familiar to every physician to render a detailed description of the symptoms desirable. Six galvano-faradic baths restored her to perfect health.

CASE XII. Sub-hemiplegia from Cerebral Hemorrhage.—Mrs. S., æt. 30, married, from the practice of Dr. Krebich, was sent by Dr. K. to take baths July 3d, 1874. It was a routine case, differing in no respect from what is ordinarily observed as a sequence of cerebral hemorrhage. Six baths, taken at intervals of two and three days, restored almost entirely the muscular power of the affected side.

I have taken the above twelve cases at random from a large number of which I have notes. I have not included among them any case of neurosis of the sympathetic, although I have had occasion to observe and to treat, by electrical baths and otherwise, a large number of affections of the sympathetic system, with very satisfactory results. I have purposely omitted these cases, because I felt that I could not do them justice in this connection. They possess sufficient pathological interest to entitle them to especial individual consideration, and for this I reserve them. I will merely state that I have met with affections of the sympathetic much more frequently than I could have been led to anticipate from any books or statistics on the subject. I will state here also, that in all forms of *agrypnia* I have found electrical baths superior to any hypnotic of the materia medica.

A word on the mode of action of electrical baths. I have been asked repeatedly by physicians, in what

respect these baths differ from "general electrization"—galvanization or faradization, as may be the case. I have never had any difficulty in convincing any one who asked me this question, not only that there is a vast difference between electrical baths, *properly administered*, and general electrization, but that *electrical baths are the only real general electrization*, what has been known under that name being neither more nor less than *alternate local electrization*. A moment's reflection will make it apparent that general electrization, as expressive of electrical baths, and alternate local electrization, as expressive of methods advanced under the title of "general faradization," etc., must differ vastly in their effects. A process by which the galvanic current is made to impinge simultaneously on *all* the peripheral endings of nerves, must have reflex effects that can never be obtained from a like influence brought to bear within the domain of a single nerve only, or even several. Again, where every organ in the body (excepting of course the head and face) is traversed at one and the same time by the galvanic current, an alternative effect is obtained that is unapproached by any other remedy or method that I know of. By the use of the faradic current in the baths, in place of single muscles, or at best a group of muscles, being affected, as is the case in local faradization, all or nearly all the muscles of the body can be brought into action at one and the same time, or the action of the current can be limited to certain of the extremities, the entire abdomen, etc., *ad libitum*. It is scarcely necessary for me to adduce further facts in order to show that the two procedures are anything but identical. No one can be more appreciative than myself of the therapeutic value of the methods the *apollation* of which I object to, or more ready to concede the advantages they possess. But to call "general" that which is "local," is an etymological incongruity which is the more to be deprecated when permitted to creep into the nomenclature of a science where exactitude is one of the first desiderata.

160 SECOND AVENUE, NEW YORK.

A CASE OF PERTYPHLITIS—OPERATION—RECOVERY.

By CHAS. KELSEY, M.D.,

NEW YORK.

Boy, æt. 11. When first seen the patient and his mother together gave the following history:

July 5, 1874.—First complained of pain in abdomen, which had never since entirely left him. With the first attack of pain there was some diarrhœa, lasting a couple of days, followed by constipation for three or four days. These alternations continued for two weeks, during which time there was also loss of appetite, and a marked desire on the part of patient to lie on his back and keep still.

At the end of two weeks a tumor was first noticed low down in right side, with great tenderness on pressure; two days later, and twelve days before operation, he took to his bed, and remained four days. Then he went for a ride, but returned in great pain, and had not since been up.

During the last week in July the tumor increased in size, tenderness, and pain; the bowels were generally constipated; there was some fever, and complete loss of appetite.

Aug. 1st.—Slight chill; also same day three large voluntary passages from bowels, the first of which was normal, the second containing blood and mucus.

Up to Aug. 1st the pain and constitutional disturbance steadily increased, as did the size of tumor, and by this time the loss of flesh was very noticeable.

Aug. 4th.—Boy first seen by Dr. Zemanski, of St. Luke's Hospital. Temperature 101.5. Pain so great as to forbid examination of tumor, which was visible to eye. The diagnosis of perityphlitis was made by him, and arrangements made for an operation next morning. On account of his duties elsewhere, he then kindly transferred the case to me.

Aug. 5th.—On the time of my first visit, the boy was easier, but gave history of a very restless night. Temperature 100.2. Pallor and emaciation marked.

Physical examination revealed a tumor located in the right iliac fossa, bounded below by Poupart's ligament, with its upper edge, which could be distinctly felt with fingers, extending half-way to umbilicus, dullness over tumor, great pain on pressure, no fluctuation, no redness of surface. Thigh was flexed on abdomen for ease, but could be extended at will.

Operation, assisted by Drs. Zemanski and W. M. Kemp.

Incision four inches long, made parallel with, and one inch above, Poupart's ligament, and layers of abdominal wall cut through on director. After reaching fibres of internal oblique, the tissues were so matted together by inflammation as to make their separation impossible; but at both ends of the cut the dissection was carried down till the fascia transversalis was exposed, and then the mass of tissue in the middle was divided down to what seemed about the same level.

An exploring needle, introduced at this point, was followed by a free flow of blood, but no pus. This exploratory puncture was repeated three times with a small trocar and canula at different points over the tumor, twice in the line of incision, once nearer umbilicus; but each time it gave the impression of entering a solid mass, and a little blood was the only result. The operation was carried no farther; the fascia transversalis was not divided. The wound was united at the ends, and poulticed.

Next day.—Patient comfortable. No pain. Temperature 99°. Pulse 102°.

August 10th.—Fifth day after operation, the abscess burst through wound and gave exit to several ounces of fetid pus.

September 10th.—Patient entirely well—wound closed.

The doubtful point in the diagnosis of this case is known to me; still, I prefer to name it perityphlitis, and then leave each man to decide for himself. I am inclined to doubt the pressure of a foreign body in the appendix, but know of no way of deciding even this with certainty.

The case appears to me to be one of the class in which an abscess in this region follows some ulcerative process, either in the cæcæ coli or its appendix.

NEW ITALIAN MEDICAL JOURNALS.—Two new medical journals have appeared in Italy.—*La Rivista Calabrese di Medicina, Chirurgia, e Farmacia*, edited by Dr. Placido, of Reggio, and *La Sfera*, a popular journal of hygiene and education, edited by Drs. Temistocle and Ulisse Santopadre.

DR. J. MARION SIMS.—At the annual meeting of the State Woman's Hospital, held on the 19th inst., Dr. J. Marion Sims resigned his position as one of the attending surgeons.

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, Nov. 11, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

CANCER OF LIVER.

DR. FINNELL presented a specimen of cancer of the liver, removed from an unmarried female aged 40 years. For three years previous to her death she suffered from gastric symptoms, which were recognized as belonging to cancer of the pyloric orifice of the stomach. There were, however, no symptoms which pointed to any disease of the liver.

At the autopsy, the liver was so completely infiltrated with cancerous material that hardly any healthy structure was to be seen. The gall-bladder was entirely free, and the pyloric orifice, besides being the seat of cancerous disease, had attached to its outer surface a closed sac, resembling in gross appearance a small ovarian cyst, and containing a chocolate-colored fluid.

The specimen was, on motion, referred to the Committee on Microscopy.

MORBUS COXARIUS.

DR. SAYRE presented a specimen removed by operation from a child aged 21 months, to whom he was called in consultation by Dr. Husted. The patient had a large abscess of the left hip, which Dr. Husted had aspirated three weeks before. About three ounces of pus was discharged by that means, and afterwards an incision was made giving a freer exit to the pus. The mother was a feeble woman, and as the child depended entirely upon her for nourishment, it became very much emaciated. The affected limb was extremely oedematous, and presented a strange contrast with the rest of the body.

Three months ago the little patient suffered from double pneumonia, from which it recovered. While convalescing, and being quite feeble, it attempted to climb upon a chair which was upon a wet hearth, when it slipped and the left leg became strongly abducted, probably producing at the time diastasis of the head of the femur. Some weeks after this occurrence Dr. Husted was called to treat an inflamed gland in the left groin. A few months after, an abscess formed in the neighborhood. The incision for its evacuation was made upon the outer and anterior portion of the thigh, and the discharge after that operation was satisfactorily profuse. Dr. Sayre enlarged the opening and passed his finger down into the joint. The end of the femur was found to be eroded. The entire limb was then very carefully rubbed for an hour or two, with the idea of reducing the swelling, and then a bandage was applied from the toes to the groin.

DR. SAYRE saw the patient at the end of a week after this, and in the meantime, having been fed upon nutritious diet, was in a condition to bear an operation. With the assistance of Dr. Husted chloroform was administered. The incision was increased upwards, and passing the finger down into the wound bare bone was reached. This bone was removed *in situ* by means of a metacarpal saw, no risk being run in tearing away the periosteum by forced luxation. The part expected was from the inner portion of the femur, was wedge-shaped, and entirely denuded of

periosteum. The head of the femur was almost destroyed, and its remains were picked out of the wound.

The opening having been made upon the anterior portion of the thigh, in a position unfavorable for drainage, a counter-opening was made posteriorly and a tent introduced. By last accounts the patient was doing well. Dr. Sayre remarked that this was the youngest case upon which he had operated, and altogether it was the most interesting and remarkable one.

Dr. Sayre presented a second specimen of morbus coxarius, also removed by exsection. The patient was a child aged 7 years, who was brought from Otsego county. Three years ago he fell from a pile of lumber, injuring the left hip. This injury was followed by inflammation, which continued through the different stages of morbus coxarius, until destruction of the joint was reached. The resulting emaciation was extreme, and the deformity was remarkable. When seated in a chair the diseased limb was so completely flexed that the knee was brought over nearly to the opposite side of the abdomen. There were five or six sinuses in the neighborhood of the joint which were connected with dead bone.

The operation for exsection was performed on the 9th of October, before the class of the Bellevue Hospital Medical College. The head and neck of the femur were entirely destroyed. The upper portion of the bone being diseased, the section was made as low as an inch below the trochanter minor. The acetabulum was perforated, and contained some loose splenda of bone. The internal periosteum was fortunately intact. After the operation the patient was dressed in wire breeches.

Dr. S. remarked that this was his fiftieth case of exsection of the femur for morbus coxarius, and the result of it was the most gratifying, the child being able to walk at the end of four weeks and the shortening being less than half an inch.

SCISSORS SWALLOWED BY INSANE PATIENT AND ESCAPING THROUGH THE ABDOMINAL WALLS.

DR. SANDS presented a broken scissors which had been swallowed by an insane woman, and which had found its way through the abdominal walls. The following was a history of the case, as furnished by Dr. Farrells, of Nova Scotia, the attending physician.

"I was called, September 15th, by Dr. Fraser, the Assistant Physician of the Nova Scotia Hospital for the Insane, who had charge of the Hospital in the absence of Dr. De Wolfe, the Medical Superintendent, to see Bridget Millar, *et. 51* years, one of the inmates of the Hospital.

"The case gave the following history: Her mania has been suicidal since her admission, and she states that she has frequently swallowed various articles to destroy her life, such as needles, thimbles, and other things that she found about the wards; at one time she says she swallowed the stopper of a bath-tub, with the chain attached. Some of these she says she has passed per rectum, and others still remain within her body; she says she passed the stopper and chain soon after she swallowed it.

"A few days before I saw her, she asked Dr. Fraser to examine her side, where she complained of considerable pain, stating at the same time that about two months before she had swallowed a large pair of scissors, after breaking off one of the bows or handles. She was not believed at first, as she was constantly making such statements, without giving any symptoms; her bowels acted well, and she took her food like the rest of the patients.

"On examination of the seat of pain, the Dr. discovered a hard, circumscribed, painful swelling, about two and a half inches above the umbilicus, and three quarters of an inch to the right of the median line. She was ordered to bed, and a poultice applied. The next day a very hard spot was perceptible in the middle of the swelling, and soon a point of ulceration in the abdominal wall, and it was evident that a hard, pointed body, which could now be felt, was pushing its way through. The opening in the wall of the abdomen enlarged somewhat by ulceration, and the foreign body could be grasped and lifted out a little, and it was found to be the point of a pair of scissors closed. Her general condition showed but little effect from the changes going on in the intestines; pulse good, appetite good, bowels acting every day, stools very black.

"On consultation it was decided to let nature continue her efforts to get rid of the foreign body for the present. During the two following days her condition remained the same, the opening enlarged a little and now discharged the contents of the bowel, stained with bile and without offensive odor. As the opening enlarged, the foreign body could be drawn out about two inches and returned, without any ill effect, and it was determined to dilate the opening with spongetents. The first sponge-tent acted very well; after the second one, the scissors were slowly and gently withdrawn until the screw between the two blades was reached, this was forcibly broken, and the blade from which the handle had been broken was easily withdrawn. During the process of dilatation she had a chill followed by considerable fever and constitutional irritation, and it was necessary to stop the treatment for two days. The next day after the part of the scissors was withdrawn, a large needle came through the opening. When the fever subsided, we found that the sponge only dilated the external opening, and the handle of the remaining blade was held at the junction of intestine and the internal surface of the abdominal wall. Two sea-tangle tents were now used, passed well into the intestine; they dilated the internal opening well in about fourteen hours, and with very little force the remaining blade was withdrawn. In twelve hours the opening had closed considerably, looked healthy, little discharge from intestines. Two days after the operation the opening had healed. The patient is now (October 10th) as well as usual.

"The arms of the patient were held fast by part of a strait-jacket while the foreign body was coming through the abdominal wall."

Dr. SANDS was of the opinion that the foreign body had probably made its way through the stomach and the abdominal walls covering it, rather than through any other portion of the intestinal tract.

Dr. SANDS presented a second specimen, which he had removed by operation a few hours before the meeting. The patient was admitted to the Roosevelt Hospital, having been sent to Dr. S. by Dr. Knapp. It appears that the man had applied to Dr. Knapp on account of paralysis of the orbicularis muscle of the right eye, when Dr. K. discovered that the paralysis was due to the presence of a tumor in the parotid region. It was also observed that the paralysis was not confined to the orbicularis muscle, but involved the whole of that side of the face.

The patient was sixty-three years old, and the tumor had existed for thirty-one years. Its growth had been very slow until two years ago, when it increased in size more rapidly, and about the same time the symptoms of paralysis first made their appearance. On examination the tumor was found to occupy the right

parotid region, elevating the lobule of the ear, extending forward over nearly the whole extent of the masseter muscle, and downwards upon the sterno-cleido-mastoid muscle, to which latter it proved, on examination, to be firmly adherent. It also passed in to a considerable depth behind the angle of the jaw. The skin covering of the tumor was freely movable, except on its most prominent portion, while the greater portion of its base was firmly adherent.

Enucleation of the tumor was out of the question, and after the removal of the larger portion of the mass the remainder had to be taken away piecemeal by a tedious dissection. There was no hemorrhage to speak of, and no large vessel was divided in the operation. The tumor was examined microscopically by Drs. Knapp and Heintzmann, and although the examination was a cursory one, it was discovered that the growth was mainly scirrhus in character, some portions being softened by a myxomatous process.

Dr. SANDS, in connection with this specimen, exhibited some photographs of tumors removed by him from this locality, and also one large fibroma, successfully operated upon by Dr. Parker.

TUMOR OF BRAIN.

Dr. JANEWAY presented an interesting specimen of tumor of the brain, with the following history:—

Hermann G., *et.* thirty years, married, was admitted to Bellevue Hospital, September 26th, 1874. His father died of phthisis, but no other known disease capable of possible transmission existed. He was healthy until date of present illness, with the exception of a soft chancre. Five months before admission he complained of weakness in the small of the back, then in the left leg, and about a month later in the left arm. During this time he would have an ache in the posterior portion of the head, which would last about two days, and would occur about once in two or three weeks. He was able to walk with a stick till the date of admission. Dizziness was present most of the time, and on account of this he sometimes fell. There was inability to retain urine previous to admission.

Patient, when admitted, was a pretty well-nourished man. His mental faculties were retained, though considerably impaired. He answered questions but slowly, but sometimes forgot the word he wished to use, though he recollects most words, and the forgotten word he could utter when told.

The eyesight was normal to all appearances. Hearing was good on both sides, and the sense of smell appeared diminished on both sides, and almost lost on the left. Slight loss of expression existed on the left side of face on laughing. There was slight diminution of tactile sensibility also on the left side of face. He protruded the tongue normally. Great impairment of power existed in the left arm and leg, associated with a rigid state of the flexors. The sensibility was diminished on the left side. Involuntary evacuations of urine and feces occasionally took place. Since admission the left arm and leg had been useless, and in the condition described.

October 1st, he passed into a state of partial unconsciousness, which lasted for thirty-six hours, during which time he took food, but would not answer questions nor do anything which he was told.

October 8th, passed into a similar condition, and remained in it forty-eight hours. A slight bed-sore developed on his nates on the 12th, owing to the condition of bedding, and for this he was transferred to a water bed.

October 14th, mental condition about as on admission, and pupils natural and react to light. He stated

that he could see well; hearing good; tongue natural. Left arm—partial flexion throughout; flexors moderately rigid; no voluntary movements possible; slight reflex action; sensibility diminished slightly. Left leg—partial flexion of leg on thigh, and thigh on abdomen, with slight rigidity of flexors; no reflex action. He was able to flex the legs to a very slight extent some little time after being asked to do so. Right arm presented a slight convulsive movement (jactitation). The orderly stated that this had existed for two days, and occurred several times a day when the arm was quiet. Otherwise, save that the right arm and leg were a little weaker than normal, nothing is noticeable about them. Muscles reacted readily to faradic current.

October 24th. The patient remained in about the same state as at last note till yesterday, when another attack of unconsciousness occurred, lasting twenty-four hours. The jactitation of right arm had occurred several times since last note.

November 1st. Had another attack of unconsciousness on October 28th, lasting six hours, and since that date his head, which always inclined to right side, had been more markedly turned to that side.

November 5th. Passed into another state of unconsciousness, which lasted till morning of the 8th, and in the afternoon passed into it again. In the evening of this day his pulse became rapid, 140; temperature 103° F. at 10 P.M., and at 4 A.M. of November 9 he died.

The temperature throughout the disease, with the exception of the day preceding death, and on one other occasion, did not exceed 99° , and was usually normal. Pulse regular and slow.

Post-mortem examination.—No lesion of other organ than skull and brain.

The skull-cap had an exostosis on its inner surface, situated one inch to the inner side of sagittal suture, on right parietal bone, near coronal suture.

The exostosis was irregular, about one-half inch long, three-fourths broad, and contained irregular depressions in which a new growth was situated. The dura mater was tightly stretched, and presented a depression corresponding to the site of exostosis, and in this also a new growth is situated. On opening the dura mater the arachnoid was found dry, and the sub-arachnoid space contained no fluid, and the brain bulged out as if contained in too small a place. The convolutions of both sides were small, and especially the right, and were flattened. The longitudinal sinus contained fluid blood, but was much narrowed along anterior lobe of brain.

The dura mater was adherent to brain for a space of 2×3 inches along longitudinal fissure, on the anterior lobe of brain, right side. This reached nearly to the posterior extremity of this lobe. The anterior lobe of brain on the right side was the seat of a new formation $3\frac{1}{2}$ inches long, 2 inches in depth, and $2\frac{1}{2}$ in width at widest portion. Section through it, near its posterior extremity, showed it to be of a grayish color, moderately firm, yielding a whitish material on scraping. It was distinctly circumscribed, and had a thin capsule over it. At this point it was covered by a thin layer of brain-tissue about $\frac{1}{16}$ th inch thick.

Its shape, as seen on the surface of the brain, was irregular. It commenced $1\frac{1}{2}$ inches from anterior extremity of anterior lobe, and extended to the transverse convolution of middle lobe. Its anterior extremity was rounded in a somewhat pointed manner, the posterior more globular. It projected into the longitudinal fissure nearly as far as the corpus callosum, covered, as before mentioned, by a thin layer of cerebral tissue, and it had caused a depression in the anterior lobe of

the left side, forming a fissure of a rounded shape about $\frac{1}{2}$ an inch in depth. Below, its lower portion reached nearly to the corpus callosum. The pons varolii seemed a little smaller than usual, and looked somewhat compressed. The small vessels of the pia seemed injected, but otherwise the brain contained less than usual blood. The brain contained only a few drops of serum. The cerebellum appeared normal. The medulla presented no change. Anterior pyramids appeared equal on the two sides.

Stated Meeting, November 25, 1874.

DR. H. KNAPP, PRESIDENT, in the Chair.

DR. SATTERTHWAIT, on behalf of the Committee on Microscopy, presented a detailed report of the microscopic examination of specimens referred to said committee at the previous meeting. The tumors exhibited by Dr. Post were found to be calcified lymphatics. The liver presented by Dr. Finnell was infiltrated with medullary cancer. The cyst from the pyloric extremity of the stomach consisted mostly of pus, in which were a few fat granules, some epithelial elements, some of which were ciliated in character, and a number of plates of cholesterine. The tumor of the parotid, removed by Dr. Sands, was of a mixed character, consisting of chondroma, myxoma, and carcinoma.

CARDIAC DILATATION, WITH AORTIC, MITRAL, AND TRICUSPID INSUFFICIENCY.

DR. DELAFIELD presented a heart, removed from the body of a farm-laborer, a native of Vermont, aged 26, who entered the Roosevelt Hospital, October 2, 1874. He was perfectly well, up to one year ago, when he was seized with what appeared to be an epileptiform convulsion, which began with a sensation of oppression in the epigastric region. This was speedily followed by loss of consciousness, continuing several seconds, and was succeeded for several minutes with clonic spasms of the extremities. He then enjoyed a feeling of comfort for half an hour, when vomiting set in, and persisted for several days. He was left much prostrated, and with severe pain in the epigastrium, and from which he was more than a week in recovering. He had four such attacks up to the time of admission, at intervals ranging from two weeks to six months. All these occurred during the day, and followed the same course. He did not suffer otherwise; had no cough, dyspnoea, or palpitation; no oedema of the lower extremities; no difficulty of micturition; no disturbance of vision, hearing, nor memory. He had been treated for epilepsy, and by the advice of his physician had not engaged in any hard work during the previous year.

On admission, he was found to be well nourished, being a large, muscular, robust man, of florid color, with good appetite, clean tongue, bowels regular, and with pulse and temperature normal. He complained only of slight dizziness when stooping. His urine was 1,030°, contained no albumen.

At the end of the fourth day after admission, he awoke with a sensation as if a weight were resting on his stomach, and appeared to be much agitated, his pulse being 190 per minute. There was, however, no dyspnoea. An hypodermic injection of carbolic Magendie's solution was administered, but gave him no relief. On the following morning (October 7), the patient began to vomit a transparent greenish fluid. He complained of great thirst, but vomited water immediately after it had been drunk. He lay flat in bed,

was very restless, heart beating violently, but had no dyspnoea. There being severe pain in the epigastrium, another injection of Magendie's solution was administered with good effect.

The vomiting abated somewhat after this, and hyposulphite of soda was administered, and after the symptom had ceased bicarb. of soda was presented in five-grain doses every three hours. Nothing occurred worthy of note until the fifteenth, when he fell to the floor unconscious, but recovered in a few seconds. Soon after he began to vomit a greenish watery fluid in great quantity, at the same time complaining of thirst and intense pain in the epigastrium. The hypodermic administration of Magendie's solution was necessitated twice in twenty-four hours to afford relief. He went on as usual until the nineteenth, when, seated at his bed, he lost consciousness for a few seconds; pulse 24 per minute, heart sounds normal. The succeeding day he suffered from nausea and pain in the epigastrium. His urine had a specific gravity of 1.020, contained a trace of albumen, with hyaline and granular casts in great abundance.

Dr. Delafield saw him on the 21st. The vomiting still continued, as did also the pain and distress in the epigastrium; pulse 48. The heart-beat was labored, irregular, feeble, and diffused, with an increased area of dullness. No impulse at apex was perceptible. The heart was beating so tumultuously that no valvular sounds could be discerned. Tinct. of digitalis was ordered as a cardiac sedative, and citrate of iron and quinine as a tonic. There was no particular change in the symptoms until the 7th of November, when the patient was seized with great distress. The heart beat tumultuously, and the radial pulse could not be felt. There was, however, no dyspnoea, no cyanosis. There was no perceptible change in his symptoms until the 13th of November, when he quietly died.

Autopsy.—Brain normal. The lungs were congested and oedematous to a very considerable extent. The liver was in the usual congested condition so often seen in patients dead of heart disease. The spleen was also firm and congested. The kidneys were considerably increased in size, and were tolerably far advanced in Bright's disease. The mucous membrane of the stomach was congested. The trachea was of a red color, but there was no particular coating of mucus.

The heart weighed two pounds, and both ventricles were dilated. The aortic valves were slightly insufficient, as was also the mitral and tricuspid valves.

The case was interesting from the way in which the stomach symptoms marked those of the heart. The man had no idea that there was anything the matter with his heart; and until Dr. D.'s attention was called to him by the house-physician, he was inclined to look upon the case as one of irritative dyspepsia with attendant vomiting. Even if one knew the heart was in the condition described, the real condition of affairs would be impossible of detection until careful auscultation. The cause of death was oedema of the lungs produced by the irregular action of the heart.

THORACIC ANEURISM.

Dr. W. H. THOMSON presented a specimen of thoracic aneurism. His attention was called to a patient in Bellevue Hospital, suffering from repeated paroxysmal attacks of dyspnoea with stridulous cough. She had been an inmate of the hospital on two or three occasions previously, with symptoms of emphysema, chronic bronchitis, and asthmatic breathing. On one

occasion, her urine having been tested, was found to be albuminous.

The paroxysmal attacks of dyspnoea and stridulous cough led Dr. T. to suspect thoracic aneurism. On inspection of the chest the sternal veins were found to be enlarged and centring at the depression of the sternum. On examination of the heart a systolic murmur at the base was detected, while a second murmur was discovered at the apex. The breathing was markedly asthmatic, and was accompanied with such a number and variety of râles that auscultation of the heart was not very satisfactory. There was marked pulsation in the supra-sternal space, and in placing the finger there a slight thrill could be felt. Auscultation at that point discovered a very distinct aneurismal bruit.

The patient did not complain specially of any symptoms but the dyspnoea and the cough. There was no difference between the pulsations at the wrists. There was no interval between the beats of the heart and the pulse beat; the patient did not complain of any abnormal sensations about the head, neck, or down the arm. She denied ever having syphilis, but acknowledged that she had been a moderate drinker. She was well nourished, no symptoms of marasmus having as yet been developed.

On the morning of the 24th she expectorated blood, and had some considerable dyspnoea and dysphagia; this latter having made its appearance gradually a few days before. These symptoms increased in severity with great rapidity until the evening she vomited a gallon of blood, and then succumbed.

At the autopsy the semilunar valves were found somewhat thickened. Two aneurisms were found, one of the ascending, the other of the descending branch of the aorta, one of these sacs bursting into the trachea. There did not seem to be any occlusion of any of the vessels, as far as could be ascertained by a cursory examination. The heart was only slightly hypertrophied. The kidneys were quite healthy, the presence of albuminuria being explained by the disease in the mitral valves.

DEATH FOLLOWING A VAGINAL INJECTION.—The following case is recorded by Lorain as one of those occasional instances where death has apparently been due to some mild manipulatory procedure on the female genitals.

A young girl, sixteen years of age, of delicate constitution, and who had commenced menstruating three months previously, entered the hospital to obtain treatment for vaginitis. A decoction of althea was employed as an injection at first, but it was soon changed for a solution of nitrate of silver (gr. x. = 5i.). This fluid was injected without force, the greater part returning through the vagina. Immediately afterwards, however, the patient complained of pain in the belly, and it increased so violently that she tossed about in the bed, her eyes became fixed, the skin became cold, the pulse small, and the face pinched. These severe symptoms abated after three hours; but vomiting then set in and continued, though in the following day the pain in the belly had moderated. Some days after, while the vomiting was still persisting, and she was suffering great distress, she gave a sudden cry and died. Tardieu made the autopsy, and found a purulent inflammation of the mucous membrane of the uterus, and the Fallopian tubes filled with pus. They were discharging into the peritoneal cavity, and there was diffuse peritonitis.—*Allg. Med. Central-Ztg.*, 1, 1874.

MEDICAL SOCIETY OF COUNTY OF NEW YORK.

Stated Meeting, Nov. 23, 1874.

THE meeting was called to order by Dr. Ellsworth Eliot. After the transaction of some business the President delivered his Valedictory Address, and declared the Sixty-ninth Annual Meeting adjourned.

Dr. H. B. SANDS, President elect, immediately took the Chair, and called the Society to order.

The following names were announced:

HENRY T. PIERCE, 247 E. 116th St. A graduate in medicine at the College of Physicians and Surgeons, Med. Dep't of Columbia College, in 1870.

LAWRENCE JOHNSON, 319 W. 26th St. A graduate of Bellevue Hospital Medical College in 1868.

CHARLES ROTH, 232 E. 52d St. A graduate of medicine at the University of Giesen, Germany, in 1853, and College of Physicians and Surgeons, in 1866.

ROBERT CAMPBELL, 194 Lex. Ave. A graduate in medicine at Queen's University, Dublin, in 1872.

GEORGE T. HARRISON, 221 W. 23d St. A graduate in medicine at the University of Virginia, in 1866.

AUGUST HERMANN, 341 E. 49th St. A graduate in medicine at the College of Physicians and Surgeons, University of the State of New York, in 1858.

READ J. MCGAY, 160 W. 34th St. A graduate in medicine at the College of Physicians and Surgeons, Med. Dep't of Columbia College, in 1868.

JOSEPH SCHUETTER, W. 40th St. A graduate of the University of Würzburg, Bavaria, in 1864.

J. MURDOCH HARVEY, 107 W. 45th St. A graduate of Bellevue Hospital Medical College, in 1871.

EMIL ROSENBERG. A graduate in medicine at the University of Berlin, Germany, in 1855.

Library Committee.—C. A. Leale, J. S. Frazer, T. H. Hologate.

Committee on Intelligence.—F. A. Castle, L. D. Buckley, D. C. Carr, W. H. Katzenbach, R. J. McKay, P. B. Porter, Isaac Adler, Mary Putnam Jacobi, Eugene Peugnot.

Committee on Disputes.—Charles P. Russel, George Bayles, A. B. De Luna, G. H. Humphreys, J. M. Kellogg, J. V. S. Morley, Gouverneur M. Smith; and the

Metereological Committee.—D. H. Goodwillie, J. W. S. Arnold, R. P. Lincoln, A. B. Judson.

Committee on Finance.—J. E. Janvriu, E. Bradley, H. P. Farnham.

Committee on Hygiene.—Moreau Morris, E. H. Jones, C. P. Russel, S. A. Raborg.

The President then read a letter, received from the Academy of Medicine, signed by Dr. Austin Flint, President, which contained a solicitation for the co-operation of the County Medical Society in the direction of securing a suitable building for the convenience of all the medical societies of the city. All members of the profession were invited to be present at a meeting of the Academy of Medicine, to be held the first Thursday evening in December, at which time the question would be discussed.

The letter was commended to the earnest attention of the Society.

PRESIDENT'S INAUGURAL.

At 8.30 P.M., the President began the delivery of his Inaugural Address, and spoke substantially as follows:

GENTLEMEN:—I accept with diffidence, but with unfeigned pleasure, the office to which you have called me; and I feel especially grateful for the honor you have conferred upon me, as I am constrained to regard

it rather as an expression of your good-will than as a reward for any contributions which I have made to your scientific records or transactions. May I crave a continuation of your indulgence, while, with limited experience, I endeavor to discharge my duties as your presiding officer.

I can hope to do little more than strive to maintain the present usefulness and activity of the Society; but even to accomplish this I must invoke your cordial and earnest support. Surrounded as we are by many societies, we cannot afford to rest upon laurels already won, but must still continue to put forth our strength for the achievement of new honors, if we would hope to retain our vitality and prosperity.

In the act of incorporation, the objects of this Society are said to be the following: First, to regulate the practice of physic and surgery; and, secondly, to contribute to the diffusion of true science, and particularly the knowledge of the healing art. Let us inquire, very briefly, how far, and in what manner, we may hope to attain the objects thus set forth. As regards the first-named object, it may be said to have a historic rather than a present interest. Although in former times the authority of the County Medical Society to grant diplomas, licensing their possessors to practise medicine and surgery, was often exercised, such authority has been, during many years past, virtually superseded by that of the chartered medical schools. An attempt has been made, however, within the present to revive, by legislative enactment, the authority of the county medical societies; but it must be confessed that the law is too vague and uncertain to accomplish any great results. The law, however, I am inclined to regard as a step in the right direction; but I am not sanguine that under our form of government much will be done by State legislation to elevate the standard of medical requirement, and yet it is evident that until this end is accomplished, the ranks of our profession will continue to increase in numbers rather than in strength. There is one radical error, as I conceive, underlying everywhere our system of medical education. I allude to the authority of medical schools to grant degrees. So long as they possess this power, there is every reason to believe that they will abuse it; and that the competition between them will tend to lower rather than to elevate the standard of requirement for graduation. If, by legislation or otherwise, the authority to grant diplomas were vested in a competent board of examiners, independent of colleges, a great advance, in my opinion, would be made in medical education. The standard of requirement would then be made uniform, and could be easily raised high enough to exclude the ignorant and unqualified. Moreover, the competition among the different schools would be put upon a legitimate basis. Whether, at the present day, such a change is practicable, may perhaps be doubted; yet it can hardly be denied that it would greatly improve the tone of our profession, and win for it an increase of public confidence and support.

The second subject of our Society, namely, the diffusion of scientific knowledge, is the one to which our labor must be chiefly devoted. Our County Society is truly representative in character, and must be accepted as the exponent of scientific medicine in our city. A verdict obtained from it, upon questions of general interest and scientific value, may be regarded as the verdict of an impartial medical tribunal. The Society is devoted to no speciality, yet includes among its members many who are distinguished for special knowledge. The division of labor which specialism involves cannot fail to yield beneficial results; but it

may be carried so far as to be injurious; indeed, so far that the specialist may become distinguished not less for his ignorance of some things than for his knowledge of others, unless he occasionally surveys the whole domain of medicine, and is led to understand and acknowledge the inter-dependence and harmony of its various branches. Let us then, fellow-members, earnestly and honestly unite in the pursuit of scientific truth, each one of us contributing his treasure—be it little or great—to the common stock of knowledge, whence we may all derive something that shall enable us to practise, with greater certainty and success, the noble and beneficent art of medicine. Finally, gentlemen, I desire once again to thank you for the honor you have conferred upon me, and to assure you, that I shall strive, to the utmost of my ability, to discharge the important duties you have committed to my care.

ESMARCH'S BLOODLESS OPERATION.

Upon motion, the Inaugural Address was accepted.

The President then read a paper upon "Esmarch's Method of Bloodless Operation."

The following is a brief synopsis of the paper:—

In April, 1873, at the meeting of the German Surgical Congress of Berlin, Prof. Esmarch announced an important discovery, namely, that by the application of an elastic bandage to a limb, it could be rendered bloodless; and an operation could be performed when a limb was thus bandaged without loss of blood.

The principle may be old, but the success of the plan is doubtless due to the use of the *elastic* bandage as recommended by Esmarch. The subject was considered under three heads: (1) Mode and arrangement of application; (2) Advantages and disadvantages; (3) An estimate of the advantage as tested by our own experience.

The apparatus consists, first, of an elastic bandage or sheet-rubber, about two and a half inches wide, and, for convenience, divided into strips about three yards in length; second, a constricting band, for which some surgeons use a piece of the bandage; others, a rubber-cord, etc.; while Esmarch himself uses a piece of non-vulcanized rubber-tubing, which is much softer than the rubber-cord.

Several specimens of the articles employed were exhibited.

In ordinary cases the application of the bandage is quite simple, extending it from the tips of the fingers or toes up the limb, drawing it sufficiently tight to force all blood from the limb. As it advances, and when the point is reached at which the constricting band is to be used, the constricting band is made to take a few turns around the limb, is fastened by tying a knot, or by hook and chain, according to Esmarch's original plan. Then the bandage is removed, and the limb is ready for the operation.

Some experience is needed in order to apply the bandage with a proper degree of force, lest damage be done to the tissues by applying it too tightly, or venous hemorrhage permitted by applying it too loosely. As long as the constricting band is kept in position the operation remains bloodless. It cannot be employed in operations upon the trunk or face.

Advantages.—Prevention of loss of blood during the larger operations; it renders more certain and complete healing processes; diminishes the tendency to septicæmia; enables the surgeon to make difficult dissections with facility; permits easy extraction of foreign bodies, and facilitates examination of bones, etc.

Objections.—It is alleged that the pressure necessary for the proper application of the bandage and constricting band may seriously impair the vitality of the tissues—produce injuries to nerve-trunks, thus giving rise to paralysis.

Hemorrhage has been ascribed to the method. It is said that it may cause plethora of internal organs; cause gangrene; and that poisonous fluids may be pressed from the tissues into the general circulation.

The author of the paper then proceeded to analyze 141 cases, in which the method had been employed. The cases occurred in this city and Brooklyn, and included those which terminated favorably and unfavorably.

These operations were amputations of thigh, primary and secondary; leg, primary and secondary; wrist; forearm; secondary amputation of arm; primary of toes; double amputation of leg; amputation at knee-joint; excision of wrist and elbow; removal of tumor from popliteal space; ligaturing of wounded arteries; removal of large mammary tumor; necrosis, etc., etc.

The percentage of recoveries after amputations, of which there were forty-four primary for injury, and twenty-three secondary for disease, was believed to be much better than usually obtained. In no case were any serious results obtained from forcing blood back into the body, although the quantity must have been considerable, as in amputation of the thigh. A more exact observation is needed, however, to closely determine the safety of the bloodless method in this respect. It may be that such distention of the blood-vessels will prove to be dangerous in those persons who are suffering from certain organic diseases affecting internal organs.

The method is perfect in its results, so far as the bloodless character of the operation is concerned. It commonly happens that some venous oozing follows removal of the constricting band; but, taking this into consideration—in some cases it may be considerable in quantity—the patient will have proportionately more blood after the operation than before it; and in many cases this saving of blood is certainly very desirable.

No argument is needed to prove the excellency of the method in connection with operations upon deep-seated tissues. It is chiefly on account of hemorrhage that so great difficulty is experienced in exposing arteries, or nerves, or other important structures upon the living subject, as compared with that with which they may be exposed upon the cadaver. By this method dissections can be made upon the living body with as much facility as upon dead subjects; hence its very great value as an assistant in removal of deep-seated tumors, ligation of deep-seated vessels, operations upon bones, etc.

Caution.—Blood-vessels are somewhat liable to accidental division, on account of the bloodless condition of the tissues, and to pass unrecognized. The veins, from the thinness of their coats, are especially liable to this accident; hence a good use of anatomical knowledge is necessary, lest what is a bloodless operation in the beginning, may be a very bloody one before the wound is closed. The surface of the wound should therefore be closely observed, lest an open vessel be overlooked. In the Hunterian operation for aneurism this method is not allowable, because the artery can generally be easily exposed and the bandage might endanger rupture of the sac while being applied. The production of local anesthesia is claimed for the method, but the question is one which calls for further experience.

Disadvantages.—(1) Sloughing; (2) Secondary hemorrhage; (3) Paralysis.

First—With regard to sloughing, it was said to follow this method in nine cases. Seven of those cases were primary amputations. The histories were read. The inference was drawn that the sloughing in these cases could hardly be attributed to the method. The elastic bandage may have had some share in producing sloughing; and if hereafter it becomes established that this compression is dangerous, of course we shall be obliged to abstain from its employment. The minimum degree of pressure should be carefully obtained, and the material for constricting the limb should be of the softest quality. The solid cord should be abandoned. The operation should not be prolonged more than is absolutely necessary. The constricting band has been retained one hour without unfavorable results; but a great majority of operations can be performed in much less time.

Second—Hemorrhage. There were four cases in which hemorrhage was said to occur; but from the histories of the cases the inference was legitimate that in none of them was the hemorrhage the consequence of the use of the method.

Third—Paralysis. This had occurred in one case, following amputation of the arm. The patient almost completely regained motion. There was one case in which neuralgic pains followed the operation. It was probable that the results in both these cases were due to too great pressure produced by the cord. It is doubtless a very wise precaution to apply the bandage above gangrenous tissues, thus avoiding the danger of forcing poisoned fluids into the system.

Properly applied and carefully guarded by precautions, it is one of the most valuable surgical expedients of modern times.

At the close of the reading of the paper Vice-President Dr. Emmet took the chair, and discussion ensued as follows:

Dr. JAMES R. WOOD remarked that he had resorted to this method in twenty-five cases without a single bad result that could be attributed to it. From his experience, sloughing has not been so great as when the operation had been performed without the use of the elastic bandage. Hemorrhage, of course, will occur in connection with this method, when vessels are neglected and left unsecured, the same as when the operation is performed in any other manner; but he was of the opinion that hemorrhage was not as liable to take place when this method is employed as when the operation is performed in the old style. So far as oozing of blood is concerned, after the constricting band is removed, it has, in his experience, usually been but trifling, and was easily controlled by the application of cold or dry lint. With reference to the cord, he had discarded it from the first. He then related a case showing the value of the method in ligating arteries, in which he had tied the deep palmar arch, after the application of the elastic bandage, without any difficulty whatever, for the reason that he could pursue his dissection with perfect ease, without having the view obstructed by blood, which would have been impossible without the assistance of this method. The constricting band he employs consists of a strip of the material used for bandaging the limb, doubled, making it half as wide as the original bandage. This makes a broad surface, which is not liable to injure the tissues by pressure, and he regards it as better than either cord or tube. If it becomes necessary to amputate for the removal of parts which have been invaded by gangrene, apply the bandage, commencing above the gangrenous tissues. In children and old

people the cord, for purposes of constriction, should never be used. He certainly had fallen in love with the method, and believed that Esmarch was entitled to the credit of having brought it before the profession. It is true, he himself had for more than twenty years been accustomed to elevate limbs to be amputated, carefully forcing all the blood possible into the general circulation, and in many cases had applied a roller bandage before securing the tourniquet. So far, however, as applying the elastic bandage and rendering the tissues bloodless, he believed Esmarch justly entitled to the credit of having fully brought out the method. Dr. Wood continued the discussion at some length by relating cases and calling up points of interest connected with the operations.

Dr. FRANK H. HAMILTON remarked that he had employed the method in eight cases; four amputations and four excisions. The histories of the cases were briefly referred to. No accidents had followed the operations which could be positively attributed to Esmarch's method, and he fully approved of its use.

Dr. MARKOR remarked that his experience in the adoption of this method had been quite limited; but in the cases in which he used it he had been much gratified and satisfied regarding its efficacy as a method for preventing hemorrhage, particularly in sections made for the removal of necrosed bone. In one case, and one only, an accident occurred which is perhaps worth marking down as one to be kept in mind. The operation was amputation at the knee-joint, upon a boy at Roosevelt Hospital. The limb had already commenced to slough at the lower portion, but it was determined to cut quite near the diseased parts, within an inch of the parts already in a condition of slough, and the operation terminated very satisfactorily, for there was no sloughing following the operation. Five or six weeks afterwards, however, the stump being healed, there occurred in the middle of the thigh, just opposite the point where the cord passed around the limb, a deep-seated abscess, nearly down to the bone, which was freely opened. At the point of suppuration there seemed to be a sort of sclerosis of the tissues which extended down to the end of the stump, and suggested that too great pressure had been made by the rubber cord at the time of the amputation. He was of the opinion that the cord was not a proper article with which to make pressure. This case gave rise to the impression in his mind that the constricting portion of the apparatus should be a somewhat broad bandage, something like that suggested by Dr. Wood, and perhaps it would be well, in addition, to first cover the skin with a few turns of a roller bandage.

Dr. KRACKOWIZER (who was the first surgeon to use the method in this city) remarked that he had little or nothing to add to what had already been said. He was, however, in full accord with the suggestion that all suppurating or gangrenous tissues should be carefully excluded from the pressure of the elastic bandage. The constricting band can hardly be too soft and broad. He had been accustomed to use a soft rubber hose about three fingers wide and three feet long. He had also been accustomed to fastening the ends of the constricting band, not by making a knot, which is sometimes troublesome to loosen, and is liable to produce undue pressure, but by bringing the ends of the band together perpendicular to the surface of the limb, and then fastening them close to the limb with a piece of tape. Esmarch himself is now using a sort of clamp similar to that used for securing the pedicle in ovariectomy. In order to get a bandage he splits a rubber hose large enough to give the necessary width;

this makes a bandage that can be much more easily cleansed, is much more readily obtained, and is much less liable to be the medium of communication for poisonous elements.

DR. WATROUS reported a case which came under his observation in Niagara Co., in which sloughing followed amputation of the forearm.

DR. WILLARD PARKER approved of Esmarch's method, although he had had no personal experience in its use. He was of the opinion that it would do for the surgeon about what anesthetics had already done for the patient. Anesthetics place the patient in a condition of perfect rest while undergoing the most severe operations, and now comes in the Esmarch apparatus to relieve the surgeon of all annoyance from blood in very many cases, and permits him to sit down and deliberately perform his operation. There was one thing, however, it seemed to him, which should not be forgotten, namely, the age of the patient should be taken into consideration, for tissues are much more liable to slough, as the result of pressure, in the young and old subject than in the middle-aged, other things being equal. Again, condition of system, whether the patient is vigorous or feeble, should not be lost sight of, etc., etc. All these things must come in to enable us to form a correct judgment with regard to the value of the method, and to decide with reference to the cases in which it can be most satisfactorily and safely employed.

DR. GURDON BUCK spoke decidedly in favor of this method of controlling hemorrhage. He expressed the opinion that, in cases of compound fracture which required the application of some controlling force to arrest hemorrhage, such force could be attained by means of this method *without* producing the same amount of suffering as would be realized from the application of the tourniquet.

DR. J. H. POOLEY, JR., of Yonkers, reported six cases of amputation where the Esmarch bandage was used, and good results followed in all the cases. He valued it highly in smaller operations; and spoke of removal of the ungual phalanx in case of felon; also of removal of needle from the finger of a washerwoman with the greatest facility, after applying an elastic bandage.

DR. RAPHAEL remarked that he fully approved of the method under discussion, but believed that every surgeon should be careful about carrying it to extremes, lest it fall into disrepute. He was of the opinion, for example, that in very many instances where persons vigorous, healthy, and full of blood had suffered from injuries which might render amputation of the leg, or arm, or thigh necessary, such patients would do better with some loss of blood; and that the loss of blood which might follow amputation after the ordinary plan might be desirable rather than otherwise.

Discussion closed. There being no further business, the Society adjourned at 10.20 p.m.

NEW YORK MEDICAL LIBRARY AND JOURNAL ASSOCIATION.

Stated Meeting, November 20, 1874.

DR. J. C. PETERS, PRESIDENT, in the Chair.

AGE IN RELATION TO CHILD-BEARING.

THE paper for the evening was read by Dr. Fordyce Barker, upon "The Age of Women when the Capacity for Childbearing Ceases." The question is, Can the limits of capacity for conception in women be positively determined?

Questions are frequently asked professional witnesses in courts of law relative to the truthfulness of reports from men of unquestioned veracity, which have an immediate bearing upon the question now under discussion. For example, "Do you know that Dr. Benjamin Rush, one of the signers of the Declaration of Independence, has reported a case of a woman who gave birth to a child after she had reached the advanced age of sixty-one years; and do you doubt in the least that his report is a true one?" Questions of like dignity are frequently propounded to the medical witness. There are plenty of cases reported in medical books where it is said that women have given birth to children when over fifty-eight years of age, etc.

The object of the paper was to show that, physiologically, and as a matter of experience, there are *limits* in the reproductive functions of women.

The ordinary opinion is, that conception and menstruation travel hand in hand, and that when menstruation commences and ceases, capacity for conception also commences and ceases.

But there are thousands of women who menstruate regularly, and yet are sterile, without apparent pathological cause; and, on the other hand, many women have given birth to children after menstruation has entirely ceased.

There are well-authenticated cases—indeed such cases had fallen under the observation of the author of the paper—where women have given birth to large families of children, and *yet never menstruated at all*.

It sometimes happens that women menstruate irregularly and scantily previous to marriage, and when marriage takes place menstruation ceases entirely, yet give birth to children. One case of this kind was reported as having occurred in the doctor's own practice, where the woman gave birth to *ten* children.

There are many cases, in which the evidence is unmistakable, where children have been born after menstruation has ceased for a number of years. Cases of this kind were given from the author's own practice, in which children had been born three and five years after the cessation of menstruation.

The conclusion was reached that ovulation and menstruation, though often coincident, do not necessarily bear the relation to each other of cause and effect.

Ovulation does not always occur at the time of menstruation. This proposition was substantiated by reference to several standard authorities.

Menstruation, therefore, is to be regarded as an accidental and incidental phenomena, and is simply a flow of blood from the interior of the uterus at stated periods, irrespective of ovulation. Ovulation is essential to conception, but menstruation is not. The occurrence of a regular flow of blood from the genital organs of a woman over fifty-five or fifty-eight years of age, is no evidence of the occurrence of ovulation at the same time. When senile atrophy of the ovaries takes place, ovulation ceases, and conception is no longer possible. This period is reached, as a rule, between the fortieth and fiftieth year of the woman's age. In very exceptional cases, this change does not take place until one, two, three, or four years later.

These are well-established physiological facts, and have been proven by thousands of *post-mortem* examinations; and, in addition to this, not a single case of any scientific value has been known of a woman over fifty-five years of age who has given birth to a child, except in the case of Sarah, the wife of Abraham.

There are many cases reported where women from fifty-eight years of age to eighty years of age have

given birth to a child; but in a scientific inquiry the Doctor holds that we are bound to reject all statements which are opposed to the universal experience of mankind, where the probabilities against the truth of the assertion are as a million to one, unless the statement is supported by such evidence as would be regarded as conclusive in a court of law.

Some of the cases reported have their foundation in tradition; others in newspaper sensations, etc. Others, again, have arisen from misquotation and perversion of correct reports, etc.

Several cases which have been referred to and accepted by writers upon medical jurisprudence, were taken up and considered.

The case reported by Pliny, which has been so often referred to by medical writers, was one in which the child was born 163 years *b.c.*, while Pliny wrote twenty-three years subsequent to the birth of Christ. The very length of time between the occurrence of the event and the record of the historian is sufficient to confirm the belief that the story probably had its foundation in tradition. Again, cases are quoted from Haller to prove that women have given birth to children at the advanced age of sixty-three to seventy years. There is no evidence, however, that Haller ever practised midwifery; and by reference to his *Elementary Physiology*, published in 1563, it will be found that he simply says: "That he has read of such cases," etc.

The case of Ann Woods, so frequently referred to, as reported by Dr. Benjamin Rush, in which it is said that she gave birth to a child after she was sixty-one years of age, is founded upon the simple statement of the old woman herself, when she came to the door of Dr. Rush begging for food.

Several other reports were reviewed, and rendered doubtful with regard to truthfulness. One authentic case has been found where the woman gave birth to a child after she had reached the age of fifty-five years.

This case has been reported by Dr. Davies, of Hertford, England. There are many well-established cases where women have given birth to children between the ages of fifty and fifty-four years, and the author of the paper had personally attended three women in confinement who were over fifty years of age—one being fifty-three years of age.

The question of age at which childbearing is possible is one frequently brought before the courts. At this point the decisions of the courts, especially in England, were quoted somewhat extensively. The final proposition submitted was, that the laws of physiology, the experience of mankind, and decisions of the courts will justify the medical witness in declaring that a woman over fifty-five years of age is past the period of childbearing.

Dr. PALLEN remarked that although the presumption is against women's bearing children after fifty years of age, still he would dislike to state in a court of law that the woman who had the monthly flux *per vagina*, and who had no indications that the retrograde metamorphosis of age had manifested itself in the uterus or ovaries, even if she were fifty-five years of age, was incapacitated for childbearing. Discharges from the vaginas of old women may be the result of various *pathological* causes; but there are cases well authenticated in which extensive disease or degeneration of the ovary has taken place, yet menstruation took place regularly and conception has taken place under those circumstances.

Dr. MUNDE remarked that he was of the opinion that menstruation and ovulation continued together, and when one ceases the other also ceases. Upon that

supposition he reported several cases, and gave numerous data, bearing upon the question of the appearance and continuation of menstruation. There are exceptions, to be sure, but the general rule he believed to be that the power of conception ceased with the cessation of menstruation.

Dr. HUBBARD reported a case of ovulation and conception in a lady who never menstruated after marriage, but had given birth to *eight* children. Here was evidence that ovulation and conception may take place without the occurrence of menstruation.

Dr. ROGERS mentioned a case in which the woman had been delivered of a child at the age of fifty-three years.

Dr. CARO remarked that during his residence in Sicily the government recognized the possibility of childbearing commencing at the age of eleven years and two months, and continuing to the age of fifty-four or fifty-five years. He reported a case, of which he had personal knowledge while living there, in which the woman had given birth to thirty-one children; and that twenty-two of them had sat at the same table. This woman gave birth to her last child when she was fifty-four years old. It was also supposed that she had a double uterus, from the fact that a child was born every *six months*. Unfortunately, when the woman died *no post-mortem* was obtained.

Dr. SMITH asked Dr. Barker concerning the evidence that menstruation and ovulation did not necessarily occur together.

Dr. BARKER replied that menstruation and ovulation are most frequently coincident, but they do not necessarily bear the relation to each other of cause and effect (without entering upon theories): (1) because the one may exist without the other, as proven by numerous well-authenticated cases; (2) cicatrices have been found in ovaries, indicating rupture of Graafian vesicles, many years previous to the appearance of menstruation; and have also been found in old women (fresh cicatrices) after menstruation had ceased for a long time; (3) we now have eight well-authenticated cases in which women have menstruated and continued to menstruate after both ovaries were removed, rendering ovulation impossible. This, to him, was conclusive evidence that menstruation or monthly sanguineous flow is not dependent upon ovulation.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 19, 1874.

DR. AUSTIN FLINT, President, in the Chair.

MAMMARY DISEASES DURING LACTATION.

The paper for the evening was read by Dr. Salvatore Caro upon "Diseases of the Mammary Gland during Lactation."

After brief reference to enlargement of the gland, and what is known as milk-fever, associated with the establishing of the process of lactation, the author of the paper turned his attention to the consideration of some of the anomalies of this function. Of these agalactia and galactia were first considered in their etiology, symptomatology, and treatment. The most reliable remedy for agalactia, according to the author's experience, was the leaves of the plant *Ricinus Communis*. The powdered beans may be employed in absence of the leaves, but are not nearly as efficacious. In absence of both, *nursing*, good food, etc., are sometimes of great benefit.

With regard to galactia three things should be observed with the view of preventing injury to the

mother: (1) Ascertain whether the woman has a well-developed nipple or not; (2) whether the infant is healthy and without deformities or not, such as tongue-tie, hare-lip, etc.; (3) whether the woman intends nursing or not.

Haggerty's "Ladies' Companion" was regarded as the best instrument for removing milk from the breast.

Various remedies were mentioned that had been employed for the purpose of arresting the secretion of milk, but the application regarded with the most favor by the author of the paper was ext. bell., gum camph., and stramonium ointment combined. Spread this over the breast every four hours and cover with oil-silk.

Galactoele was next considered. The doctor remarked that he had been in the habit of opening these collections as early as possible, and had been annoyed, as a result of this procedure, by failure in healing of the opening made until the mother had ceased lactation. The aspirator, however, may be resorted to with very great satisfaction. By the use of this instrument nursing need not be interrupted, and danger of rupture of the milk-duct be avoided. The operation can be repeated without inconvenience. Obstruction of lactiferous ducts by colostrum casts was mentioned as a common cause of this difficulty.

Affections of the nipple were next considered somewhat in detail, and the liability of being followed by mammary abscess. Prevention of nipple troubles by attention *precious* to confinement was regarded as being of prime importance. Haggerty's nipple-shield was recommended.

Mastitis is by far the most serious affection, and the general outline of treatment was such as the profession at least *should* be familiar with.

Dr. GARDNER spoke somewhat at length upon the subject under discussion. He was of the opinion that ice should *never* be used in cases of mastitis, for the reason that he had seen one case in which *both breasts* were frozen, and subsequently completely sloughed away.

Dr. Lusk favored treatment of galactoele by means of the aspirator. He had never derived very much benefit from the castor-oil leaves in cases of agalactia. He had been much more successful in establishing lactation in such cases by having the breast well stroked from base to nipple by an experienced nurse, and making traction upon the nipple by a breast-pump, than by any method he had ever resorted to. There are cases in which there is lack of development in the acini of the breast, and certainly in such cases applications or treatment of any kind would be useless. In those cases in which it becomes necessary to draw the nipple out, as a general rule, he believed it better to remove the child entirely, than to run the risk of developing abscess by nursing and pulling at the nipple.

When the breast is properly emptied before the third day after confinement, milk-fever is rare. In all those cases in which erosion and fissure of the nipple are present, it is better to remove the child from the breast at once, for there is much less liability of developing abscess if the milk is renewed by some artificial means rather than by permitting the child to nurse.

Dr. PEASLEE remarked that there are cases in which it is very desirable to arrest the secretion of milk *entirely*—for example, when the child is still-born.

The important question is, Do we know of any method of completely preventing the secretion of milk? He believed that in any case we may realize

an entire arrest of the function of lactation by the use of belladonna.

R. Aqu. ext. bell.	℥i.
Aqua, or	
Glycerin.	℥i.
M.	

Keep the breasts constantly wet with this solution, commencing before any signs at all of tumefaction have appeared, is the plan he adopts, and has never had any trouble at all with such cases.

Dr. SELL remarked that occasionally he had found it difficult to arrest the secretion of milk by the use of belladonna alone. In such cases he had had admirable success (1) by enjoining abstinence from fluids as much as possible; (2) by giving a few doses of iodide of potassium, in addition to the belladonna. By these three things combined he had *never* failed to produce perfect agalactia.

With regard to mammary abscess, prophylaxis was regarded as the essential element. Sore nipples being a frequent cause, they must be carefully looked after, and not only that, but one step further should be taken, and guard against the occurrence of sore nipples. He mentioned the fact that he had seen eight thousand successive cases of confinement in one hospital in Europe, and not a single mammary abscess among them all, for the reason that prophylactic treatment was rigidly observed.

Dr. HUBBARD remarked that in case the child was still-born, he did nothing at all with the breast, except to apply camphorated oil and lead-plaster perhaps, and let them entirely alone. He had never had any trouble with this plan of management.

Dr. Lusk sustained the remarks of Dr. Hubbard.

The Academy then adjourned.

Correspondence.

MEDICAL MATTERS IN PHILADELPHIA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR:—I unintentionally did injustice in my last letter to the "Woman's Hospital and Dispensary," by intimating that this institution was only just now entering upon its course of usefulness in the construction of its new building. The latter, I should have said, is intended for the purposes of the Woman's College, which at present occupies a portion of the hospital proper. When the college building is completed, the hospital will be able to accommodate itself to the wants of the future, by the construction of additional pavilions; but even now it is said to be unusually well adapted by its elevated position and admirable ventilation for success in operation. So much opposition has at various times crossed the path of the women, in their efforts to promote medical teaching and learning, that I was doubtless regarded by them, for the phraseology of my last letter, as another recruit in the same adverse cause, especially as I so completely ignored the fact that the annual report of the hospital last January was the thirteenth so offered; that during the year there had been treated 207 patients at the hospital, 602 at their homes, and 2,044 in the dispensary.

I am disposed to think, from my own observation, that the profession in Philadelphia is not so much cut up into sectional cliques as it seems to be in your own city. There appear to be more generally harmonious relations and mutual confidence here; less jealousy of successes; a more cordial interchange of friendly salu-

tation and professional fraternity. I think we have far fewer specialists here, in proportion to the whole number engaged in practice, than in New York. There are very few of us who can or do sit in our offices the whole morning, receiving calls from sufferers with affections of the throat, the chest, or the brain, and can afford to ignore the claims of general practice. Few here would make a living on specialties alone, and I am very sure that few could or would have the conscience to charge the fees that we hear of sometimes in New York, or would be likely to retain their patients at such exorbitant figures. The rule that a second party will estimate the first in proportion to the latter's estimation of himself will not always hold good in our old-fashioned way of valuation of individuals according to their true merits. Even in the rivalry of competing schools here, there is at the present day a kindly element of mutual congratulation at the result of honorable labor in teaching, that is in marked contrast with the olden times, when, for example, a professor in one institution falsely charged the professors of another medical college with lying in wait at depôts and students' boarding-houses for the purpose of securing additions to their classes; and even maliciously intimated that when one of the latter corps of medical instructors was once an assistant of his, the assistant's collection of calculi was very small, while it had now become remarkably large. In those days the students were conveyed from the college to the Blockley Hospital, over the river, on alternate clinical days—which at that time were every Wednesday and Saturday—in omnibuses, or in large sleighs, when necessary; but a great transformation has now taken place. The Pennsylvania Hospital, which at that period was looked on as almost an appendage of the University, is likely now, from a certain amount of propinquity, to be patronized in its clinics chiefly by the students of the Jefferson Medical College; while the University and the Philadelphia Hospital (almshouse) are such near neighbors that they can almost shake hands with one another. It may be said as a literal truth, without implying the slightest disparagement to that noble institution, that the University, by its removal, has certainly gone to the almshouse. It seems probable that in the course of years the ground now occupied by the latter public institution will be sold—for the ground is very valuable along the western edge of the Schuylkill—and a new almshouse constructed at a greater distance from the centres of population and trade; but even then the University will have its already successful hospital within its own grounds, with all its facilities extended and its means of usefulness in every way amplified.

The proceedings of the American Public Health Association, which met here last week, were so fully reported in your daily papers that any detailed account of them at this time would be superfluous. The Convention made a most favorable impression, and did good service to the cause it had so much at heart. It went seriously to work with its programme of papers, and did not step aside for purposes of feasting and enjoyment, even in the evenings, when two or three hours were regularly employed in addresses of great practical utility. Our Board of Health pales its insignificant fires and sinks deep into its shoes, as the juvenile element of the population would express it, in the presence of such an assemblage of earnest philanthropic men; for be it known that in Philadelphia every "Board," no matter what its objects, is nothing if not political, and our local sanitary council, even though composed of men of different party views, does not assume a status above that of political

machines in general. Our city would be absolutely startled if the Board of Health of Philadelphia should ever rise above the notoriety of imperfection in street-cleaning, and attempt to grapple with the general principles of public health. It is an interesting query why it was not represented at this national gathering, the absence of such a delegation being a confession of weakness that should not have been tolerated by sensible, health-loving citizens. Otherwise, as one of the daily press suggested, the national association might have been enlightened on points of great practical moment, being particularly those referring to the problem, how not to do a thing, illustrated by new views on street-cleaning and kindred topics. There seems to have been a wide diversity of views in the Health Association on the best modes of hospital construction.

The construction that might be put on Professor Gross's sweeping remarks on hospitals by the laity, is something of a different nature; for while others contended that barrack hospitals or larger buildings were the more desirable form, he expressed the view that "hospitals, however well constructed, especially during the prevalence of epidemics, are, as a rule, pest-houses, or breeders of disease-germs, and therefore, under such circumstances, unfit as receptacles for sick, wounded, and lying-in persons." It will be seen that in this view, hospitals are looked on as pest-houses at all times, but much more so at some times than others. We may anticipate many a reply to this rather broad view of the subject from those who honestly believe that even the old hospitals, which were built before the light of modern experience was thrown upon them, have not justly deserved this wholesale condemnation as disease-breeders. We shall not wonder if, with a very natural sensitiveness, these institutions will now give us statistics that will prove how much they have accomplished, with but moderate loss of life. And yet, such papers as those presented by Professor Gross, and other gentlemen of the association, give much food for thought, and induce many a reflection which might not otherwise have been indulged in, as to the possibilities of past successes of treatment under different hospital arrangements, and the probabilities of happy results in the days to come. Dr. Billings referred to the model hospital of the future, with its rooms for one or two patients; but not a word was said about the model patient himself in these after-days of perfection in hospital construction, when it will be a luxury to be sick, even in the absolute solitude of a single-bedded ward. In the fertility of our imagination we think we see him now, lonely and deserted, in his own private ward, with fresh-air flued or fresh air-flued (we are getting slightly confused) opening in the wall near the head of his bed, with air-holes in the floor beneath it, and a funnel over it, "communicating with the aspirating channels;" what more could he desire? With so much air introduced, and got rid of by these excellent contrivances, we are afraid the model patient of the future will be tempted to put on airs himself.

We had the pleasure of a visit to our city a few days since from Drs. L. A. Sayre and Jas. R. Wood, of your city, who, I believe, fell into the hands chiefly of our surgical friends here. In addition to these, we had a strong representation of your active workers in another field, in the persons of the gentlemen who attended the sessions of the Health Association, of whom I may mention, without being considered invidious, as one of those who contributed much to its success, the courteous secretary, Dr. Elisha Harris.

THE MEDICAL RECORD:

A SEMI-MONTHLY JOURNAL OF MEDICINE
AND SURGERY.

GEORGE F. SHRADY, A.M., M.D., Editor.

Published on the 1st and 15th of each Month by

WM. WOOD & CO., 27 Great Jones Street, N. Y.

New York, December 15, 1874.

THE CLOSE OF VOLUME IX.

WITH the present number the Ninth Volume of THE MEDICAL RECORD closes. We have striven to render it worthy of the confidence of the profession; and if the liberal support which we have obtained during the past year, and the hearty endorsement of the course which THE RECORD has taken in the discussion of subjects of current medical interest, are to be taken as guarantees of the appreciation of such labors, we are satisfied. We have endeavored to be impartial, truthful, and just; and if our efforts to make the journal thoroughly independent have not met with the approbation of all, we have at least the consciousness of having performed our duty to the best of our ability.

The communications coming from the representative men in this and other countries can speak for themselves, and we believe their character for practical utility fully sustains one of the leading features of this periodical. In returning thanks to our contributors we take pleasure in specially mentioning the services of the respective members of our staff. In the department of Progress of Medical Science, Dr. T. E. SATTERTHWAITE has worked up the German exchanges; Dr. F. A. CASTLE, the French and English; Dr. E. B. BRONSON, the American; and Dr. GEORGE R. CUTTER, the Dutch, Scandinavian, Italian, and Portuguese. Dr. WESLEY M. CARPENTER has furnished us with the reports of the Practice of the Hospitals in New York and Philadelphia, and has supplied the Lecture Department with many verbatim, as well as the usual reports from the Societies.

The Review Department has been enriched by criticisms from acknowledged experts, and the opinions therein expressed should carry with them the requisite amount of unbiassed authority.

With the next number we commence THE RECORD as a weekly issue; and, while hoping for continued fa-

vors, we shall leave nothing undone to make it a valuable, practical medical journal for the general practitioner.

VIVISECTION.

SOME of the County Societies in this State have taken a very commendable interest in declaring in favor of vivisection, and by the passage of appropriate resolutions have shown how strongly the current of professional opinion sets against Mr. Bergh. We do not see why all the societies in the State should not put their protest upon record. There is no doubting the fact that there would be but one opinion upon the subject; but the accumulation of such opinions is what will tell against any adverse legislation during the coming winter. The State Society will doubtless speak upon this subject at its next annual meeting, and in order that it may do so with becoming effect, every auxiliary body should send to it in time individual expressions of opinion. In view of the threats made by the Society for the Prevention of Cruelty to Animals, this course will be a wise one and may prevent much trouble.

TREATMENT OF THE INSANE IN PHILADELPHIA.

TO the general reader, as to the general public, the investigation held in Philadelphia, a few days since, into the condition of the Hospital and Insane Departments of the Philadelphia Almshouse presented some features which reflected rather severely on the powers that be, and their failure to provide the necessary accommodation for the health and comfort of those afflicted creatures. It is bad enough in these days to have poverty as your warmest friend, clinging to you through all your cares and troubles, and to be obliged to be a private in one of the regiments of paupers, wearing the almshouse garb for no other crime than this; but to be compelled, as many of the insane have been, to share the occupancy of their cells with violent maniacs, and suffer maiming or personal injury, and even death in consequence, is more than ordinary humanity can bear to think of without a shudder. We always wake up to reformation in such matters after the mischief has been committed. Nothing would so stir up the activity of sluggish local legislators as a few murders or atrocious maimings of the insane by the insane; and yet nothing is more likely to occur at any moment than some sensational incident of this kind. Nothing would remedy the present condition of things half so well as the placing of a few councilmen in the cells as companions of those already occupying them. There is nothing like experience as a teacher. It was shown in the published testimony of the attending physician and surgeon, that in the Insane Department there are accommodations for only 600, while they have 1,106 patients. The Board were therefore compelled to place four, five, and six patients in one cell, with manacles on their hands or feet, to prevent them from attacking each other.

Dr. Maury, who has been connected with the hospi-

tal department for thirteen years, said that the accommodations were at times stretched to double their capacity by placing patients on the floor, and in the performance of his duties he had been compelled, night after night, to step across the patients thus placed. Dr. Pepper said that a remedy might be found in the erection of one-story inexpensive structures upon the grounds of the institution by the Guardians of the Poor. He expressed only the universal sentiment of the medical fraternity of that city when he said that increased surgical and medical accommodations were imperatively needed. Dr. Wood said that in a ward which is but 72 feet long, 18 feet wide, and 7 feet 4 inches high, with inadequate ventilation, the population in the winter is generally thirty and over. This overcrowding resulted in a largely increased mortality over other hospitals. He favored the erection of one-story frame or brick hospital barracks. Dr. Richardson thought the best plan would be to erect a separate asylum somewhere in the country for the insane, for about 500 patients, for the treatment of curable cases, and to keep the present hospital for chronic cases. A few nights ago, one patient had his collar-bone broken; another had his ear bitten off, and another had his cheek bitten. The recovery of insane patients is greatly hindered by this overcrowding. Dr. Parry said that he had been connected with the hospital for ten years, and in that time the mortality in confinements had increased from one in 152 to one in 25. Is it not time that the matter was looked into?

Reports of Hospitals.

BUFFALO GENERAL HOSPITAL, BUFFALO, N. Y.

NOTES ON SURGICAL CASES.

By C. C. F. GAY, M.D.,

ATTENDING SURGEON.

VALGUS HALLUX—RESECTION OF HEAD OF THE FIRST METATARSAL BONE.

Emma W., aged nineteen years, was brought to hospital on account of being disabled from abduction of both great toes. One toe was turned at a right angle, overlying the smaller toes; the other was turned nearly to a right angle, underlying the smaller toes.

The metatarsal prominence was much inflamed, the inflammation involving both integument and bone.

The process of abduction commenced nine years ago. The patient had been a dancing girl, and had been accustomed to sustain her weight often upon the great toes, and to this she attributes the present deformity. She has suffered greatly from pain, and has heretofore obtained but temporary relief from treatment of the existing arthritis.

May 2d, 1874, I operated, in the presence of several members of the hospital staff, upon both the feet. Esmarch's bandage was applied from the toes up, embracing two-thirds of the leg. Chloroform was used. I made a single longitudinal incision over the meta-

tarso-pharyngeal prominence down to the bone, one and a half inches in length, disarticulated the joint, passed the chain-saw around the metatarsal bone, and removed half an inch of the head of the bone. The toe now dropped into line with the longitudinal axis of the foot. I immediately operated, in the same manner, upon the opposite foot.

Not a drop of blood was lost in either operation, and consequently sponging was not required; but to prevent hemorrhage when the bandage should be removed, a compress was applied to the wound, which was sufficient to prevent loss of more than a few drops of blood from the returning current. The wound was left open, and warm-water dressings applied. On the 20th the wound of the left foot was closed. An abscess occurred on the dorsal aspect of right great toe, which delayed union of the wound.

June 10th. Both toes are well, the patient walking about the ward, and the result is perfect, the patient having the entire use of the toes, with the deformity completely relieved, but with a half inch shortening.

I am induced to report these two cases from having read in THE MEDICAL RECORD the report of a case operated upon by my friend Dr. Frank H. Hamilton, on April 7th, 1873, which, so far as I know, is the first case on record for relief of the deformity by this method.

My cases recovered equally well with Dr. Hamilton's, without the submersion of the feet in warm water, but had the necessary apparatus been at hand I should have used the same method of after-treatment which the doctor recommends.

VARICOSE ULCERS.

Chronic ulcers of the legs, standing in relation to varicose veins as cause and effect, are treated in this hospital by obliteration of the veins, or rather partial *occlusion* or *diminution* of the calibre of the veins;* and since the treatment in all cases by potassa cum calce has invariably been attended with success, this at present is the only method employed. As the treatment and after-treatment has varied during the past year from that formerly adopted, I will report in brief one of the more recent cases treated.

H. D., sailor, aged thirty-eight years, entered hospital May 13th, 1874. Has varicose ulcers upon both legs, just above the external and internal malleoli, two inches in length by an inch in breadth, existing for eighteen months. The varices are small but numerous.

18th.—To-day produced six eschars upon each leg, over the more prominent veins, and applied warm-water dressings instead of slippery-elm poultices, as practised formerly.

24th.—Made four additional eschars upon each leg. In four days three more eschars were made.

In just one week from the application of the second crop of eschars, the ulcers were entirely closed and well.

On June 20th the eschars were healed and patient discharged.

The variation alluded to, in treatment of this from former cases, consists in causing a rapid succession of eschars and in the use of warm-water dressings. The cases progressed as rapidly and kindly as when the poultice is used, no erysipelas or hemorrhage having supervened.

FRACTURE OF THE NECK OF THE SCAPULA (RIGHT SIDE).

H. B., teamster, aged twenty-four years, was thrown from his wagon, striking upon the right shoulder; was

* Vide Theory of Varices, by the writer, published in *Duffalo Medical and Surgical Journal*, May, 1873, page 275.

brought to hospital April 7th, 1874. There was acromial prominence, with corresponding infra-acromial depression, entire mobility of the arm, and when the patient was placed upon his back in the recumbent posture the deformity was removed and crepitation obtained.

Dr. Moore's clavicular bandage was applied, and its use alone continued until May 30th, when the patient was discharged with entire use of the arm, and without perceptible deformity.

RADICAL CURE OF HYDROCELE.

Mr. M., aged twenty-five years, entered hospital as private patient, December 19th, 1873, with large hydrocele of left side. On December 20th, I operated by the method heretofore so successfully employed at the hospital by the silk seton.

The seton was introduced by means of a needle five inches in length, threaded at the point with four strands of ordinary-sized suture silk. Introduced at the fundus of the scrotum, the point of the needle was made to emerge four inches above the point of entrance. On withdrawing the needle some fluid escaped. The trocar was then employed, drawing off the whole of the fluid. On December 25th, there was much swelling but no pain. The seton was removed. December 27th, constitutional symptoms were developed which subsided the following day. The scrotum now became erythematous, the redness extending up the abdomen as far as the umbilicus. The erythema lasted for five days. Lotion of acetate of lead was applied to scrotum.

The swelling gradually diminished, but not until there had been a considerable quantity of pus discharged from the puncture made by the needle.

The patient left hospital with scrotum still enlarged. On October 1st, 1874, there remains no vestige of the disease. The scrotal tissue is redundant. By the use of a suspensory bandage a varicocele which formerly existed has entirely disappeared. In operating by this method I prefer introducing the needle first and using the trocar afterwards. I prefer to do so, not because it is simpler and easier in performance—which is not the case—but because I have thus far obtained better results than when the trocar had been first employed.

ARMY NEWS.

GENERAL ORDERS }
No. 125. }

WAR DEPARTMENT,
ADJUTANT-GENERAL'S OFFICE,
Washington, Nov. 17, 1874.

AN important part of the duty of a medical officer of the army is the supervision of the hygiene of the post or command to which he is attached, and the recommendation of such measures as he may deem necessary to prevent or diminish disease among the troops.

For this purpose he shall at least once a month examine and note in the medical history of the post the sanitary condition of the quarters, including all buildings belonging to the post, the character and cooking of the rations, the amount and quality of the water supply, the drainage, and the clothing and habits of the men, and make a report thereon in writing to the commanding officer, with such recommendations as he may deem proper. If the recommendations be approved and carried out, the medical officer shall note the fact in the medical history of the post. If the action recommended be deemed impracticable or undesirable, the commanding officer shall indorse his objections on the report and forward it to the Department Commander. A copy of such endorsement shall be

furnished to the medical officer, who shall record it in the medical history of the post.

The Annual Sanitary Reports now required from medical officers shall in future be forwarded through their commanding officers, who shall forward them through the regular channels, with such remarks as shall be necessary.

The same course will be taken with the Special Sanitary Reports called for by Circular Orders No. 2, Surgeon-General's Office, October 15, 1874, which, as modified, is as follows:

"Medical officers will forward, with the Sanitary Reports of December 31, 1874, a special report on the following subjects, to be made as full and be as carefully prepared as possible, as the results are desired for publication:

"I. On the food of the army, its quantity, quality, and mode of preparation. What is the character of the articles forming the regular ration as furnished to the post? What is the average amount of saving for post fund? What articles of food, and in what amount, are purchased by the post fund, obtained from post garden, or by hunting or fishing? Ice, how obtained and in what quantities furnished?

"How is the cooking done for the men? Give bill of fare for a week at different seasons. Is the food of the men inspected daily? How often is it inspected by the medical officer? Have any complaints been made by the men about the food, and have any cases of disease occurred which may be attributed to the food or its mode of preparation? If so, specify. Character of kitchen and bakery fixtures. Has any special apparatus, such as the Warren cooker or the felt box been tried? If so, give results. Character and amount of extra articles furnished by the Commissary Department for officers' use. Diet of the sick, and hospital fund. Remarks, suggestions, and recommendations.

"II. Duties of medical officers in scouting parties and expeditions. Nature and amount of medical supplies required; how carried. Means of transportation for wounded. Remarks.

"III. On military punishments and their effect on the health and morale of the soldier. Give instances, recommendations, etc.

"IV. Personal cleanliness of the men. What are the post regulations, if any, with regard to bathing? What facilities are afforded? How often are the men's blankets washed?

"The above report must be forwarded promptly through the proper channel to the Medical Director on or before January 1st. Medical Directors will forward them through the Department Commanders, with their own observations and comments on the points above referred to."

The medical history of the post shall be kept with the hospital records, and shall not be removed therefrom. It shall be open to the examination of the commanding officer, and the attention of inspecting officers is especially directed to this book, and they will report the manner in which it is kept.

By order of the Secretary of War:

E. D. TOWNSEND,
Adjutant General.

Official:

Assistant Adjutant General.

Official List of Changes of Stations and Duties of Officers of the Medical Department United States Army, from November 19 to December 4, 1874.

GIBSON, J. R., Assistant Surgeon.—Granted leave of absence for 15 days, upon completion of his examination for promotion. S. O. 260, c. s., A. G. O.

HUBBARD, V. B., Assistant Surgeon.—Assigned to duty at Jackson Barracks, New Orleans, La. S. O. 187, Department of the Gulf, Nov. 17, 1874.

PHILLIPS, H. J., Assistant Surgeon.—Assigned to duty at Fort Ontario, Oswego, N. Y. S. O. 236, Military Division of the Atlantic, Nov. 30, 1874.

KINSMAN, J. H., Assistant Surgeon.—Relieved from duty at Fort Abercrombie, D. T., and to report in person at these Headquarters. S. O. 252, Department of Dakota, Nov. 16, 1874.

HEIZMANN, C. L., Assistant Surgeon.—Relieved from duty in Department of the Platte, to report in person to the president of the Army Medical Board for examination for promotion, and upon its completion, by letter to the Surgeon-General. S. O. 260, c. s., A. G. O.

YEOMANS, A. A., Assistant Surgeon.—Granted leave of absence for 3 months on surgeon's certificate of disability. S. O. 250, A. G. O., Nov. 17, 1874.

DICKSON, J. M., Assistant Surgeon.—Assigned to duty at Savannah, Ga. S. O. 186, Department of the South, Nov. 17, 1874.

By S. O. 260, War Department, Nov. 30, 1864, the following named Assistant Surgeons (recently appointed) are directed to report as follows for assignment to duty:

WINNE, CHARLES K., in person, to Commanding General, Department of the Platte.

AINSWORTH, F. C., in person, to Superintendent U. S. Military Academy, West Point, N. Y., for temporary duty.

HAYARD, VALERY, by letter, to the Commanding General, Department of Dakota.

HOFF, JOHN VAN R., by letter, to the Commanding General, Department of the Platte.

PAULDING, H. OFFLEY, in person, to the Commanding General, Department of Dakota.

ADAIR, GEORGE W., in person, to Commanding Officer, Newport Barracks, Ky., for temporary duty.

BROWN, PAUL R., by letter, to the Commanding General, Military Division of the Atlantic.

MOSELEY, EDWARD B., by letter, to the Commanding General, Department of the South.

JACKSON, DONALD, in person, to the Commanding General, Department of Texas.

SEMITZ, BERNARD G., by letter, to the Commanding General, Department of California.

SKINNER, JOHN O., in person, to the Commanding General, Department of the Columbia.

FINLEY, JAMES A., in person, to the Commanding Officer, Fort Monroe, Va., for temporary duty.

DE LOFFRE, AUGUSTUS A., in person, to the Commanding General, Department of the Missouri.

BEDAL, SYLVESTER S., by letter, to the Commanding General, Military Division of the Atlantic.

HAMILTON, JOHN B., in person, to the Superintendent Mounted Recruiting Service, St. Louis Barracks, Mo., for temporary duty.

WILCOX, JOHN B., in person, to the Commanding General, Department of the Missouri.

MAUS, LOTIS M., by letter, to the Commanding General, Department of the South.

MAUS, L. M., Assistant Surgeon.—Assigned to duty at McPherson Barracks, Atlanta, Ga. S. O. 191, Department of the South, Nov. 25, 1874.

JOHNSON, HENRY, Medical Storekeeper.—Granted leave of absence for 3 months. S. O. 253, A. G. O., Nov. 20, 1874.

Medical Items and News.

VIVISECTION.—At a meeting of the New York Pathological Society, held Nov. 12th, 1874, the following preamble and resolutions were unanimously adopted:

Whereas, Certain publications have recently been brought to the notice of this Society, having for their object to excite a prejudice against the propriety and utility of experiments upon living animals, as performed for the purpose of medical investigation, and to control or prohibit such experiments by legal enactment; and

Whereas, The members of this Society have abundant reason to know that the method of experimentation upon animals has been productive of many useful discoveries in pathology, as well as in physiology and practical medicine; therefore,

RESOLVED, I. That experimentation upon animals is of the same value for investigation and discovery in medicine as experiments in physics and chemistry for the corresponding branches of Natural Science;

II. That this method of investigation, by increasing our knowledge of the causes and consequences of disease, leads to enlarged facilities for its prevention and cure, and has thus been the means, in many instances, of preserving human life, and relieving human suffering;

III. That, in the opinion of this Society, it would be in the highest degree impolitic and unjust to prohibit experimental investigations of this nature, or to withdraw from them the protection and recognition which is wisely afforded by the law.

Unanimously adopted.

H. KNAPP, M.D., *President*.

GEO. F. SHRADY, M.D., *Secretary*.

NEW YORK LARYNGOLOGICAL SOCIETY.—At the annual meeting of the New York Laryngological Society, held Nov. 12th, at the residence of Dr. Clinton Wagner, the following officers were elected for the ensuing year:

President, Andrew H. Smith; *Vice-Prest.*, Woolsey Johnson; *Secretary*, George M. Lefferts.

Executive Committee, Morris J. Asch, Charles McBurney, Beverley Robinson.

THE FRENCH GOVERNMENT offer a prize of \$60,000 for the discovery of an effectual means of destroying the vine scourge, *phylloxera*; and a committee has been appointed to regulate the mode of competing. Voluntary subscriptions on the part of departments, parishes, companies, or private persons will be allowed to increase the value of the prize.

ABSENCE OF THE CORPUS CALLOSUM.—Dr. Malinverni, Professor of Pathological Anatomy in the University of Turin, reports in the *Gazzetta delle Cliniche* a case in which there was no corpus callosum. The patient, who died of typhoid fever, was well known to have had well-developed intellectual faculties. The septum lucidum and the convolution of the corpus callosum were absent, and the lateral ventricles communicated freely with each other.

Medical Department of Life Insurance.

TOBACCO AND LIFE INSURANCE.

By E. R. MAXSON, M.D.,

OF SYRACUSE, N. Y.

THERE are so many in the Life Insurance business who use tobacco in some form or other, that it subjects one to the liability of bringing down upon himself the execrations of all thus under the influence of the weed, to even make a suggestion bearing upon the influence of the habitual use of tobacco in shortening human life.

And yet it must be admitted by every candid and well-informed man, not under its influence, and who has taken the pains to think, that the poisons of tobacco—nicotin, nicotianin, and its empyreumatic oil, as introduced into the human system, in the various modes in which it is used—by chewing, smoking, and snuffing—tend strongly, not only to produce various forms of fatal disease, but by directly depressing vitality, in every instance, to greatly lessen the average of human life; and, what is still worse, they cause a strong inclination for intoxicating drinks.

The fatal diseases caused by the poisons of tobacco are undoubtedly very numerous. But cancer of the lip, disease of the heart, and collapse of the nervous system, with symptoms very like apoplexy, may perhaps be the most frequent; and all of them are to be dreaded by life insurers. As an examiner, medical practitioner, and careful observer, in this country and abroad, I am confident that many other diseases, tending to shorten human life, indirectly, are the result of the habitual use of tobacco. I could, did space permit, refer to numerous cases that have fallen under my observation and care during the past year, in which there was a collapse of the nervous system, simulating apoplexy, and evidently a direct result of the accumulation of nicotin in the system, from the habitual use of tobacco. I was called to see one such case in a distant State, and the man recovered under the use of tonics; he was quite largely insured, as I learned; another, an insurance agent, less fortunate, because his disease was longer neglected, or not diagnosticated, died of imbecility, and so his agency wound up.

Intoxicating drinks, the terror of life-insurers, are taken as a rule, I am confident, by those who become habitual drunkards, to counteract the depression of vitality caused by the poisons of tobacco previously used. And hence, in tobacco may be found not only the direct cause of many fearful and fatal diseases, but also of most of the drunkenness and disease attending the use of intoxicating drinks.

Insanity is admitted to be a frequent result of the use of tobacco by those most competent to judge. And yet, I am not aware that life insurers have ever taken into account that tobacco produces an imbecility short of insanity, disqualifying all who use it in a greater or less degree from exercising that care and discretion in the observance of the laws of health which they might and would employ were they not under the influence of the poison. It should be remembered that very many physical and mental ills are thus produced, which, with all the direct effects, tend to make tobacco one of the most pernicious influences in destroying and shortening human life, and hence to be dreaded by life insurers.

In view of all the facts bearing upon this important subject, I respectfully suggest: That as human life is greatly shortened, directly and indirectly, by the use

of tobacco, if tobacco users are to be insured at all, their average of life should be estimated separately from those not addicted to its use, and they should be charged accordingly, thus relieving those not addicted to the use of the weed; and further, that all life insurance agents should be selected from among those not addicted to the use of tobacco.

THE LONGEVITY OF BRAIN-WORKERS.*

By GEORGE M. BEARD, A.M., M.D.,

OF NEW YORK.

THOMAS HUGHES, in his life of "Alfred the Great," makes a statement that "the world's hardest workers and noblest benefactors have rarely been long-lived."

That any intelligent writer of the present day, and especially a writer who, like Mr. Hughes, is a thoughtful student of mental hygiene, should make a statement so absolutely untrue, shows how hard it is to kill an old superstition.

The remark is based on the mischievous theory, which—against the clearest evidence of general observation—has been held for centuries, that the mind can be used only at the injurious expense of the body. This theory has been something more than a mere popular prejudice; it has been a professional dogma, and has inspired nearly all the writers on hygiene since medicine has been a science.

Between 1864 and 1866, while preparing a thesis for graduation, I obtained statistics on the general subject of the relation of occupation to health and longevity that convinced me of the error of the accepted teachings in regard to the effect of mental labor. These statistics, which were derived from the registration reports of this country and of England, and from a study of the lives of many prominent brain-workers, were incorporated in an essay on the subject, that was delivered before an Association of Army and Navy Surgeons in New Orleans in 1863, and afterwards published in the "Hours at Home" Magazine. The views I then advocated, and which I enforced by statistical evidence, were:—

1st. That the brain-working classes—clergymen, lawyers, physicians, merchants, scientists, and men of letters—lived very much longer than the muscle-working classes.

2d. That those who followed occupations that called both muscle and brain into exercise, were longer lived than those who lived in occupations that were purely manual.

3d. That the greatest and hardest brain-workers of history have lived longer on the average than brain-workers of ordinary ability and industry.

4th. That clergymen were longer lived than any other great class of brain-workers.

5th. That longevity increased very greatly with the advance of civilization; and that this increase was too marked to be explained merely by improved sanitary knowledge.

6th. That although nervous diseases increased with the increase of culture, and although the unequal and excessive excitements and anxieties attendant on mental occupations of a high civilization, were so far both prejudicial to health and longevity, yet these incidental evils were more than counterbalanced by the fact that fatal inflammatory diseases have diminished in frequency and violence in proportion as nervous dis-

* An extract from the advance sheets of the Transactions of the American Public Health Association.

cases have increased; and also that brain-work is, *per se*, healthful and conducive to longevity.

Many of these views have since received various and powerful confirmation, and by a number of independent observers. The statistics on this subject I have endeavored to use without abusing them; to draw from them only those lessons that they are really capable of teaching. Among those classes who live mainly by routine and muscular toil (mechanics, artisans, laborers, etc.), change of occupation is the rule rather than the exception, especially in this country; and any statistics of mortality derived from the Registration Reports, are, so far as these classes are concerned, of but little value in the study of the relative effects of the different occupations on health and longevity. Another important complication arises from the fact that certain occupations, as clerkships, positions in factories, teaching, etc., are followed almost exclusively by the young and middle-aged; while other callings, as judgeships, are filled only by those in middle and advanced life. Another difficulty arises from the fact that some important occupations, as journalism, for example, are adopted only by a limited number; and the number in them who annually die is too small to afford any basis for comparison. But this generalization is, I am persuaded, admissible, that the greater majority of those who die in any one of the three great professions—law, theology, and medicine—have, all their lives, from twenty-one upwards, followed that profession in which they died. The converse generalization, that the great majority of those who die in the muscle-working avocations have all their lives followed some kind of muscle-working employment, however frequently they may have changed from one to another at different periods, is also true. Very few who once fairly enter theology, medicine, or law, ever permanently change to a purely physical calling; and, on the other hand, the number of those who begin life as farmers, laborers, and mechanics, and end it as lawyers, physicians, or clergymen, is quite limited, even in the United States, where every man has a better chance to follow the bent of his genius than in any other country.

A comparison, therefore, of the longevity of the professional and of the muscle-working classes, as derived from Registration reports, such as I have made, is quite justifiable. The value of this comparison would be vitiated if it could be proved that those who enter the professions are originally healthier and stronger, and come from better stock than those who enter physical avocations; but in this country, the practice has been to allow the more delicate members of a family to enter a profession, whilst the tough and hardy work on the farm or learn a trade. Here, as in Europe, there is growing up a distinctively intellectual class who live solely by brain-work; it is, however, not from this class alone, but from the farming, mercantile, and artisan class that the ranks of the professions are filled.

Great Longevity of Great Men. I have ascertained the longevity of five hundred of the greatest men in history. The list I prepared includes a large proportion of the most eminent names in all the departments of thought and activity.

It would be difficult to find more than two or three hundred illustrious poets, philosophers, authors, scientists, lawyers, statesmen, generals, physicians, inventors, musicians, actors, orators, or philanthropists, of world-wide and immortal fame, and whose lives are known in sufficient detail, that are not represented in the list. My list was prepared, not for the average longevity, but in order to determine at what time of life men do

their best work. It was, therefore, prepared with absolute impartiality; and includes, of course, those who, like Byron, Raphael, Pascal, Mozart, Kents, etc., died comparatively young. Now the average age of those I have mentioned I found to be 64.20.

The average age at death, at the present time, of all classes of those who live over twenty years, is *about fifty*. Therefore, the greatest men of the world have lived longer, on the average, than men of ordinary ability in the different occupations by fourteen years; six years longer than physicians and lawyers; nineteen or twenty years longer than mechanics and day laborers; from two to three years longer than farmers; and a fraction of a year longer than clergymen, who are the longest-lived class in our modern society. The value of this comparison is enforced by the consideration that longevity has increased with the progress of civilization, while the list I prepared represents every age of recorded history. A few years since I arranged a select list of one hundred names, comprising the most eminent personages, and found that the average longevity was *over seventy years*. Such an investigation any one can pursue; and I am sure than any chronology, comprising from one to five hundred of the most eminent personages in history, at any cycle, will furnish an average longevity of from sixty-four to seventy years. Madden, in his very interesting work, "The Infirmities of Genius," gives a list of two hundred and forty illustrious names, with their ages at death. The average I found to be sixty-six and a fraction.

In view of these facts, it may be regarded as established that "the world's hardest workers and noblest benefactors" have usually been very long-lived.

CAUSES OF THE GREAT LONGEVITY OF BRAIN-WORKERS.

The full explanation of the superior longevity of the brain-working classes, would require a treatise on the science of sociology, and particularly of the relation of civilization to health. The leading factors, accounting for the long life of those who live by brain-labor, are as follows:—

1. *The inherent and essential healthfulness of brain-work.* To work is to grow; and growth, except it be forced, is always healthful. It is as much the function of the brain to cerebrize, as of the stomach to digest; and cerebration, like digestion, is normal, physiological, and healthful. In all organizations of force, the exercise of force develops more force; work evolves strength for work. A plant that is suffered to bud and bloom is more sturdy and longer lived than the plant that is kept from the light, or trimmed of all its blossoms. By thinking, we gain the power to think; functional activity, within limits, tends to vigor and the self-preservation of an organ, and of the body to which the organ belongs. The world has been taught that the brain can be developed only at the expense of the other organs of the body; granting that brain-work strengthens the brain itself, the rest of the body is impoverished thereby—hence disease, and early death. But recent investigations in cerebro-physiology, seem to indicate that the centres of thought in the anterior region of the brain, are also the centres of muscular motion; and hence it may perhaps be inferred that to develop the brain may be one method of developing the muscles.* It is certain that the brain-working class are, on the average, well developed muscularly; and in size and weight are superior to the purely muscle-working classes.

* I here refer to the experiments of Hitzig, of Berlin, on the electrical irritation of the brains of living animals.

2. *Brain-workers have less worry, and more comfort and happiness than muscle-workers.* Worry is the converse of work; the one develops force, the other checks its development, and wastes what already exists. Work is growth; worry is interference with growth. Worry is to work what the chafing of a plant against the walls of a greenhouse is to limitless expansion in the free air. In the successful brain-worker, worry is transferred into work; in the muscle-worker, work too often degrades into worry. Brain-work is the highest of all antidotes to worry; and the brain-working classes are therefore less distressed about many things, less apprehensive of indefinite evil, and less disposed to magnify minute trials, than those who live by the labor of their hands. To the happy brain-worker, life is a long vacation; while the muscle-worker often finds no joy in his daily toil, and very little in the intervals. Scientists, physicians, lawyers, clergymen, orators, statesmen, literati, and merchants, when successful, are happy in their work, without reference to the reward; and continue to work in their special callings long after the necessity has ceased. Where is the hod-carrier, that finds joy in going up and down a ladder; and, from the foundation of the globe until now, how many have been known to persist in ditch-digging, or sewer-laying, or in any mechanical or manual calling whatsoever, after the attainment of independence? Good fortune gives good health. Nearly all the money of the world is in the hands of brain-workers; to many, in moderate amounts, it is essential to life, and in large or comfortable amount it favors long life.

Longevity is the daughter of luxury. Of the many elements that make up happiness, mental organization, physical health, fancy, friends and money—the last is, for the average man, greater than any other, except the first. Loss of money costs more lives than the loss of friends, for it is easier to find a friend than a fortune. Almost all muscle-workers are born, live, and die poor. To live on the slippery path that lies between extreme poverty on one side, and the gulf of starvation on the other; to take continual thought of to-morrow, without any good result of such thought; to feel each anxious hour that the dreary treadmill by which we secure the means of sustenance for a hungry household may, without warning, be closed by any number of forces, over which one has no control, to double and triple all the horrors of want and pain, by anticipation and rumination,—such is the life of the muscle-working classes of modern civilized society; and when we add to this the cankering annoyance that arises from the envying of the fortunate brain-worker who lives in ease before his eyes, we marvel not that he dies young, but rather that he lives at all.

3. *Brain-workers live under better sanitary conditions than muscle-workers.* They have better food and drink, warmer clothing, breathe purer air, and are less exposed to fatal accident and the poison of disease. None of the occupations are ideal; none fulfill all the laws of health; but the muscle-working callings are all more or less unhealthy; tradesmen, artisans, common laborers, and even farmers (who combine muscle with brain-work), all are forced to violate sanitary law every hour of their lives; not one out of ten have enough good food; many are driven by passion and hunger to excess in the worst forms of alcoholic liquors; for a large number, sleep is a luxury of which they never have sufficient for real recuperation; healthful air is but rarely breathed by the laboring classes of any large city; exposure to weather, that brings on fatal inflammatory disease; accidents that cripple or kill—in all these respects,

the muscle-worker, as compared with the brain-worker, is at stupendous disadvantage.

4. *The nervous temperament, which usually predominates in brain-workers, is antagonistic to fatal, acute, inflammatory disease, and favorable to long life.* Comparative statistics have shown that those in whom the nervous temperament prevails, live longer than those in whom any one of the other temperaments prevail, and common observation confirms the statement. Nervous people, if not too feeble, may die every day. They live, but they do not die; they talk of death, and each day expect it, and yet they live. Many of the most annoying nervous diseases, especially of the functional, and some even of the structural varieties, do not rapidly destroy life, and are indeed consistent with great longevity. I have known a number of men and women who were nervous invalids for half a century or more, and died at an advanced age. It is one of the compensations of nervousness that it protects the system against those febrile and inflammatory diseases that are so rapidly fatal to the sanguine and the phlegmatic.

5. *Brain-workers can adapt their labor to their moods and hours and periods of greatest capacity for labor, better than muscle-workers.* In nearly all intellectual employments there is large liberty; literary and professional men especially, are so far masters of their time that they can select the hours and days for their most exacting and important work; and when from any cause indisposed to hard thinking, can rest and recreate, or limit themselves to mechanical details. Thus, there is less of the dreadful in their lives; they work when work is easy, when the desire and the power are in harmony; and, unlike their less fortunate brother in the mill or shop, or diggings, need not waste their force in urging themselves to work. Forced labor, against the grain of one's nature, is always as expensive as it is unsatisfactory; it tells on the health and on life. Even coarser natures have their moods, and the choicest spirits are governed by them; and they who worship their moods do most wisely; and those who are able to do so, are the fortunate ones of the earth.

Again, brain-workers do their best work between the ages of twenty-five and forty-five; before that period they are preparing to work; after that period, work, however extensive it may be, becomes largely a matter of routine. Lawyers and physicians do much of their practice after forty; but to practice is easy, to learn is hard—and the learning is done before forty or forty-five. In all directions, the French motto holds true: "It is the first step that costs." Successful merchants lay the foundations of fortune in youth and middle life, to accumulate, and recreate, and take one's ease in old age; thus they make the most when they are doing the least, and only become rich after they have ceased trying to be so.

With muscle-workers, there is but little accumulation, and only a limited increase of reward; and in old age, after their strength has begun to decline, they must, with increasing expense, work even harder than before.

To this should be added the consideration that manual employments cost as much force after they are learned as before; they can never, like many intellectual callings, become so far forth matters of routine as to require little effort. It is as hard to lay a stone wall after one has been laying it fifty years, as during the first year. The range of muscular growth and development is narrow, compared with the range of mental growth; the day-laborer soon reaches the maximum of his strength. The literary or scientific

worker goes on from strength to strength, until what at twenty-five was impossible, and at thirty difficult, at thirty-five becomes easy, and at forty a pastime; and besides he has the satisfaction that the work done so easily at thirty-five and forty is incomparably better than the work done with so much difficulty at twenty-five.

6. *Comparative Longevity of the Professions.* Inasmuch as professional men do not usually change their callings, but die in the special profession in which they have lived, the vital statistics, at least of lawyers, physicians, and clergymen become of value in determining their comparative longevity. I found in my researches made several years ago, that lawyers and physicians lived to be about fifty-seven or fifty-eight.*

CAUSES OF THE EXCEPTIONAL LONGEVITY OF GREAT BRAIN-WORKERS.

The explanation of the surprising longevity of great brain-workers is quite complex. The readiest answer to the problem would be that brain-work is healthful; and that, therefore, the better the brain and the harder it is worked, the longer the life of its possessor. Such a solution would not be entirely true; and if it were true unqualifiedly, it would clear up but one side of the question.

The answer is to be found, not in any single consideration, but in many, as follows:

1. *Great men usually come from healthy, long-lived ancestors.* Longevity is a correlated inheritance of genius. In order that a great man shall appear, a double line of tough, more or less vigorous fathers and mothers must fight in the struggle for existence and come out triumphant. However feeble the genius may be, his parents or grandparents are usually strong; or if not strong, are long-lived. Great men may have nervous if not insane relatives; but the nervous temperament holds on to life longer than any other temperament. Longevity is, of course, hereditary, like all qualities or tendencies of organized life; and if great men come from long-lived stock, this fact is one most potent explanation of their exceptional longevity.

2. *A good constitution usually accompanies a good brain.* The cerebral and muscular forces are correlated. This view, though hostile to the popular faith, is yet sound and supportable. A large and powerful brain in a small and feeble body is a monstrosity. "In monstrosities Nature reveals her secrets," says Goethe. When a specially small and delicate frame sustains a specially large and potent brain, men wonder, as at a tree bowed to the earth by the weight of its over-abundant fruit. Everywhere Nature is a slave to the necessity of correlation or correspondence of parts and organs with each other; and unless she heeds it, all organized life would become awry and misshapen. In all the animal realm there is a general though not unvarying relation between the brain and the body of which it is a part, and to which it ministers.

3. *Great men who are permanently successful have*

correspondingly greater will than common men; and force of will is a potent element in determining longevity. The one requisite for great success is "grit;" and, more uniformly than any other single quality or combination of qualities, it is found in those who attain high distinction. That longevity depends not a little on the will, no one will dispute. The whole subject of the relation of mental character to longevity is one of vast interest, and is too far-reaching to be here discussed; but this single point must be granted without argument, that of two men every way alike and similarly circumstanced, the one who has the greater courage and grit will be the longer lived. One does not need to practice medicine long to learn that men die that might just as well live if they resolved to live; and that myriads who are invalids could become strong if they had the native or acquired will to vow that they would do so.

4. *Great men work more easily than ordinary men.* Their expenditure of force to accomplish great things is less plentiful than the expenditure of ordinary men to accomplish such things. A Liverpool draft-horse draws with ease a load at which a delicate racer might tug and strain without moving it. Ruskin is quite right when he says that the greatest work is done easily. The best action is the unconscious. It is the essence of genius to be automatic and spontaneous. The common mind cannot attain this spontaneity, or, at any rate, only to a slight degree.

5. *The advantages that belong to the brain-working orders in general.* Of these I have already spoken in some detail. The great brain-workers of the world have not all been rich; neither have they all been poor; some of them have lived a portion of their lives, but very few all their lives, in extreme want; and the majority have been most of the time surrounded with at least moderate comforts.

CAUSES OF THE GREAT LONGEVITY OF CLERGYMEN.

When, in 1867, I first called attention to the fact that clergymen were longer-lived than any other class of brain-workers, serious doubt was expressed whether there might not be some error in my statistics. So much has been said of the pernicious effects of mental labor, of the ill-health of brain-workers of all classes, and especially of clergymen, that very few were prepared to accept the statement that the clergy of this country and of England lived longer than any other class, except farmers, and very naturally suspected a lurking fallacy. Other observers, who have since given special attention to the subject, have more than confirmed this conclusion, and have shown that clergymen are longer-lived than farmers.

The Rev. Josiah F. Tuttle, D.D., President of Wabash College, Indiana, has ascertained the ages of 2,442 clergymen—600 Trinitarian Congregationalists, 317 Presbyterians, 231 Episcopalians, 268 Baptists, 208 Methodists, 166 Unitarians, etc.,—and found that the average was "a little over 61 years." "Considerably over one half of the whole were over 60 years of age at their death; three fourths of the whole were over 50 years old at death; and seven-eighths of the whole were over 40 years of age at death." Dr. Tuttle found that the average age at death of 408 individuals (not clergymen), and who had died over 21 years of age, was a little over 51 years. This result pretty nearly corresponds with mine.

But by far the more thorough investigation on this subject, and one that must fully settle the question for all minds over whom facts have any influence, has been recently made by Rev. J. M. Sherwood, formerly editor of "Hours at Home," and now Secretary of the

* An investigation made by a Berlin physician into the facts and data relating to human longevity shows the average age of clergymen to be 65; of merchants, 62; clerks and farmers, 61; military men, 59; lawyers, 58; artists, 57; and medical men, 56. Statistics are given showing that medical men in England stand high in the scale of longevity. Thus, the united ages of twenty-eight physicians who died there last year, amount to 2,254 years, giving an average of more than 84 years to each. The youngest of the number was 80; the oldest, 93; two others were 92 and 89 respectively; three were 87, and four were 86 each; and there were also more than fifty who averaged from 74 to 75 years."

"Society for Promoting Life Insurance among Clergymen." This gentleman has labored long and patiently in this department, and has ascertained that the average age of our ministers at death is sixty-four. The report (I quote from Document No. 3 of the Society) states: "this is four years more than the longevity of the most favored (?) class; ten years more than in the other professions; and from twelve to nineteen years above that of mechanics, artisans, miners, operatives, and the like."

These conclusions differ slightly from mine, but the difference is in favor of clergymen. Mr. Sherwood informs me that he had obtained the average from a list of ten thousand clergymen, whose ages at death he ascertained at great labor by consulting "the minutes of ecclesiastical bodies for thirty years past, the catalogues of theological seminaries, Wilson's 'Historical Almanac,' Dr. Sprague's 'Annals of the American Pulpit,' biographical dictionaries, the files of religious journals, etc."

A list of ten thousand is sufficient and more than sufficient for a generalization; for the second five thousand did nothing more than confirm the result obtained by the first. It is fair and necessary to infer that if the list were extended to ten, twenty, or even one hundred thousand, the average would be about the same.

In England, also, clergymen live to a greater age than any other class. According to the report of the Secretary of the Clerical Mutual Life Assurance Society, the mortality is less than that in twenty other companies by a very important percentage.

THE DISEASES CAUSED

BY THE

INHALATION OF THOSE KINDS OF DUST WHOSE PRESENCE IN THE PULMONARY TISSUE MAY BE DEMONSTRATED.

THE first part of Dr. Merkel's work, a translation of which was given in the numbers of this Journal for Aug. 15 and Oct. 15, related to those "Diseases which may be Induced or Rendered Worse by the Inhalation of any kind of Dust." The affections discussed in Part II. differ from the above diseases in that the connection between them and the inhalation of dust may be verified *ad oculos*. In the diseases which we are now to consider, it is possible, either by ocular inspection simply, or with the aid of the microscope, or by means of chemical tests, to demonstrate the corpora delicta—the particles of dust imbedded in the tissue of the lungs. While it is not pretended that all of the changes which the lungs exhibit in these diseases are directly due to the inhalation of dust, there can be no doubt that in every instance the irritation induced by the foreign bodies in the pulmonary parenchyma is the cause of its disease, and may be shown to be immediately related to the majority of the morbid anatomical changes.

The idea that particles of dust might be taken up into the lung-tissue was first broached long ago. But for many years much confusion existed as to the true nature of the pulmonary pigment, whether this was foreign to the tissue and derived from without, or an inherent organic product. In many of the earlier descriptions of "the miner's lung," as it was called, this confusion was very apparent. Pearson thought the pigment identical with real coal. Lawrence believed that it was derived from the inhalation of soot float-

ing in the atmosphere. Henle and Virchow insisted upon its organic nature, claiming that it was a product of the blood. Robin advocated the "coal-inhalation theory."

A very important contribution to the study of this subject was made by Traube in 1860. He published the case of a charcoal-burner, whose lungs were found, *post-mortem*, filled with a black material which was evidently coal-dust. Particles of the dust had been seen in the sputa for some time before death. But in this case no coal was found in the parenchyma, only in the alveoli. Therefore the question of the "miner's lung" was not yet fully decided.

Villaret, while avowing the theory that the changes in the miner's lung are due to the intrusion of particles of dust upon the lung-tissue, contended that the deposit took place by way of the organs of digestion. He claimed that the particles were swallowed and carried from the stomach and intestines through the portal circulation to the right side of the heart, and thence to the tissue of the lungs. His position was based upon experiments in which he fed rabbits upon matters containing coal-dust, and afterwards found, particles of the coal in the mesenteric glands, in the blood of the mesenteric veins and right side of the heart, and in the liver and spleen. His conclusions, however, were not confirmed.

The intrusion of dust upon the pulmonary tissue was at length verified by Zenker, who described lungs in which he found coloring matter which was quite distinct from the ordinary pigment. Virchow, also, was soon forced to admit that besides the abnormally pigmented lung which he had described, there existed a true anthracosis pulmonum.

It having been ascertained that dust may penetrate into the lung-tissue, it remained to discover by what means it gets there. Villaret's theory met with slight favor, and was especially opposed by the case described by Traube, where the coal-dust, by means of inhalation, had gained access to the alveoli. We should naturally suppose that the ciliary movements of the epithelium would prevent the dust penetrating so far as this, and that the particles would be expectorated almost as soon as inhaled. But the catarrh which is soon induced by breathing the dusty atmosphere tends gradually to destroy this expulsive power, and the dust, once arrived in the alveoli, finds comparatively easy access to the parenchyma. For whether the air-cells possess no epithelium, or only at certain intervals, or, as claimed by Buhl, are mere air-containing lymphatic spaces, the passage of fine molecules of dust through the thin walls would meet with far less resistance than from the bronchial mucous membrane.

Rindfleisch describes the probable course taken by the particles of coal as follows:

"The sharp points and dense structure of the molecules, which would be the same in the minutest divisions of the coal as in the large pieces, renders the particles of dust especially calculated to penetrate the soft tissues of the body whenever even a slight impulse is imparted to them from any direction. The particles having once entered the parenchyma of the lung, they will follow the general course of the extravascular, nutritive fluids, and so tend towards the lymphatic system. But now and then on their way they encounter cellular elements which are capable of permanently entangling solid bodies in their protoplasm."

"First of these come the stellate connective-tissue cells, next the wandering-cells which have an amoeboid nature, and carry the black particles with them wherever they go. Whatever remains over, which the cells do not seize, is then swept on towards the roof of the

lung, and thence arrives in the lymphatic vessels of the mediastinum.

"Here an insuperable obstacle is presented to their further course, since all the numberless lymphatic corpuscles, which are here accumulated, stand ready to take up as many of the black particles as their protoplasm will hold."

This theoretical description is fully endorsed by Merkel, who observes that its probability is increased from the fact that "the deepest pigmentation is found in the connective tissue surrounding the bronchi and arterioles, and, in general, corresponds to the arrangement of the lymphatic system." "Where the pigmentation is not very deep the microscope shows that the stellate connective-tissue cells take the chief part in imbibing the pigment, while the vicinity of the larger lymphatic vessels is generally occupied by a dense cloud of black granules. In the lymphatic glands the lymphatic sinus is seen to become filled first, and afterwards the parenchyma becomes so beset with them that finally every trace of its structure disappears. If the particles of coal are replaced by particles of iron, and the black by red, we have the appearance of the red iron lung; and so of the other varieties of lung, due to the inhalation of other kinds of dust."

It is obvious that the presence of foreign matter in the pulmonary tissue cannot be indifferent to its health and to the normal processes of nutrition. The degree of derangement to which it may give rise will depend mainly upon four conditions, viz.: (1.) Upon the previous health or disease of the lungs affected; (2.) Upon the susceptibility of the lungs to irritation depending upon the general power of resistance of the individual to morbid influences; (3.) Upon the amount of dust in the atmosphere inhaled, or upon the duration of the exposure to it, and (4.) Upon the quality of the dust, "whether the molecules are sharp-edged and angular, or roundish, whether they are very soft or very hard, whether chemically noxious or innocuous." Of course, those kinds of soluble dust which act as poisons to the general system are not here included.

The pulmonary disease to which the deposition of particles of dust in the lung-tissue gives rise is generally designated by the term *Pneumokoniosis*, from *ἡ πνευμων*, the lung, and *ἡ κονις*, the dust. Five different forms of the disease are described, corresponding to the different kinds of dust inhaled. The first form of the disease which Merkel describes is caused by the inhalation of coal-dust.

THE DEPOSITION OF COAL-DUST IN THE LUNGS.

Synonyms.—Black infiltration of the lungs—False melanosis—Coal-miner's lung—Melanidie—Encombrement charbonneux des poumons—Anthraxosis pulmonum—Pneumokoniosis anthracotica.

This form of the disease has been the most thoroughly studied of all the pneumokonioses. It may be caused by the inhalation of coal-dust in any form, whether from mineral or wood coal, from graphite, or in the form of soot; and the denser the dust the finer the particles; the more confined and the more poorly ventilated the space in which the dusty atmosphere is inhaled, the greater will be the chances of anthracosis being developed.

Pathological Anatomy.—The appearances will vary in different lungs, depending upon their susceptibility to irritation. In the above-mentioned case of Traube's the only changes were found in the alveoli of the lungs. The latter were filled with a black fluid,

which, when the lungs were cut, flowed over the hand of the operator. But the parenchyma of the lung was unaffected, so that in this case the cause of death cannot be ascribed to the anthracosis. This case is typical of many others, where the inhalation of dust under the worst circumstances has been followed by no perceptible ill effects.

"But in by far the greatest number of cases a different state of things exists.

"We find just beneath or even in the pleura pulmonalis, black depo its, which occur mostly in spots, rarely in stripes. In certain places rather hard, black nodules occur, from the size of a pin's-head to a pea, which consist wholly of coal particles, or we find perfectly ink-black indurations, which grate under the knife. Chronic pneumatic processes occur also, terminating in caseous degenerations, but they are rare. Cavities are very seldom found, according to Sedlmann, and they are mostly of small size, lie partly in inflated tissue, partly in indurated portions, and may be situated in any part of the lung. Their walls are uneven and ragged, and the contents of the cavities consist of pus merely, or they are colored gray or black, through the presence of coal granules. Possibly true tubercles may at length develop. When the dense accumulations of coal approach near to the periphery small circumscribed pleuritic effusions may take place, which may culminate in general pleurisy. In all cases, without exception, enlargement and pigmentation of the bronchial glands occur. No other observer beside Villaret, so far as we know, has ever found any coal deposits in other organs."

The secondary organic affections, such as dilatation and hypertrophy of the right side of the heart, congestion of the liver, etc., are natural consequences of the foregoing, and require no special mention.

"Bronchial catarrh is invariably present. There is never any marked pigmentation of the tracheal or bronchial mucous membrane, nor any ulceration, unless due to the cavities mentioned above."

Unless the person has been inhaling the dusty atmosphere but a short time before death, we shall be unable, by microscopic examination, to detect the particles of coal in any part of the air-passages, except they be contained in the large swollen cells of the alveoli. "They occur, however, in the alveolar and infundibular septa in abundance, and are often present in such quantity as to wholly obscure the natural structure. The connective-tissue cells are crammed full of black molecules, and the sheaths of the vessels and bronchioles swarm with them. It has been pointed out already that these passages coincide with the courses of the lymphatic vessels. The indurations and nodules consist mainly of dense fibrous tissue, in which the particles of dust appear to be imbedded, corresponding mostly to the course of the fibres, and from which they cannot be removed either by brushing or washing.

"In the chronic pneumatic spots, and also in the caseous deposits, the outlines of the alveoli are often indicated by lines of black molecules, corresponding in their situation with the interstices of the trabeculae.

"In the lymphatic glands the deposition corresponds most exactly with the above theoretical description of Rindfleisch."

The best criterion for deciding that black granules found in a lung are coal, will be the fact of not finding such pigment forms as are evidently derived from the blood. "Small crystalline forms of a bright brown, or especially of a golden brown color in the vicinity of black masses of pigment, will render it probable that the pigment masses have originated in the lung."

With regard to the molecules of charcoal, however, it will be possible to recognize them by means of their form, their pores, etc. Chemical reagents are of but little value in determining the nature of coal granules. Moreover, the anatomical appearances remain the same whether they are due to the dust of mineral coal, or charcoal, or to graphite.

Symptoms of Anthracosis.—The cough has but little value as a diagnostic sign, unless it persists for a considerable time after the person has left the dusty atmosphere. At first it is directly due to the irritation of the foreign particles in the air-passages, its object being simply to expel the dust. But when it begins to remain long after the patient has ceased to inhale the dust, it is obviously due to a commencing catarrh. It is the signal that Nature's safeguards against the intrusion of foreign matters into the lungs are becoming inadequate. The ciliated epithelium is probably partially destroyed. The sputa contain but slight mucus at first, but gradually they become more copious, tougher, and contain a larger proportion of mucus. At length they become purulent and pass through the different variations which correspond to the pathological changes in grave pulmonary disease. Of course, the expectoration will be tinged in varying shades from gray to black, according to the amount of coal-dust in it, from the very start. The dark color is not a sign of disease, however, unless it continues for a considerable period after the patient has left his work. At first the particles of coal will be found free in the sputa, afterwards, also, enclosed in swollen cells. The patient not returning to his work, the particles which are free first gradually disappear from the expectoration, and then also those contained in cells. And so a recovery may take place, all the coal having been expectorated, or what remains being enclosed in the tissues as to be innocuous and create no further irritation. But, on the other hand, should the expectoration of free particles of coal still persist long after they were inhaled, the prognosis will be less favorable. Under these circumstances the free particles can only come from the tissue of the lung. According to Seltmann, a copious serous effusion into the parenchyma washes the granules out of the tissue, and forces them into the alveoli again. In case the occupation is still pursued, damage to the pulmonary tissue may be inferred from the presence of elastic fibres in the sputa.

One of the most prominent of the symptoms of anthracosis is *dyspnoea*. It is, doubtless, partly due to the presence of the foreign accumulation in the lungs, clogging the air-cells and interfering with a complete interchange of gases. But in most cases the course of the dyspnoea is to be referred to the bronchial catarrh which is commonly present, and in no less measure, perhaps, to emphysema. Whether the emphysema, which is an extremely common affection of colliers, is solely dependent upon the inhalation of coal-dust, is doubtful. The excessive muscular exertions which this class of laborers are compelled to make would suffice to account for the production of emphysema independently of the dust inhaled. Finally, anæmia is very apt to exist in coal-miners, due to insufficient aeration of the blood, and this also may be one source of the dyspnoea, particularly in the earlier stages.

All writers on anthracosis concur in the opinion that it seldom leads to consumption. The rarity of the occurrence of phthisis in connection with this affection has given rise to the presumption that the inhalation of coal-dust has a prophylactic effect against tuberculous or pneumonic consumption.

Although workers in coal are not entirely exempt from chronic and interstitial pneumonic affections, these diseases are very rare, in comparison with the frequency of their occurrence amongst those who work in other kinds of dust. Moreover, the fact that these affections occur only in the highest grades of anthracosis, and that while most common in the English colliers they are unusual even there, favors the presumption that the coal-dust does afford a certain protection against phthisis. The dust inhaled by the English colliers contains, besides coal, large quantities of silicious earths; the miners are also excluded from the light and fresh air, besides leading very irregular lives—the very conditions under which we should expect to find grave pulmonary diseases of the most common occurrence. But though the inhalation of coal-dust of itself rarely causes degeneration of the pulmonary tissue, phthisis and anthracosis may be coincident diseases. In some cases, too, the bronchial catarrh, when of high grade and of long duration, may give rise to an extension of the inflammatory process to the adjacent lung-tissue, resulting in induration and degeneration. Again, the presence of large quantities of coal-dust imbedded in the tissue of the lungs might, in case of an accidental pneumonic process, predispose the tissue to mortification. Why the lungs of one individual should succumb earlier than those of another, is explained by the difference in the susceptibility of different individuals.

CONCERNING THE LABORERS WHOSE OCCUPATIONS OBLIGE THEM TO INHALE COAL-DUST.

All writers agree in the statement that, as a rule, workers in coal are an exceedingly healthy class. According to statistics collected by Hirt, out of 39,879 cases of various internal diseases occurring in miners, during six years, 6,553 were cases of catarrh of the respiratory organs, 1,836 cases of pneumonia, 394 emphysema, and 345 phthisis.

Another table of Hirt's shows that of 100 phthisis patients, 26 per cent. worked in inorganic dust, 17 per cent. worked in organic dust, 11 per cent. in no dust, and 1.3 per cent. in coal-dust.

A table designed to show the proportions of various chest diseases in colliers is given below:

	Phthisis.	Chronic Bron. Catarrh.	Emphysema.	Pneumonia.
In UPPER SILESIA, 143,429 examined; 39,879 with internal diseases.....	0.8	16.4	0.9	4.7
In RHODE (Arnsberg)..... 14,490 patients.....	1.1	18.3	(?)	3.6
In BRENLAUT, 49 patients.....	2.0	22.4	8.1	14.4
				46.9

In these tables it is remarkable that so few cases of emphysema and phthisis were noted. Most writers regard the former disease as more common than here stated. But it is to be noticed that in one instance 16.4 per cent., and in another 18.3 per cent., were cases of bronchial catarrh. It is probable that many of these cases were associated with emphysema, since the two diseases are often combined, and that only pure, uncomplicated cases were denominated as emphysema. The statement is made by Hirt, that the number of cases of emphysema in the coal miners at

Brussels diminished as soon as the galleries had been so excavated that the miners were able to work standing erect; heretofore they had been obliged to work with their bodies bent forward in a stooping posture.

With regard to phthisis, these statistics show conclusively that the inhalation of coal-dust not only does not usually tend to develop pulmonary consumption, but is rather disposed to counteract it. Investigations concerning the firemen in engine-rooms show a similar result. Statistics regarding the charcoal-burners indicate a still better state of health, probably because the workmen, though inhaling a very dusty atmosphere are generally in the open air. The same is true of those who work in soot. Statistics made by Lewin indicate that chimney-sweepers are a very healthy class.

In the iron and metal foundries, where the moulds are prepared by sprinkling them with a fine mixture of charcoal and graphite, the moulders are constantly surrounded by a dense black cloud of dust. Dr. Merckel states, that according to his observation, these workmen are apt to suffer from chronic catarrhs and their consequences. But the workmen who cast the metal are much more liable to pulmonary phthisis. Their exposure to the intense heat, and to the danger of taking cold afterwards, as well as to the noxious vapors which are sometimes produced in the process of casting the metal, have a very pernicious effect upon their health, rendering them exceedingly liable to phthisis. In the manufacture of lead-pencils there is but little dust from the graphite, since it is ground while wet, and in cutting the pencils there is much more wood-dust than graphite in the atmosphere.

The form of pneumokoniosis next described is that caused by the deposition of metallic dust in the lungs.

(To be continued.)

Miscellaneous.

THE PLAGUE IN TRIPOLI.—About two months ago, Europe was startled with the news that the plague had broken out in Merdj and Benghazi, two cities not far from Tripoli. At first there was a disposition to doubt the nature of the disease, but it soon became evident that this epidemic was in reality the genuine bubo plague. Ali Djenni Pascha, Governor of Benghazi, sent a request through the French Consul of that place to Dr. Laval, a pensioned surgeon of the French army, to visit the scene of the epidemic, and report upon it. Dr. Laval arrived in Merdj on the 7th of June, and on the evening of the following day sent a brief dispatch to Ali Pascha stating that he would report to him more in detail as soon as he had had an opportunity of studying the disease. Unfortunately, however, Dr. Laval himself very soon afterwards fell a victim to the very disease he was sent to study; but he left behind him a few interesting facts regarding this particular epidemic, and its probable mode of origin. These are in brief the following:

The disease first broke out among a number of Bedouins who belonged to the tribes of Orpha, Drusi, and Brassa, and all lived in the neighborhood of Merdj. These Bedouins are in the habit of spending the day in Merdj, doing work for the different business houses, and returning at night to their tents. During the past winter they purchased, for their own use, a quantity of cast-off underclothing, such as is frequently offered for sale there, and carried it home with them. In the middle of March, they left the vicinity of Merdj, and travelled a few miles in search of new

pastures for their cattle. They numbered then thirty-four souls all told, nine men, eleven women, and fourteen children. Their fare had been wretched for at least a full year, and perhaps even two; they had lived mostly upon vegetables cooked with barley-meal and a little milk. As they had a long time previously sold their covers, they were obliged to sleep on rag-heaps of which they owned about eight. On the 1st of April, one child fell sick and died at the end of five days. Three days later, the father of the child fell sick and died in six days. Three days after this, a boy of twelve, and a man of forty years of age fell sick in another tent. In the course of twenty days, there were in all ten persons sick with the plague, seven of whom died. Among those who recovered were two men who still had traces of the plague-boils over their shoulder-blades. In from twenty to twenty-five days, however, they had both fully recovered their strength. The third, a woman, was a full month in regaining her strength. From these people it was further ascertained that the last case of the disease occurred on the 6th of May. Each of the patients had had a large boil, either in the region of the groin, on the shoulder, or upon the neck. This boil appeared usually on the first or second day of the disease, and was followed by vomiting, severe headache, and, in several of the cases, by delirium. In three instances, death occurred between the third and fifth days, in one on the sixth, and in the others on the seventh day. In those who recovered, convalescence set in between the fifth and the seventh days. If the statements of the Bedouins are to be trusted, they did not have any communication whatever, during this entire epidemic, with either Merdj, or with any other tribe of Bedouins. On the 15th of May, they returned again to the vicinity of Merdj, and brought with them the three convalescents mentioned above, each one having upon the shoulder a small conical tumor about the size of an acorn. The little city of Merdj consists of about fifty small houses which have been built upon the ruins of the ancient city of Barca; the inhabitants number about one hundred. During the months of March and April, malarial fever prevailed in the place, and on the 28th of May, after the return of the Bedouins, the first case of the plague showed itself. Thereupon twenty-five persons contracted the disease, and of these eight died. There were at that time in Merdj some twenty soldiers, but none of them contracted the disease, owing to the strict discipline introduced by Dr. Laval, who had forbidden them any intercourse with the people. It was Dr. Laval's intention to remain in Merdj until the disease had completely died out, but as already stated, it was his fate to lose his life on the altar of his profession. It is probable, however, that after his death, the rules, which he had established to prevent the extension of the plague to Benghazi, were neglected, for it eventually visited that place; and not only there, but also in Derna it sacrificed its victims.—*Deutsche Versicherungs-Zeitung.*

CHAMBER OF LIFE INSURANCE.—At a recent meeting of the Chamber of Life Insurance the new sets of blank forms (application and medical examiner's report) prepared by the law and medical committees was finally adopted. The chief feature of these new blanks is the transfer of all questions of a medical nature from the application proper to the portion which the examiner is required to fill out. These blanks have been very carefully prepared, and will, we believe, give greater satisfaction to the companies using them than any hitherto employed.
